Olaparib	Ovarian cancer: after two or more chemotherapies with deleterious *BRCA* mutation (germline and/or somatic); maintenance therapy when in complete or partial response to platinum-based chemotherapy Breast cancer: for the treatment of adult patients with deleterious or suspected deleterious gBRCAm, HER2– metastatic breast cancer who have been treated with chemotherapy in the neoadjuvant, adjuvant, or metastatic setting; if HR+, after prior endocrine therapy or inappropriate for endocrine therapy Pancreatic cancer: maintenance treatment of adult patients with deleterious or suspected deleterious gBRCAm metastatic pancreatic adenocarcinoma whose disease has not progressed on at least 16 weeks of a first-line platinum-based chemotherapy regimen	Nausea, fatigue, anemia, thrombocytopenia, neutropenia, stomatitis, liver function abnormalities	Myelodysplastic syndrome; rare interstitial pneumonitis
Rucaparib	Ovarian/fallopian tube/primary peritoneal cancer: as with olaparib	Nausea, fatigue, anemia, thrombocytopenia, neutropenia, stomatitis, liver function abnormalities	Severe heme toxicity with emergence of myelodysplastic syndrome
Talazoparib	Ovarian/fallopian tube/primary peritoneal cancer: as with olaparib	Nausea, fatigue (including asthenia), vomiting, abdominal pain, anemia, diarrhea, neutropenia, leukopenia, decreased appetite, constipation, stomatitis, dyspnea, and thrombocytopenia	Monitor for emergence of myelodysplasia; rare interstitial pneumonitis should lead to discontinuation; avoid with strong or moderate CYP3A inhibitors, but if concomitant use cannot be avoided, reduce dose; avoid with strong or moderate CYP3A inducers
Miscellaneous			
Arsenic trioxide	APL (target PML-RARα and redox homeostasis)	↑ QT_c; hypersensitivity with vasomotor symptoms	APL differentiation syndrome (see under tretinoin)
Glasdegib	AML: in combination with low-dose cytarabine, for the treatment of newly diagnosed AML in adult patients who are ≥75 years old or who have comorbidities that preclude use of intensive induction chemotherapy	Monitor ECG and electrolytes for QTc prolongation and interrupt treatment if it occurs	Targets smoothened receptor in hedgehog pathway; CYP3A4; avoid with QTc-prolonging drugs, but if co-administration is unavoidable monitor for increased QTc
Sonidegib	Metastatic basal cell carcinoma	Muscle spasm, fatigue, transmission through semen	Targets smoothened receptor in hedgehog pathway; CYP3A4
Tagraxofusp-erzs	Blastic plasmacytoid dendritic cell neoplasm	Hypersensitivity reactions (require premedication with steroids, antihistamines); hepatotoxicity, capillary leak syndrome	Targets CD123 (IL-3 receptor) to deliver a fragment of the diphtheria toxin
Tretinoin	APL, t(15;17) positive	Cutaneous including cheilitis, skin dryness; increased intracranial pressure; hyperlipidemia, abnormal liver function tests, usually resolve	Targets PML-RARα; APL differentiation syndrome: pulmonary dysfunction/infiltrate, pleural/pericardial effusion, fever
Vismodegib	Metastatic basal cell carcinoma	GI, hair loss, fatigue, muscle spasm, dysgeusia; no blood donation for 7 months after last dose	Targets smoothened receptor in hedgehog pathway
Ziv-aflibercept	Metastatic colorectal cancer in combination with 5-fluorouracil, leucovorin, irinotecan; resistant to or has progressed following an oxaliplatin-containing regimen	Fistula formation, GI perforation, hemorrhage, thrombosis, arterial thromboembolism, proteinuria, reversible posterior leukoencephalopathy	Targets VEGF by a solubilized receptor-trapping mechanism

[a]All agents in this category should be regarded as potentially fetotoxic, and use during pregnancy is either contraindicated or undertaken with clear understanding of risk of fetal harm; likewise not recommended for use during lactation.

Abbreviations: ACE, angiotensin-converting enzyme; ALL, acute lymphocytic leukemia; ALT, alanine aminotransferase; AML, acute myeloid leukemia; APL, acute promyelocytic leukemia; AST, aspartate aminotransferase; AV, atrioventricular; BRCP, breast cancer resistance protein drug transporter; BSA, body surface area; CHF, congestive heart failure; CLL, chronic lymphocytic leukemia; CML, chronic myeloid leukemia; CNS, central nervous system; CPK, creatine phosphokinase; CYP, cytochrome p450 interactions with drugs metabolized by the indicated isoform; DLBCL, diffuse large B-cell lymphoma; dMMR, deficient mismatch repair; ECG, electrocardiogram; EGFR, epidermal growth factor receptor; ER, estrogen receptor; FDA, U.S. Food and Drug Administration; FL, follicular lymphoma; gBRCAm, germline mutated breast cancer associated protein; GI, gastrointestinal; GVHD, graft-versus-host disease; HBP, high blood pressure; MEK, mitogen activated protein kinase; HR, hormone receptor; HER2, human epidermal growth factor receptor 2; IDH, isocitrate dehydrogenase; INR, international normalized ratio; LVEF, left ventricular ejection fraction; MSI-H, microsatellite instability-high; mTOR, mammalian target of rapamycin kinase; NSCLC, non-small-cell lung cancer; PDGFR, platelet-derived growth factor receptor; Pgp, P-glycoprotein; PT, prothrombin time; QTcF, QT corrected by Frederika formula; RCC, renal cell carcinoma; SLL, small lymphocytic lymphoma; TKI, tyrosine kinase inhibitor; TSH, thyroid-stimulating hormone; UGT, uridine diphosphate glucuronosyltransferase; VEGFR, vascular endothelial growth factor receptor.

tumors. Larotrectinib and entrectinib may be quite useful in managing these tumors; indeed, these agents are exemplary of "histology agnostic" agents, where the utility of the drug is not tied to a particular histologic diagnosis, but to the possession of a specific *NRTK* gene alteration. Neurotoxicity, a long half-life of the agents, and hepatotoxic adverse events are of concern. Also, assuring that solid tumors have been appropriately screened for the existence of such sensitizing mutations can be logistically and economically challenging.

RAS/RAF/MEK Antagonists The *BRAF* V600E mutation drives a substantial fraction of melanomas and certain NSCLCs and has been detected in certain thyroid tumors, colorectal tumors, hairy cell leukemias, and unusual gliomas. BRAF inhibitors such as dabrafenib, vemurafenib, and encorafenib have activity as single agents in many such tumors but are usually most active when co-administered as "doublets" with the MEK inhibitors trametinib, cobimetinib, and binimetinib, respectively, to promote "shut down" of RAF/MEK signaling at more than pathway member. Cutaneous adverse events including generally indolent cutaneous second neoplasms and thromboembolic, cardiac, and ocular toxicity can occur.

Sotorasib is a first-in-class inhibitor of *KRAS* G12C signaling that in early clinical reports has evidence of effecting stable disease in patients with a variety of neoplasm histologies bearing that mutation, with fewer actual responses. Its initial very favorable safety profile encourages further clinical investigations alone and in combination with other agents.

Multikinase Inhibitors Agents in this class also target specific macromolecules promoting the viability of tumor cells. They are "small-molecule" ATP site-directed antagonists that inhibit more than one protein kinase and may have value in the treatment of several solid tumors. Drugs of this type with prominent activity against the VEGFR tyrosine kinase have activity in renal cell carcinoma. Sorafenib is a VEGFR antagonist also with activity against the RAF serine-threonine protein kinase, and regorafenib is a closely related drug with value in relapsed advanced colon cancer. Pazopanib also prominently targets VEGFR and has activity in renal carcinoma and soft tissue sarcomas. Sunitinib has anti-VEGFR, anti-PDGFR, and anti-KIT activity. It causes prominent responses and stabilization of disease in renal cell cancers and GISTs. Side effects for agents with anti-VEGFR activity, similar to those of the anti-VEGF antibody bevacizumab, prominently include hypertension, proteinuria, and, more rarely, bleeding and clotting disorders, perforation of scarred gastrointestinal lesions, and posterior leukoencephalopathy, probably reflecting CNS vascular damage. Also encountered are fatigue, diarrhea, and hand-foot syndrome, with erythema and desquamation of the distal extremities, in some cases requiring dose modification, particularly with sorafenib.

Other agents in this class include agents such as brigatinib (clinical activity in ALK-dependent NSCLC, but also with anti-EGFR action), entrectinib (clinical activity in NTRK fusion protein diseases, but also in *ROS*-mutated NSCLC), and fedratinib (clinical activity in myeloproliferative neoplasms, but with RET activity in addition to JAK2 and FLT3 antagonism).

Cyclin-Dependent Kinase Inhibitors Cyclin-dependent kinases (CDKs) are activated as the result of oncogene pathway activity, and CDK4 and CDK6 phosphorylate the retinoblastoma (RB) tumor-suppressor gene to allow entry into S-phase. Palbociclib, abemaciclib, and ribociclib, selective inhibitors of CDK4 and CDK6, have noteworthy activity in advanced breast cancers also expressing the estrogen receptor, usually in conjunction with continued efforts to suppress estrogen receptor signaling, and frequently in conjunction with mTOR inhibitors. Further clinical investigations in other RB intact tumors may broaden their role.

Protein Homeostasis Modulators The proteasome is a macromolecular complex that degrades misfolded proteins tagged for removal by ubiquitin ligases. Proteasome inhibitors were originally designed as potential anti-inflammatory agents owing to proteasome activity to produce inflammatory cytokines but had unexpected antiproliferative activity in a variety of cell types. Proteasome inhibitors have clinical utility in myeloma and lymphoma, where unbalanced synthesis of immunoglobulin components can accumulate after proteasome inhibitor treatment and induce apoptosis or starve cells for amino acids, inducing autophagy. Boronic acid proteasome inhibitors, including bortezomib and ixazomib, cause thrombocytopenia, gastrointestinal dysfunction, and neuropathy. Carfilzomib is a distinct chemotype with attenuated neuropathy but increased incidence of infusion reactions and cytokine release, with attendant risk of cardiopulmonary adverse events.

Exportin 1 is a nuclear membrane transport protein that is responsible for normal exit and entry of a variety of nuclear proteins. Selinexor is an inhibitor of exportin action, resulting in abnormal nuclear accumulation of, e.g., tumor-suppressor gene products or needed export of other products, e.g., oncogene products. Useful clinical activity has been seen in myeloma and diffuse large B-cell lymphomas including those arising from previously treated indolent lymphomas. Cytopenias, gastrointestinal distress, and hyponatremia are features of its clinical use.

Chromatin-Modifying Agents Gene function is altered not only by mutation of DNA structure, but also by "epigenetic" mechanisms that alter the capacity of DNA to be transcribed or interact with regulatory proteins in the nucleus including transcription factors. Initial epigenetic approaches to modulate gene expression extended from the observation that low concentrations of certain nucleosides (5′azacytidine and decitabine) caused loss of methylated cytosine in DNA, associated with gene silencing, and had clinical activity in causing differentiation of AML cells with notably less toxicity than higher concentrations. 5′Azacytidine and decitabine are misincorporated into DNA and then scavenge DNA methyl transferase to disable DNA methylation of tumor-promoting genes and thus alter their transcription.

Histone deacetylase inhibitors alter the histone protein "packing" density of chromatin and induce global changes in expression of cell cycle regulatory proteins. Vorinostat, belinostat, and romidepsin are useful in cutaneous and peripheral T-cell lymphomas; panobinostat has activity in multiple myeloma. The agents are generally well tolerated but with the potential for cytopenias. The histone methyltransferase inhibitor tazemetostat is a first-in-class inhibitor of histone methyltransferase with unique activity in epithelioid sarcoma owing to its modulation of transcriptional mechanisms unique to that tumor and, recently, in certain follicular lymphomas.

Cancer Cell Metabolism Modulators Oncogenic transformation causes a "rewiring" of cellular metabolism away from oxidative phosphorylation to glycolysis (historically defined as the "Warburg effect" of aerobic glycolysis in animal and human tumors) with attendant tolerance of hypoxia and production of metabolites important for sustaining cell proliferation. Recent clinical studies have defined clinical value from inhibitors of the cell lipid membrane localized phosphoinositide-3 (PI3) kinase and mammalian target of rapamycin (mTOR) (the latter is a kinase whose inhibition was originally discovered as the mechanism by which the immunosuppressant rapamycin, isolated from a soil bacterium, decreased T-cell proliferation). PI3 kinase is activated by numerous oncogenic tyrosine kinases to ultimately cause a cascade of metabolic alterations including increased glucose uptake and activation of mTOR isoforms, which selectively increase translation efficiency of key regulators of cell cycle progression and protein synthetic capacity.

Temsirolimus and everolimus are mTOR inhibitors with activity in renal cancers. They produce stomatitis and fatigue; some hyperlipidemia (10%) and myelosuppression (10%); and rare lung toxicity and immunosuppression in regimens used clinically. Everolimus is also useful in patients with hormone receptor–positive breast cancers displaying resistance to hormonal inhibition and in certain neuroendocrine and brain tumors, the latter arising in patients with sporadic or inherited mutations in the pathway activating mTOR. Isoform-specific PI3 kinase inhibitors are of increasing importance in breast cancers with mutated *PI3Kα* (alpelisib; hyperglycemia and cutaneous

eruptions can occur) or owing to selective use of PI3Kδ by lymphoid tissues in lymphomas (idelalisib, copanlisib, and duvelisib).

Isocitrate dehydrogenase (IDH) inhibitors (ivosidenib specific for IDH1 and enasidenib specific for IDH2) have activity in tumors with IDH mutants (AML, cholangiocarcinomas) that generate the "oncometabolite" 2-hydroxyglutarate, which alters DNA and histone methyltransferase activity. The drugs thus function indirectly as epigenetic chromatin modulating agents through effects on cellular metabolism.

DNA Repair Pathway Modulators DNA repair systems act physiologically to lessen the impact of environmental genomic damaging agents and influence the susceptibility to certain chemotherapy agents. DNA repair enzyme mutations underlie inherited cancer susceptibility syndromes such as mutated *BRCA* tumor-suppressor gene–associated breast and ovarian cancers, among others.

Laboratory investigations revealed that poly-ADP ribose polymerase (PARP) acts as a synthetic lethal gene with mutations in the homologous recombination repair pathway, including the *BRCA* gene. PARP responds to detection of DNA lesions by creating chains of poly-ADP, which serve as scaffolds for the localization of DNA repair proteins still active even with mutated *BRCA* isoforms. However, without PARP activity, the scaffolds cannot form, and the DNA damage becomes lethal. This observation immediately suggested the potential utility of PARP inhibitors (e.g., olaparib) as treatments potentially useful for *BRCA*-induced tumors. Recently, PARP inhibitor utility has been extended to tumors that do not harbor *BRCA* mutations but have given evidence of responding to platinum drugs, as a way of extending the useful effect of the chemotherapy treatment. This finding underscores the likelihood that sensitivity to DNA-directed cytotoxic drugs on the part of a tumor is at least in part related to the drugs' ability to take advantage of a sensitizing effect of a tumor's endogenous DNA repair capacity.

Miscellaneous Targeted Therapies The t(15;17) chromosomal translocation is diagnostic of acute promyelocytic leukemia (APL), a subset of AML. The translocation produces a chimeric fusion protein joining the retinoic acid receptor (RAR) α to the transcription factor PML. The abnormal protein, encoding PML-RARα, blocks differentiation of the cancer cells. All-*trans*-retinoic acid (ATRA) binds to the chimeric protein, releasing the block to differentiation inducing response in APL with fewer complications from cytopenias and disordered coagulation seen with cytotoxic agents. Its use can be attended by a "differentiation syndrome" characterized by cytokine release from and organ infiltration by the tumor cells. Pulmonary function can be severely compromised but is generally responsive to glucocorticoids. Increased intracranial pressure can occur from ATRA, and headache should occasion fundoscopic exam.

Arsenic trioxide was found empirically to also be of value in treating APL, and further study revealed that it also modulates PML-RARα levels, along with decreasing the tolerance of APL cells for free radical damage, inducing apoptosis. The combination of arsenic trioxide and ATRA is productive of very high rates of complete remission in APL. Arsenic trioxide can cause lengthening of the QT interval, and careful attention to concomitant medications, Mg^{2+}, ionized Ca^{2+}, and K^{+} is necessary during treatment.

The sonic hedgehog transcription factor pathway is regulated by the WNT ligands, which are active during embryonic and fetal life and in certain neoplasms. The sonic hedgehog inhibitors sonidegib and glasdegib are useful in non–surgically treatable cutaneous basal cell carcinomas and certain AMLs, respectively, where the pathway is active.

High-affinity binding to receptors on tumor cells can deliver toxins to tumor cells, exemplified by the IL-3–diphtheria toxin fusion protein tagraxofusp-erzs, targeting the IL-3 receptor (CD123) and useful in blastic plasmacytoid dendritic cell neoplasms. Capillary leak syndrome induced by the toxin component requires careful monitoring of fluid balance to avoid pulmonary dysfunction in particular. Specific receptors for cytokines and growth factors can also serve as "traps" to sequester needed growth factors. Ziv-aflibercept is not an antibody, but a solubilized VEGF receptor VEGF binding domain, and therefore may have a distinct mechanism of action from bevacizumab, but with comparable side effects.

SYSTEMIC RADIATION THERAPY

Systemically administered isotopes of iodide have an important role in the treatment of thyroid neoplasms, owing to the selective upregulation of the iodide transporter in the tumor cell compartment. Likewise, isotopes of samarium and radium have been found useful in the palliation of bony metastases of prostate cancer owing to their selective deposition at the tumor-bone matrix interface. Antibody-radioisotope complexes such as Y^{90}-ibritumomab-tiuxetan target CD20, are useful in treating lymphoma, or an isotope can be complexed to a ligand for which the tumor has high affinity. The latter strategy is employed by Lu^{177}-dotatate, where an analog of somatostatin brings the lutetium isotope close to tumors such as somatostatin receptor–positive gastroenteropancreatic neuroendocrine tumors.

RESISTANCE TO CANCER TREATMENTS

Resistance mechanisms to the conventional cytotoxic agents were initially characterized in the late twentieth century as defects in drug uptake, metabolism, or export by tumor cells. The *multidrug resistance* (*MDR*) gene, encoding P-glycoprotein (Pgp), is prototypic of transport proteins that efficiently excrete many drugs from tumor cells; no clinically useful modulator of this process has yet emerged. Drug-metabolizing enzymes such as cytidine deaminase are upregulated in resistant tumor cells, and this is the basis for so-called "high-dose cytarabine" regimens in the treatment of leukemia. Another resistance mechanism defined during this era involved increased expression of a drug's target, exemplified by amplification of the dihydrofolate reductase gene, in patients who had lost responsiveness to methotrexate, or mutation of topoisomerase II in tumors that relapsed after topoisomerase II modulator treatment.

A second class of resistance mechanisms involves loss of the cellular apoptotic mechanism activated after the engagement of a drug's target by the drug. This occurs in a way that is heavily influenced by the biology of the particular tumor type. For example, decreased alkylguanine alkyltransferase expression defines a subset of glioblastoma patients with the prospect of enhanced benefit from treatment with temozolomide but has no value in predicting benefit from temozolomide in epithelial neoplasms. Likewise, ovarian cancers resistant to platinating agents have decreased expression of the proapoptotic gene *BAX*.

A related class of resistance mechanisms emerged from sequencing of the targets of agents directed at oncogenic kinases, revealing mutated targets, as described previously. This relates to the phenomenon of tumor heterogeneity. Tumors harbor distinct populations of subclones that arise during the process of carcinogenesis, sharing to variable degrees mutations that may promote the growth of some subclones, but that are absent or are no longer relevant to the growth of other subclones. Really useful targeted therapies address a target present in all subclones and to which all tumor subclones require for tumor growth.

Finally, other mechanisms of resistance to targeted agents include the upregulation of alternate means of activating the pathway targeted by the agent. Thus, melanomas initially responsive to *BRAF* V600E antagonists such as vemurafenib may reactivate RAF signaling by employing variant isoforms that can bypass the drug. Likewise, inhibition of HER2/neu signaling in breast cancer cells can lead to the emergence of variants with distinct ways of activating downstream effectors such as PI3 kinase.

SUPPORTIVE CARE DURING CANCER TREATMENT

MYELOSUPPRESSION

Cytotoxic chemotherapeutic agents almost invariably affect bone marrow function. Titration of this effect determines the tolerated dose of the agent on a given schedule. Polymorphonuclear leukocytes (PMNs; $t_{1/2}$ = 6–8 h), platelets ($t_{1/2}$ = 5–7 days), and red blood cells (RBCs; $t_{1/2}$ = 120 days) have most, less, and least susceptibility, respectively, to usually administered cytotoxic agents. The nadir count of each cell type

in response to classes of agents is characteristic. Maximal neutropenia occurs 6–14 days after conventional doses of anthracyclines, antifolates, and antimetabolites. Alkylating agents differ from each other in the timing of cytopenias. Nitrosoureas, DTIC, and procarbazine can display delayed marrow toxicity, first appearing 6 weeks after dosing.

Complications of myelosuppression result from the predictable sequelae of the missing cells' function. *Febrile neutropenia* refers to the clinical presentation of fever and <1500 granulocytes/μL. Management of febrile neutropenia is considered in **Chap. 74**. Transfusion of granulocytes has no role in the management of febrile neutropenia, owing to their exceedingly short half-life, mechanical fragility, and clinical syndromes of pulmonary compromise with leukostasis after their use. Instead, colony-stimulating factors (CSFs) are used to augment bone marrow production of PMNs. The American Society of Clinical Oncology has developed practice guidelines for the use of granulocyte CSF (G-CSF) and GM-CSF **(Table 73-7)**.

TABLE 73-7 Indications for the Clinical Use of G-CSF or GM-CSF

Preventive Uses
With the first cycle of chemotherapy (so-called *primary CSF administration*)
Not needed on a routine basis
Use if the probability of febrile neutropenia is ≥20%
Use if patient has preexisting neutropenia or active infection
Age >65 years treated for lymphoma with curative intent or other tumors treated by similar regimens
Poor performance status
Extensive prior chemotherapy
Dose-dense regimens in a clinical trial or with strong evidence of benefit
With subsequent cycles if febrile neutropenia has previously occurred (so-called *secondary CSF administration*)
Not needed after short-duration neutropenia without fever
Use if patient had febrile neutropenia in previous cycle
Use if prolonged neutropenia (even without fever) delays therapy
Therapeutic Uses
Afebrile neutropenic patients
No evidence of benefit
Febrile neutropenic patients
No evidence of benefit
May feel compelled to use in the face of clinical deterioration from sepsis, pneumonia, or fungal infection, but benefit unclear
In bone marrow or peripheral blood stem cell transplantation
Use to mobilize stem cells from marrow
Use to hasten myeloid recovery
In acute myeloid leukemia
G-CSF of minor or no benefit
GM-CSF of no benefit and may be harmful
In myelodysplastic syndromes
Not routinely beneficial
Use intermittently in subset with neutropenia and recurrent infection
What Dose and Schedule Should Be Used?
G-CSF: 5 mg/kg per day subcutaneously
GM-CSF: 250 mg/m^2 per day subcutaneously
Pegfilgrastim: one dose of 6 mg 24 h after chemotherapy
When Should Therapy Begin and End?
When indicated, start 24–72 h after chemotherapy
Continue until absolute neutrophil count is 10,000/μL
Do not use concurrently with chemotherapy or radiation therapy

Abbreviations: CSF, colony-stimulating factor; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor.

Source: From the American Society of Clinical Oncology: J Clin Oncol 24:3187, 2006.

Dangerous degrees of thrombocytopenia do not frequently complicate the management of patients with solid tumors receiving cytotoxic chemotherapy (with the possible exception of certain carboplatin-containing regimens), but they are frequent in patients with certain hematologic neoplasms where marrow is infiltrated with tumor. Severe bleeding related to thrombocytopenia occurs with increased frequency at platelet counts <20,000/μL in patients with acute leukemia and <10,000/μL in patients with solid tumors and is prevalent at counts <5000/μL.

The precise "trigger" point at which to transfuse patients has been defined as a platelet count of 10,000/μL or less in patients without medical comorbidities that may increase the risk of bleeding. This issue is important not only because of the costs of frequent transfusion but also because unnecessary platelet transfusions expose the patient to the risks of allosensitization and loss of value from subsequent transfusion, as well as the infectious and hypersensitivity risks inherent in any transfusion. Prophylactic transfusions to keep platelets >20,000/μL are reasonable in patients with leukemia who are stressed by fever or concomitant medical conditions. Careful review of medication lists to prevent exposure to nonsteroidal anti-inflammatory agents and maintenance of clotting factor levels adequate to support near-normal prothrombin and partial thromboplastin time tests are important in minimizing the risk of bleeding in the thrombocytopenic patient.

Anemia associated with chemotherapy can be managed by transfusion of packed RBCs. Transfusion is not undertaken until the hemoglobin falls to <80 g/L (8 g/dL), compromise of end-organ function occurs, or an underlying condition (e.g., coronary artery disease) calls for maintenance of hemoglobin >90 g/L (9 g/dL). Randomized trials in certain tumors have raised the possibility that erythropoietin (EPO) use may promote tumor cell survival.

NAUSEA AND VOMITING

The most common side effect of chemotherapy administration is nausea, with or without vomiting. Nausea may be acute (within 24 h of chemotherapy), delayed (>24 h), or anticipatory of the receipt of chemotherapy. Highly emetogenic drugs (risk of emesis >90%) include DTIC, cyclophosphamide at >1500 mg/m^2, and cisplatin; moderately emetogenic drugs (30–90% risk) include carboplatin, cytosine arabinoside (>1 g/m^2), ifosfamide, conventional-dose cyclophosphamide, and anthracyclines; low-risk (10–30%) agents include 5-FU, taxanes, etoposide, and bortezomib, with minimal risk (<10%) afforded by treatment with antibodies, bleomycin, busulfan, fludarabine, and vinca alkaloids.

Serotonin antagonists (5-HT$_3$) and neurokinin 1 (NK1) receptor antagonists are useful in "high-risk" chemotherapy regimens. The combination acts at both peripheral gastrointestinal and CNS sites that control nausea and vomiting. For example, the 5-HT$_3$ blocker dolasetron, 100 mg intravenously or orally; dexamethasone, 12 mg; and the NK1 antagonist aprepitant, 125 mg orally, are combined on the day of administration of severely emetogenic regimens, with repetition of dexamethasone (8 mg) and aprepitant (80 mg) on days 2 and 3 for delayed nausea. Alternate 5-HT$_3$ antagonists include ondansetron, given as 0.15 mg/kg intravenously for three doses just before and at 4 and 8 h after chemotherapy; palonosetron at 0.25 mg over 30 s, 30 min before chemotherapy; and granisetron, given as a single dose of 0.01 mg/kg just before chemotherapy. Emesis from moderately emetic chemotherapy regimens may be prevented with a 5-HT$_3$ antagonist and dexamethasone alone for patients not receiving doxorubicin and cyclophosphamide combinations; the latter combination requires the 5-HT$_3$/dexamethasone/aprepitant on day 1, but aprepitant alone on days 2 and 3. Emesis from low-emetic-risk regimens may be prevented with 8 mg of dexamethasone alone or with non-5-HT$_3$, non-NK1 antagonist approaches including the following.

Antidopaminergic phenothiazines act directly at the chemoreceptor trigger zone (CTZ) in the brainstem medulla and include prochlorperazine (Compazine), 10 mg intramuscularly or intravenously, 10–25 mg orally, or 25 mg per rectum every 4–6 h for up to four doses;

and thiethylperazine, 10 mg by potentially all of the above routes every 6 h. Haloperidol is a butyrophenone dopamine antagonist given at 1 mg intramuscularly or orally every 8 h. Metoclopramide acts on peripheral dopamine receptors to augment gastric emptying and is used in high doses for highly emetogenic regimens (1–2 mg/kg intravenously 30 min before chemotherapy and every 2 h for up to three additional doses as needed); intravenous doses of 10–20 mg every 4–6 h as needed or 50 mg orally 4 h before and 8 and 12 h after chemotherapy are used for moderately emetogenic regimens. 5-9-Tetrahydrocannabinol (Marinol) is a rather weak antiemetic compared to other available agents, but it may be useful for persisting nausea and is used orally at 10 mg every 3–4 h as needed. Olanzapine, an "atypical antipsychotic" acting at multiple neurotransmitter receptors, may be of value, most clearly in cases refractory to the measures described above. Some practice guidelines have endorsed its earlier use in adults receiving highly emetogenic chemotherapy regimens in combination with an NK1 antagonist plus an HT3 antagonist plus dexamethasone.

DIARRHEA

Similar to the vomiting syndromes, chemotherapy-induced diarrhea may be immediate or can occur in a delayed fashion up to 48–72 h after the drugs. Careful attention to maintained hydration and electrolyte repletion, intravenously if necessary, along with antimotility treatments such as "high-dose" loperamide (4 mg at the first occurrence of diarrhea, with 2 mg repeated every 2 h until 12 h without loose stools, not to exceed a total daily dose of 16 mg), are appropriate. Octreotide (100–150 μg), a somatostatin analogue, or intralumenally acting opiate-based preparations may be considered for patients not responding to loperamide.

MUCOSITIS

Irritation and inflammation of the mucous membranes (mucositis) particularly afflicting the oral and anal mucosa, but potentially involving the entire gastrointestinal tract, may accompany cytotoxic chemotherapy. Topical therapies, including anesthetics and barrier-creating preparations, may provide symptomatic relief in mild cases. Palifermin, a keratinocyte growth factor and member of the fibroblast growth factor family, is effective in preventing severe mucositis in the setting of high-dose chemotherapy with stem cell transplantation for hematologic malignancies. It may also prevent or ameliorate mucositis from radiation.

ALOPECIA

Chemotherapeutic agents vary widely in causing alopecia, with anthracyclines, alkylating agents, and topoisomerase inhibitors reliably causing near-total alopecia when given at therapeutic doses. Antimetabolites are more variably associated with alopecia. Psychological support and the use of cosmetic resources are to be encouraged. "Chemo caps" that reduce scalp temperature to decrease the degree of alopecia are controversial during treatment with curative intent of neoplasms, such as leukemia or lymphoma, or in adjuvant breast cancer therapy. The richly vascularized scalp can certainly harbor micrometastatic or disseminated disease.

GONADAL DYSFUNCTION AND PREGNANCY

All cancer treatments described in this chapter should be regarded as potentially injurious to the developing fetus and to newborns via lactation. However, there are gradations to the degree of reproductive harm. All agents tend to have increased risk of adverse outcomes when administered during the first trimester, and strategies to delay chemotherapy, if possible, until after this milestone should be considered if the pregnancy is to continue to term. Patients in their second or third trimester can be treated with most regimens for the common neoplasms afflicting women in their childbearing years, with the exception of antimetabolites, particularly antifolates, which have notable teratogenic or fetotoxic effects throughout pregnancy. The need for anticancer chemotherapy per se is infrequently a clear basis to recommend termination of a concurrent pregnancy, although each treatment strategy in this circumstance must be tailored to the individual needs of the patient.

Cessation of ovulation and azoospermia reliably result from regimens that contain alkylating agents and topoisomerase poison. The duration of these effects varies with age and sex. Sperm banking before treatment may be considered. Females experience amenorrhea with anovulation after alkylating agent therapy; egg preservation may be considered but may delay inception of urgent treatment. Recovery of normal menses is frequent if treatment is completed before age 30, but patients are unlikely to recover menses after age 35. Even those who regain menses usually experience premature menopause. Because the magnitude and extent of decreased fertility can be difficult to predict, patients should be counseled to maintain effective contraception, preferably by barrier means, during and after therapy. Resumption of efforts to conceive should be considered in the context of the patient's likely prognosis. Hormone replacement therapy should be undertaken in women who do not have a hormonally responsive tumor. For patients who have had a hormone-sensitive tumor primarily treated by a local modality, conventional practice would counsel against hormone replacement, but this issue is under investigation.

PALLIATIVE AND SUPPORTIVE CARE

An important perspective the primary care provider may bring to patients and their families facing incurable cancer is that, given the limited value of chemotherapeutic approaches at some point in the natural history of most metastatic cancers, *palliative care* or *hospice-based* approaches, with meticulous and ongoing attention to symptom relief and with family, psychological, and spiritual support, should receive prominent attention as a valuable therapeutic plan **(Chaps. 12** and **69)**. Optimizing the quality of life rather than attempting to extend it becomes a valued intervention. Patients facing the impending progression of disease in a life-threatening way frequently choose to undertake toxic treatments of little to no potential value, and support provided by the primary caregiver in accessing palliative and hospice-based options in contrast to receiving toxic and ineffective regimens can be critical in providing a basis for patients to make sensible choices.

Late effects of cancer and its treatment are reviewed in **Chap. 95**.

74 Infections in Patients with Cancer

Robert W. Finberg*

Infections are a common cause of death and an even more common cause of morbidity in patients with a wide variety of neoplasms. Infections in cancer patients can result directly from tissue invasion by cancerous cells (either by replacement of healthy host marrow cells or by occlusion of an orifice) **(Table 74-1)** or as a result of treatment. In the era of cytotoxic chemotherapy, neutropenia as a result of chemotherapy was the major cause of infectious complications of cancer therapy. The routine use of granulocyte-stimulating cytokines has, in most cases, shortened the duration of neutropenia, and the increasing use of checkpoint inhibitors and chimeric antigen receptor (CAR) T cells has changed the field of oncology and led to better outcomes. Unfortunately, checkpoint inhibitors and immunomodulators are also associated with an increased risk of infections—particularly intracellular pathogens. An evolving approach to prevention and treatment of infectious complications of cancer has decreased infection-associated mortality rates and will probably continue to do so. This accomplishment has resulted from three major steps:

1. *Early treatment:* The practice of using early empirical antibiotics reduced mortality rates among patients with leukemia and bacteremia from 84% in 1965 to 44% in 1972. The mortality rate due to infection in febrile neutropenic patients dropped to <10% by 2013. This dramatic improvement is attributed to early intervention with appropriate antimicrobial therapy.
2. *Empirical treatment:* "Empirical" antifungal therapy has also lowered the incidence of disseminated fungal infection, with dramatic decreases in mortality rates. An antifungal agent is administered—on the basis of likely fungal infection—to neutropenic patients who, after 4–7 days of antibiotic therapy, remain febrile but have no positive cultures.
3. *Prophylaxis:* Use of antibiotics for afebrile neutropenic patients as broad-spectrum prophylaxis against infections has decreased both mortality and morbidity even further. The current approach to treatment of severely neutropenic patients (e.g., those receiving high-dose chemotherapy for leukemia or high-grade lymphoma) is based on initial prophylactic therapy at the onset of neutropenia, subsequent "empirical" antibacterial therapy targeting the organisms whose involvement is likely in light of physical findings (most often fever alone), and finally "empirical" antifungal therapy based on the known likelihood that fungal infection will become a serious issue after 4–7 days of broad-spectrum antibacterial therapy.

A physical predisposition to infection in patients with cancer (Table 74-1) can be a result of the neoplasm's production of a break in the skin. For example, a squamous cell carcinoma may cause local invasion of the epidermis, which allows bacteria to gain access to subcutaneous tissue and permits the development of cellulitis. The artificial closing of a normally patent orifice can also predispose to infection; for example, obstruction of a ureter by a tumor can cause urinary tract infection, and obstruction of the bile duct can cause cholangitis. Part of the host's normal defense against infection depends on the continuous emptying of a viscus; without emptying, a few bacteria that are present as a result of bacteremia or local transit can multiply and cause disease.

A similar problem can affect patients whose lymph node integrity has been disrupted by radical surgery, particularly patients who have had radical node dissections. A common clinical problem following radical mastectomy is the development of cellulitis (usually caused by streptococci or staphylococci) because of lymphedema and/or inadequate lymph drainage. In most cases, this problem can be addressed by local measures designed to prevent fluid accumulation and breaks in the skin, but antibiotic prophylaxis has been used in refractory cases.

A life-threatening problem common to many cancer patients is the loss of the reticuloendothelial capacity to clear microorganisms after splenectomy, which may be performed as part of the management of hairy cell leukemia, chronic lymphocytic leukemia (CLL), and chronic myelogenous leukemia (CML) as well as Hodgkin's disease. Even after curative therapy for the underlying disease, the lack of a spleen predisposes such patients to rapidly fatal infections. The loss of the spleen through trauma similarly predisposes the normal host to overwhelming infection throughout life. The splenectomized patient should be counseled about the risks of infection with certain organisms, such as the protozoan *Babesia* **(Chap. 225)** and *Capnocytophaga canimorsus*, a bacterium carried in the mouths of animals **(Chaps. 141** and **158)**. Because encapsulated bacteria (*Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Neisseria meningitidis*) are the organisms most commonly associated with postsplenectomy sepsis, splenectomized persons should be vaccinated (and revaccinated; **Table 74-2** and **Chap. 123**) against the capsular polysaccharides of these organisms. Many clinicians recommend giving splenectomized patients a small supply of antibiotics effective against *S. pneumoniae*, *N. meningitidis*, and *H. influenzae* to avert rapid, overwhelming sepsis in the event that they cannot present for medical attention immediately after the onset of fever or other signs or

TABLE 74-1 Disruption of Normal Barriers in Patients with Cancer That May Predispose Them to Infections

TYPE OF DEFENSE	SPECIFIC LESION OR DEFICIENCY	CELLS INVOLVED	ORGANISM	CANCER ASSOCIATION	DISEASE
Physical barrier	Breaks in skin	Skin epithelial cells	Staphylococci, streptococci	Head and neck, squamous cell carcinoma	Cellulitis, extensive skin infection
Emptying of fluid collections	Occlusion of orifices: ureters, bile duct, colon	Luminal epithelial cells	Gram-negative bacilli	Renal, ovarian, biliary tree, metastatic diseases of many cancers	Rapid, overwhelming bacteremia; urinary tract infection
Lymphatic function	Node dissection	Lymph nodes	Staphylococci, streptococci	Breast cancer surgery	Cellulitis
Splenic clearance of microorganisms	Splenectomy	Splenic reticuloendothelial cells	*Streptococcus pneumoniae, Haemophilus influenzae, Neisseria meningitidis, Babesia, Capnocytophaga canimorsus*	Hodgkin's disease, leukemia	Rapid, overwhelming sepsis
Phagocytosis	Lack of granulocytes	Granulocytes (neutrophils)	Staphylococci, streptococci, enteric organisms, fungi	Acute myeloid and acute lymphocytic leukemias, hairy cell leukemia	Bacteremia
Humoral immunity	Lack of antibodies	B cells	*S. pneumoniae, H. influenzae, N. meningitidis*	Chronic lymphocytic leukemia, multiple myeloma	Infections with encapsulated organisms, sinusitis, pneumonia
Cellular immunity	Lack of T cells	T cells and macrophages	*Mycobacterium tuberculosis, Listeria*, herpesviruses, fungi, intracellular parasites	Hodgkin's disease, leukemia, T-cell lymphoma	Infections with intracellular bacteria, fungi, parasites; virus reactivation

*Deceased.

TABLE 74-2 Vaccination of Cancer Patients Receiving Chemotherapy[a]

VACCINE	USE IN INDICATED PATIENTS		
	INTENSIVE CHEMOTHERAPY	HODGKIN'S DISEASE	HEMATOPOIETIC STEM CELL TRANSPLANTATION
Diphtheria-tetanus-pertussis[b]	Primary series and boosters as necessary	No special recommendation	3 doses given 6–12 months after transplantation
Poliomyelitis[c]	Complete primary series and boosters	No special recommendation	3 doses given 6–12 months after transplantation
Haemophilus influenzae type b conjugate	Primary series and booster for children	Single dose for adults	3 doses given 6–12 months after transplantation (separated by 1 month)
Human papillomavirus (HPV)	HPV vaccine is approved for males and females 9–26 years of age. Check Centers for Disease Control and Prevention (CDC) website (*www.cdc.gov/vaccines*) for updated recommendations.	HPV vaccine is approved for males and females 9–26 years of age. Check CDC website (*www.cdc.gov/vaccines*) for updated recommendations.	HPV vaccine is approved for males and females 9–26 years of age. Check CDC website (*www.cdc.gov/vaccines*) for updated recommendations.
Hepatitis A	As indicated for normal hosts on the basis of occupation and lifestyle	As indicated for normal hosts on the basis of occupation and lifestyle	As indicated for normal hosts on the basis of occupation and lifestyle
Hepatitis B	Same as for normal hosts	As indicated for normal hosts on the basis of occupation and lifestyle	3 doses given 6–12 months after transplantation
Pneumococcal conjugate vaccine (PCV13) Pneumococcal polysaccharide vaccine (PPSV23)[d]	Finish series prior to chemotherapy if possible.	Patients with splenectomy should receive both PCV13 and PPSV23.	Three doses of PCV13, beginning 3–6 months after transplantation, are followed by a dose of PPSV23 at least 8 weeks later. A second PPSV23 dose can be given 5 years later.
Quadrivalent meningococcal vaccine[e]	Should be administered to splenectomized patients and to patients living in endemic areas, including college students in dormitories	Should be administered to splenectomized patients and to patients living in endemic areas, including college students in dormitories. An additional dose can be given after 5 years.	Should be administered to splenectomized patients and to patients living in endemic areas, including college students in dormitories. An additional dose can be given after 5 years.
Meningococcal B vaccine	See above.	See above.	See above (see *www.cdc.gov/vaccines* for updated recommendations).
Influenza	Seasonal immunization	Seasonal immunization	Seasonal immunization (A seasonal dose is recommended and can be given as early as 4 months after transplantation; if given <6 months after transplantation, an additional dose is recommended.)
Measles/mumps/rubella	Contraindicated	Contraindicated during chemotherapy	After 24 months in patients without graft-versus-host disease
Varicella-zoster virus[f]	Zoster recombinant vaccine	Zoster recombinant vaccine	Two-dose zoster recombinant vaccine recommended

[a]The latest recommendations by the Advisory Committee on Immunization Practices and the CDC guidelines can be found at *www.cdc.gov/vaccines*. [b]A single dose of TDaP (tetanus–diphtheria–acellular pertussis), followed by a booster dose of Td (tetanus–diphtheria) every 10 years, is recommended for adults. [c]Live-virus vaccine is contraindicated; inactivated vaccine should be used. [d]Two types of vaccines are used to prevent pneumococcal disease. A conjugate vaccine active against 13 serotypes (13-valent pneumococcal conjugate vaccine, or PCV13) is currently administered in three separate doses to all children. A polysaccharide vaccine active against 23 serotypes (23-valent pneumococcal polysaccharide vaccine, or PPSV23) elicits titers of antibody lower than those achieved with the conjugate vaccine, and immunity may wane more rapidly. Because the ablative chemotherapy given to recipients of hematopoietic stem cell transplants (HSCTs) eradicates immunologic memory, revaccination is recommended for all such patients. Vaccination is much more effective once immunologic reconstitution has occurred; however, because of the need to prevent serious disease, pneumococcal vaccine should be administered 6–12 months after transplantation in most cases. Because PPSV23 includes serotypes not present in PCV13, HSCT recipients should receive a dose of PPSV23 at least 8 weeks after the last dose of PCV13. Although antibody titers from PPSV23 clearly decay, experience with multiple doses of PPSV23 is limited, as are data on the safety, toxicity, or efficacy of such a regimen. For this reason, the CDC currently recommends the administration of one additional dose of PPSV23 at least 5 years after the last dose to immunocompromised patients, including transplant recipients, as well as patients with Hodgkin's disease, multiple myeloma, lymphoma, or generalized malignancies. Beyond this single additional dose, further doses are not recommended at this time. [e]Meningococcal conjugate vaccine (MenACWY) is recommended for adults ≤55 years old, and meningococcal polysaccharide vaccine (MPSV4) is recommended for those ≥56 years old. [f]Varicella vaccine is recommended for children and zoster recombinant vaccine for adults. [g]Contact the manufacturer for more information on use in children with acute lymphocytic leukemia.

symptoms of bacterial infection. A few tablets of amoxicillin/clavulanic acid (or levofloxacin if resistant strains of *S. pneumoniae* are prevalent locally) are a reasonable choice for this purpose.

The level of suspicion of infections with certain organisms depends on the type of cancer diagnosed (Table 74-3). Diagnosis of multiple myeloma or CLL should alert the clinician to the possibility of hypogammaglobulinemia. While immunoglobulin replacement therapy can be effective, in most cases, prophylactic antibiotics are a cheaper, more convenient method of eliminating bacterial infections in CLL patients with hypogammaglobulinemia. Patients with acute lymphocytic leukemia (ALL), patients with non-Hodgkin's lymphoma, and all cancer patients treated with high-dose glucocorticoids (or glucocorticoid-containing chemotherapy regimens) should receive antibiotic prophylaxis for *Pneumocystis* infection (Table 74-3) for the duration of their chemotherapy. In addition to exhibiting susceptibility to certain infectious organisms, patients with cancer are likely to manifest their infections in characteristic ways. For example, fever—generally a sign of infection in normal hosts—continues to be a reliable indicator in neutropenic patients. In contrast, patients receiving glucocorticoids and agents that impair T-cell function and cytokine secretion may have serious infections in the absence of fever. Similarly, neutropenic patients commonly present with cellulitis without purulence and with pneumonia without sputum or even x-ray findings (see below).

The use of monoclonal antibodies that target B and T cells as well as drugs that interfere with lymphocyte signal transduction events are associated with reactivation of latent infections. The use of infliximab and other anti-tumor necrosis factor (TNF) antibodies are associated with the development of reactivation tuberculosis. Similarly, the use of the anti-B cell antibody, retuximab, is associated with reactivation of hepatitis B and other latent viruses. Checkpoint inhibitors also predispose individuals to reactivation of intracellular pathogens, and clinicians must be aware of what viruses and other intracellular organisms

TABLE 74-3 Infections Associated with Specific Types of Cancer

CANCER	UNDERLYING IMMUNE ABNORMALITY	ORGANISM(S) CAUSING INFECTION
Multiple myeloma	Hypogammaglobulinemia	*Streptococcus pneumoniae, Haemophilus influenzae, Neisseria meningitidis*
Chronic lymphocytic leukemia	Hypogammaglobulinemia	*S. pneumoniae, H. influenzae, N. meningitidis*
Acute myeloid or lymphocytic leukemia	Granulocytopenia, skin and mucous membrane lesions	Extracellular gram-positive and gram-negative bacteria, fungi
Hodgkin's disease	Abnormal T-cell function	Intracellular pathogens (*Mycobacterium tuberculosis, Listeria, Salmonella, Cryptococcus, Mycobacterium avium*); herpesviruses
Non-Hodgkin's lymphoma and acute lymphocytic leukemia	Glucocorticoid chemotherapy, T- and B-cell dysfunction	*Pneumocystis*
Colon and rectal tumors	Local abnormalities[a]	*Streptococcus bovis* biotype 1 (bacteremia)
Hairy cell leukemia	Abnormal T-cell function	Intracellular pathogens (*M. tuberculosis, Listeria, Cryptococcus, M. avium*)

[a]The reason for this association is not well defined.

(mycobacteria, fungi, etc.) are likely to grow and pose a threat to an individual patient receiving these therapies. Like organ transplant recipients (Chap. 143), patients with latent bacterial disease (like tuberculosis) and latent viral disease (like herpes simplex or zoster) should be carefully monitored for reactivation disease.

SYSTEM-SPECIFIC SYNDROMES

SKIN-SPECIFIC SYNDROMES

Skin lesions are common in cancer patients, and the appearance of these lesions may permit the diagnosis of systemic bacterial or fungal infection. While cellulitis caused by skin organisms such as *Streptococcus* or *Staphylococcus* is common, neutropenic patients—that is, those with <500 functional polymorphonuclear leukocytes (PMNs)/μL—and patients with impaired blood or lymphatic drainage may develop infections with unusual organisms. Innocent-looking macules or papules may be the first sign of bacterial or fungal sepsis in immunocompromised patients (Fig. 74-1). In the neutropenic host, a macule progresses rapidly to ecthyma gangrenosum (see Fig. A1-34), a usually painless, round, necrotic lesion consisting of a central black or gray-black eschar with surrounding erythema. Ecthyma gangrenosum, which is located in nonpressure areas (as distinguished from necrotic lesions associated with lack of circulation), is often associated with *Pseudomonas aeruginosa* bacteremia (Chap. 164) but may be caused by other bacteria.

Candidemia (Chap. 216) is also associated with a variety of skin conditions (see Fig. A1-37) and commonly presents as a maculopapular rash. Punch biopsy of the skin may be the best method for diagnosis.

Cellulitis, an acute spreading inflammation of the skin, is most often caused by infection with group A *Streptococcus* or *Staphylococcus aureus*, virulent organisms normally found on the skin (Chap. 129). Although cellulitis tends to be circumscribed in normal hosts, it may spread rapidly in neutropenic patients. A tiny break in the skin may lead to spreading cellulitis, which is characterized by pain and erythema; in the affected patients, signs of infection (e.g., purulence) are often lacking. What might be a furuncle in a normal host may require amputation because of uncontrolled infection in a patient presenting with leukemia. A dramatic response to an infection that might be trivial in a normal host can mark the first sign of leukemia. Fortunately, granulocytopenic patients are likely to be infected with certain types of organisms (Table 74-4); thus, the selection of an antibiotic regimen is somewhat easier than it might otherwise be (see "Antibacterial Therapy," below). It is essential to recognize cellulitis early and to treat it aggressively. Patients who are neutropenic or who have previously

Aspergillus spp.	

[a]Often associated with intravenous catheters.

received antibiotics for other reasons may develop cellulitis with unusual organisms (e.g., *Escherichia coli*, *Pseudomonas*, or fungi). Early treatment, even of innocent-looking lesions, is essential to prevent necrosis and loss of tissue. Debridement to prevent spread may sometimes be necessary early in the course of disease, but it can often be performed after chemotherapy, when the PMN count increases.

Sweet syndrome, or *febrile neutrophilic dermatosis*, was originally described in women with elevated white blood cell (WBC) counts. The disease is characterized by the presence of leukocytes in the lower dermis, with edema of the papillary body. Ironically, this disease now is usually seen in neutropenic patients with cancer, most often in association with acute myeloid leukemia (AML) but also in association with a variety of other malignancies. Sweet syndrome usually presents as red or bluish-red papules or nodules that may coalesce and form sharply bordered plaques (see **Fig. A1-40**). The edema may suggest vesicles, but on palpation, the lesions are solid, and vesicles probably never arise in this disease. The lesions are most common on the face, neck, and arms. On the legs, they may be confused with erythema nodosum (see **Fig. A1-39**). The development of lesions is often accompanied by high fevers and an elevated erythrocyte sedimentation rate. Both the lesions and the temperature elevation respond dramatically to glucocorticoid administration. Treatment begins with high doses of glucocorticoids (prednisone, 60 mg/d) followed by tapered doses over the next 2–3 weeks.

Data indicate that *erythema multiforme* (see **Fig. A1-24**) with mucous membrane involvement is often associated with herpes simplex virus (HSV) infection and is distinct from Stevens-Johnson syndrome, which is associated with drugs and tends to have a more widespread distribution. Because cancer patients are both immunosuppressed (and therefore susceptible to herpes infections) and heavily treated with drugs (and therefore subject to Stevens-Johnson syndrome [see **Fig. A3-4**]), both of these conditions are common in this population.

Cytokines, which are used as adjuvants or primary treatments for cancer, can themselves cause characteristic rashes, further complicating the differential diagnosis. This phenomenon is a particular problem in bone marrow (stem cell) transplant recipients **(Chap. 143)**, who, in addition to having the usual chemotherapy-, antibiotic-, and cytokine-induced rashes, are plagued by graft-versus-host disease.

CATHETER-RELATED INFECTIONS

Because intravenous (IV) catheters are commonly used in cancer chemotherapy and are prone to cause infection **(Chap. 142)**, they pose a major problem in the care of patients with cancer. Some catheter-associated infections can be treated with antibiotics, whereas in others, the catheter must be removed **(Table 74-5)**. If the patient has a "tunneled" catheter (which consists of an entrance site, a subcutaneous tunnel, and an exit site), a red streak over the subcutaneous part of the line (the tunnel) is grounds for immediate device removal. Failure to remove catheters under these circumstances may result in extensive cellulitis and tissue necrosis.

More common than tunnel infections are exit-site infections, often with erythema around the area where the line penetrates the skin. Most authorities **(Chap. 147)** recommend treatment (usually with vancomycin) for an exit-site infection caused by coagulase-negative *Staphylococcus*. Treatment of coagulase-positive staphylococcal infection is associated with a poorer outcome, and it is advisable to remove the catheter if possible. Similarly, most clinicians remove catheters associated with infections due to *P. aeruginosa* and *Candida* species, because such infections are difficult to treat and bloodstream infections with these organisms are likely to be deadly. Catheter infections caused by *Burkholderia cepacia*, *Stenotrophomonas* species, *Agrobacterium* species, *Acinetobacter baumannii*, *Pseudomonas* species other than *aeruginosa*, and carbapenem-resistant Enterobacteriaceae are likely to be very difficult to eradicate with antibiotics alone. Similarly, isolation of *Bacillus*, *Corynebacterium*, and *Mycobacterium* species should prompt removal of the catheter.

GASTROINTESTINAL TRACT–SPECIFIC SYNDROMES

Upper Gastrointestinal Tract Disease • INFECTIONS OF THE MOUTH The oral cavity is rich in aerobic and anaerobic bacteria **(Chap. 177)** that normally live in a commensal relationship with the host. The antimetabolic effects of chemotherapy cause a breakdown of mucosal host defenses, leading to ulceration of the mouth and the potential for invasion by resident bacteria. Mouth ulcerations afflict most patients receiving cytotoxic chemotherapy and have been associated with viridans streptococcal bacteremia. *Candida* infections of the mouth are very common. Fluconazole is clearly effective in the treatment of both local infections (thrush) and systemic infections (esophagitis) due to *Candida albicans*. Other azoles (e.g., voriconazole) as well as echinocandins offer similar efficacy as well as activity against the fluconazole-resistant organisms that are associated with chronic fluconazole treatment **(Chap. 216)**.

Noma (*cancrum oris*), commonly seen in malnourished children, is a penetrating disease of the soft and hard tissues of the mouth and adjacent sites, with resulting necrosis and gangrene. It has a counterpart in immunocompromised patients and is thought to be due to invasion of the tissues by *Bacteroides*, *Fusobacterium*, and other normal inhabitants of the mouth. Noma is associated with debility, poor oral hygiene, and immunosuppression.

TABLE 74-5 Approach to Catheter Infections in Immunocompromised Patients

CLINICAL PRESENTATION OR ISOLATED PATHOGEN	CATHETER REMOVAL	ANTIBIOTICS	COMMENTS
Evidence of Infection, Negative Blood Cultures			
Exit-site erythema	Not necessary if infection responds to treatment	Usually, begin treatment for gram-positive cocci.	Coagulase-negative staphylococci are most common.
Tunnel-site erythema	Required	Treat for gram-positive cocci pending culture results.	Failure to remove the catheter may lead to necrosis of the involved area requiring skin grafts in the future.
Blood Culture–Positive Infections			
Coagulase-negative staphylococci	Line removal optimal but may be unnecessary if patient is clinically stable and responds to antibiotics	Usually, start with vancomycin. Linezolid, quinupristin/dalfopristin, and daptomycin are alternative agents.	If there are no contraindications to line removal, this course of action is optimal. If the line is removed, antibiotics may not be necessary.
Other gram-positive cocci (e.g., *Staphylococcus aureus, Enterococcus*); gram-positive rods (*Bacillus, Corynebacterium* spp.)	Recommended	Treat with antibiotics to which the organism is sensitive, with duration based on the clinical setting.	The incidence of metastatic infections following *S. aureus* infection and the difficulty of treating enterococcal infection make line removal the recommended course of action. In addition, gram-positive rods do not respond readily to antibiotics alone.
Gram-negative bacteria	Recommended	Use an agent to which the organism is shown to be sensitive.	Organisms like *Stenotrophomonas, Pseudomonas*, and *Burkholderia* are notoriously hard to treat, as are carbapenem-resistant organisms.
Fungi	Recommended	—	Fungal infections of catheters are extremely difficult to treat.

Viruses, particularly HSV, are a prominent cause of morbidity in immunocompromised patients, in whom they are associated with severe mucositis. The use of acyclovir, either prophylactically or therapeutically, is of value.

ESOPHAGEAL INFECTIONS The differential diagnosis of esophagitis (usually presenting as substernal chest pain upon swallowing) includes herpes simplex and candidiasis, both of which are readily treatable.

Lower Gastrointestinal Tract Disease Hepatic candidiasis (Chap. 216) results from seeding of the liver (usually from a gastrointestinal source) in neutropenic patients. It is most common among patients being treated for AML and usually presents symptomatically around the time neutropenia resolves. The characteristic picture is that of persistent fever unresponsive to antibiotics, abdominal pain and tenderness or nausea, and elevated serum levels of alkaline phosphatase in a patient with hematologic malignancy who has recently recovered from neutropenia. The diagnosis of this disease (which may present in an indolent manner and persist for several months) is based on the finding of yeasts or pseudohyphae in granulomatous lesions. Hepatic ultrasound or CT may reveal bull's-eye lesions. MRI scans reveal small lesions not visible by other imaging modalities. The pathology (a granulomatous response) and the timing (with resolution of neutropenia and an elevation in granulocyte count) suggest that the host response to *Candida* is an important component of the manifestations of disease. In many cases, although organisms are visible, cultures of biopsied material may be negative. The designation *hepatosplenic candidiasis* or *hepatic candidiasis* is a misnomer because the disease often involves the kidneys and other tissues; the term *chronic disseminated candidiasis* may be more appropriate. Because of the risk of bleeding with liver biopsy, diagnosis is often based on imaging studies (MRI, CT). Treatment should be directed to the causative agent (usually *C. albicans* but sometimes *Candida tropicalis* or other less common *Candida* species).

Typhlitis *Typhlitis* (also referred to as necrotizing colitis, neutropenic colitis, necrotizing enteropathy, ileocecal syndrome, and cecitis) is a clinical syndrome of fever and right-lower-quadrant (or generalized abdominal) tenderness in an immunosuppressed host. This syndrome is classically seen in neutropenic patients after chemotherapy with cytotoxic drugs. It may be more common among children than among adults and appears to be much more common among patients with AML or ALL than among those with other types of cancer. Physical examination reveals right-lower-quadrant tenderness, with or without rebound tenderness. Associated diarrhea (often bloody) is common, and the diagnosis can be confirmed by the finding of a thickened cecal wall on CT, MRI, or ultrasonography. Plain films may reveal a right-lower-quadrant mass, but CT with contrast or MRI is a much more sensitive means of diagnosis. Although surgery is sometimes attempted to avoid perforation from ischemia, most cases resolve with medical therapy alone. The disease is sometimes associated with positive blood cultures (which usually yield aerobic gram-negative bacilli), and therapy is recommended for a broad spectrum of bacteria (particularly gram-negative bacilli, which are likely to be found in the bowel flora).

***Clostridioides difficile*–Induced Diarrhea** Patients with cancer are predisposed to the development of *C. difficile* diarrhea (Chap. 134) as a consequence of chemotherapy alone. Thus, they may test positive for *C. difficile* even without receiving antibiotics. Obviously, such patients are also subject to *C. difficile*–induced diarrhea as a result of antibiotic pressure. *C. difficile* should always be considered as a possible cause of diarrhea in cancer patients who have received either chemotherapy or antibiotics. New approaches to treat *C. difficile*–induced diarrhea and to prevent *C. difficile* expansion as part of the gut microbiota may make this disease less troublesome in the future.

CENTRAL NERVOUS SYSTEM–SPECIFIC SYNDROMES

Meningitis The presentation of meningitis in patients with lymphoma or CLL and in patients receiving chemotherapy (particularly with glucocorticoids) for solid tumors suggests a diagnosis of cryptococcal or listerial infection. As noted previously, splenectomized patients are susceptible to rapid, overwhelming infection with encapsulated bacteria (including *S. pneumoniae*, *H. influenzae*, and *N. meningitidis*). Similarly, patients who are antibody-deficient (e.g., those with CLL, those who have received intensive chemotherapy, or those who have undergone bone marrow [stem cell] transplantation) are likely to have infections caused by these bacteria. Other cancer patients, however, because of their defective cellular immunity, are likely to be infected with other pathogens (Table 74-3). Central nervous system (CNS) tuberculosis should be considered, especially in patients from countries where tuberculosis is highly prevalent in the population.

Encephalitis The spectrum of disease resulting from viral encephalitis is expanded in immunocompromised patients. A predisposition to infections with intracellular organisms similar to those encountered in patients with AIDS (Chap. 202) is seen in cancer patients receiving (1) high-dose cytotoxic chemotherapy, (2) chemotherapy affecting T-cell function (e.g., fludarabine), or (3) antibodies that eliminate T cells (e.g., anti-CD3, alemtuzumab, anti-CD52) or cytokine activity (anti–tumor necrosis factor agents or interleukin 1 receptor antagonists). Infection with varicella-zoster virus (VZV) has been associated with encephalitis that may be caused by VZV-related vasculitis. Chronic viral infections may also be associated with dementia and encephalitic presentations. A diagnosis of progressive multifocal leukoencephalopathy (Chap. 138) should be considered when a patient who has received chemotherapy (rituximab in particular) presents with dementia (Table 74-6). Other abnormalities of the CNS that may be confused with infection include normal-pressure hydrocephalus and vasculitis resulting from CNS irradiation. It may be possible to differentiate these conditions by MRI.

Brain Masses Mass lesions of the brain most often present as headache with or without fever or neurologic abnormalities. Infections associated with mass lesions may be caused by bacteria (particularly *Nocardia*), fungi (particularly *Cryptococcus* or *Aspergillus*), or parasites (*Toxoplasma*). Epstein-Barr virus (EBV)–associated lymphoma may also present as single—or sometimes multiple—mass lesions of the brain. A biopsy may be required for a definitive diagnosis.

PULMONARY INFECTIONS

Pneumonia (Chap. 126) in immunocompromised patients may be difficult to diagnose because conventional methods of diagnosis depend on the presence of neutrophils. Bacterial pneumonia in neutropenic patients may present without purulent sputum—or, in fact, without any sputum at all—and may not produce physical findings suggestive of chest consolidation (rales or egophony).

In granulocytopenic patients with persistent or recurrent fever, the chest x-ray pattern may help to localize an infection and thus to determine which investigative tests and procedures should be undertaken and which therapeutic options should be considered (Table 74-7). In this setting, a simple chest x-ray is a screening tool; because the impaired host response results in less evidence of consolidation or infiltration, high-resolution CT is recommended for the diagnosis of pulmonary infections. The difficulties encountered in the management of pulmonary infiltrates relate in part to the difficulties of performing diagnostic

TABLE 74-6 Differential Diagnosis of Central Nervous System Infections in Patients with Cancer

INFILTRATE	INFECTIOUS	NONINFECTIOUS
Localized	Bacteria (including *Legionella*, mycobacteria)	Local hemorrhage or embolism, tumor
Nodular	Fungi (e.g., *Aspergillus* or *Mucor*), *Nocardia*	Recurrent tumor
Diffuse	Viruses (especially cytomegalovirus), *Chlamydia*, *Pneumocystis*, *Toxoplasma gondii*, mycobacteria	Congestive heart failure, radiation pneumonitis, drug-induced lung injury, lymphangitic spread of cancer

procedures on the patients involved. When platelet counts can be increased to adequate levels by transfusion, microscopic and microbiologic evaluation of the fluid obtained by endoscopic bronchial lavage is often diagnostic. Lavage fluid should be cultured for *Mycoplasma*, *Chlamydia*, *Legionella*, *Nocardia*, more common bacterial pathogens, fungi, and viruses. In addition, the possibility of *Pneumocystis* pneumonia should be considered, especially in patients with ALL or lymphoma who have not received prophylactic trimethoprim-sulfamethoxazole (TMP-SMX). The characteristics of the infiltrate may be helpful in decisions about further diagnostic and therapeutic maneuvers. Nodular infiltrates suggest fungal pneumonia (e.g., that caused by *Aspergillus* or *Mucor*). Such lesions may best be approached by visualized biopsy procedures. It is worth noting that while bacterial pneumonias classically present as lobar infiltrates in normal hosts, bacterial pneumonias in granulocytopenic hosts present with a paucity of signs, symptoms, or radiographic abnormalities; thus, the diagnosis is difficult.

Aspergillus species **(Chap. 217)** can colonize the skin and respiratory tract or cause fatal systemic illness. Although this fungus may cause aspergillomas in a previously existing cavity or may produce allergic bronchopulmonary disease in some patients, the major problem posed by this genus in neutropenic patients is invasive disease, primarily due to *Aspergillus fumigatus* or *Aspergillus flavus*. The organisms enter the host following colonization of the respiratory tract, with subsequent invasion of blood vessels. The disease is likely to present as a thrombotic or embolic event because of this ability of the fungi to invade blood vessels. The risk of infection with *Aspergillus* correlates directly with the duration of neutropenia. In prolonged neutropenia, positive surveillance cultures for nasopharyngeal colonization with *Aspergillus* may predict the development of disease.

Patients with *Aspergillus* infection often present with pleuritic chest pain and fever, which are sometimes accompanied by cough. Hemoptysis may be an ominous sign. Chest x-rays may reveal new focal infiltrates or nodules. Chest CT may reveal a characteristic halo consisting of a mass-like infiltrate surrounded by an area of low attenuation. The presence of a "crescent sign" on chest x-ray or chest CT, in which the mass progresses to central cavitation, is characteristic of invasive *Aspergillus* infection but may develop as the lesions are resolving.

In addition to causing pulmonary disease, *Aspergillus* may invade through the nose or palate, with deep sinus penetration. The appearance of a discolored area in the nasal passages or on the hard palate should prompt a search for invasive *Aspergillus*. This situation is likely to require surgical debridement. Catheter infections with *Aspergillus* usually require both removal of the catheter and antifungal therapy. Antifungal prophylaxis has led to the emergence of non-fumigatus *Aspergillus* species as well as Mucorales and *Scedosporium*/*Lomentospora* spp. **(Chaps. 217–219)**.

Diffuse interstitial infiltrates suggest viral, parasitic, or *Pneumocystis* pneumonia. If the patient has a diffuse interstitial pattern on chest x-ray, it may be reasonable, while considering invasive diagnostic procedures, to institute empirical treatment for *Pneumocystis* with TMP-SMX and for *Chlamydia*, *Mycoplasma*, and *Legionella* with a quinolone or azithromycin. Noninvasive procedures, such as staining of induced sputum smears for *Pneumocystis*, serum cryptococcal antigen tests, and urine testing for *Legionella* antigen, may be helpful. Serum galactomannan and β-D-glucan tests may be of value in diagnosing *Aspergillus* infection, but their utility is limited by their lack of sensitivity and specificity. The presence of an elevated level of β-D-glucan in the serum of a patient being treated for cancer who is not receiving prophylaxis against *Pneumocystis* suggests the diagnosis of *Pneumocystis* pneumonia. Infections with viruses that cause only upper respiratory symptoms in immunocompetent hosts, such as respiratory syncytial virus (RSV), influenza viruses, and parainfluenza viruses, may be associated with fatal pneumonitis in immunocompromised hosts. CMV reactivation occurs in cancer patients receiving chemotherapy, but CMV pneumonia is most common among hematopoietic stem cell transplant (HSCT) recipients **(Chap. 143)**. Polymerase chain reaction testing now allows rapid diagnosis of viral pneumonia, which can lead to treatment in some cases (e.g., influenza). Multiplex studies that can detect a wide array of viruses in the lung and upper respiratory tract are now available and will lead to specific diagnoses of viral pneumonias.

Bleomycin is the most common cause of chemotherapy-induced lung disease. Other causes include alkylating agents (such as cyclophosphamide, chlorambucil, and melphalan), nitrosoureas (carmustine [BCNU], lomustine [CCNU], and methyl-CCNU), busulfan, procarbazine, methotrexate, and hydroxyurea. Both infectious and noninfectious (drug- and/or radiation-induced) pneumonitis can cause fever and abnormalities on chest x-ray; thus, the differential diagnosis of an infiltrate in a patient receiving chemotherapy encompasses a broad range of conditions (Table 74-7). The treatment of radiation pneumonitis (which may respond dramatically to glucocorticoids) or drug-induced pneumonitis is different from that of infectious pneumonia, and a biopsy may be important in the diagnosis. Unfortunately, no definitive diagnosis can be made in ~30% of cases, even after bronchoscopy.

Open-lung biopsy is the gold standard of diagnostic techniques. Biopsy via a visualized thoracostomy can replace an open procedure in many cases. When a biopsy cannot be performed, empirical treatment can be undertaken; a quinolone or an erythromycin derivative (azithromycin) and TMP-SMX are used in the case of diffuse infiltrates, and an antifungal agent is administered in the case of nodular infiltrates. The risks should be weighed carefully in these cases. If inappropriate drugs are administered, empirical treatment may prove toxic or ineffective; either of these outcomes may be riskier than biopsy.

CARDIOVASCULAR INFECTIONS

Patients with Hodgkin's disease are prone to persistent infections by *Salmonella*, sometimes (and particularly often in elderly patients) affecting a vascular site. The use of IV catheters deliberately lodged in the right atrium is associated with a high incidence of bacterial endocarditis, presumably related to valve damage followed by bacteremia. Nonbacterial thrombotic endocarditis (marantic endocarditis) has been described in association with a variety of malignancies (most often solid tumors) and may follow bone marrow (stem cell) transplantation as well. The presentation of an embolic event with a new cardiac murmur suggests this diagnosis. Blood cultures are negative in this disease of unknown pathogenesis. Infective endocarditis can be a complication of cancer treatment because of the use of IV catheters that lead to bacterial infection. In addition, patients may present with infective endocarditis as an initial presentation of cancer, particularly in the case of gastrointestinal or genitourinary sources.

ENDOCRINE SYNDROMES

Infections of the endocrine system have been described in immunocompromised patients. *Candida* infection of the thyroid may be difficult to diagnose during the neutropenic period. It can be defined by indium-labeled WBC scans or gallium scans after neutrophil counts increase. CMV infection can cause adrenalitis with or without resulting adrenal insufficiency. The presentation of a sudden endocrine anomaly in an immunocompromised patient can be a sign of infection in the involved end organ.

MUSCULOSKELETAL INFECTIONS

Infection that is a consequence of vascular compromise, resulting in gangrene, can occur when a tumor restricts the blood supply to

muscles, bones, or joints. The process of diagnosis and treatment of such infection is similar to that in normal hosts, with the following caveats:

1. *In terms of diagnosis*, a lack of physical findings resulting from a lack of granulocytes in the granulocytopenic patient should make the clinician more aggressive in obtaining tissue rather than more willing to rely on physical signs.
2. *In terms of therapy*, aggressive debridement of infected tissues may be required. However, it is usually difficult to operate on patients who have recently received chemotherapy, both because of a lack of platelets (which results in bleeding complications) and because of a lack of WBCs (which may lead to secondary infection). A blood culture positive for *Clostridium perfringens*—an organism commonly associated with gas gangrene—can have a number of meanings **(Chap. 154)**. *Clostridium septicum* bacteremia is associated with the presence of an underlying malignancy. Bloodstream infections with intestinal organisms such as *Streptococcus bovis* biotype 1 and *C. perfringens* may arise spontaneously from lower gastrointestinal lesions (tumor or polyps); alternatively, these lesions may be harbingers of invasive disease. The clinical setting must be considered in order to define the appropriate treatment for each case.

RENAL AND URETERAL INFECTIONS

Infections of the urinary tract are common among patients whose ureteral excretion is compromised (Table 74-1). *Candida*, which has a predilection for the kidney, can invade either from the bloodstream or in a retrograde manner (via the ureters or bladder) in immunocompromised patients. The presence of "fungus balls" or persistent candiduria suggests invasive disease. Persistent funguria (with *Aspergillus* as well as *Candida*) should prompt a search for a nidus of infection in the kidney.

Certain viruses are typically seen only in immunosuppressed patients. BK virus (polyomavirus hominis 1) has been documented in the urine of bone marrow transplant recipients and, like adenovirus, may be associated with hemorrhagic cystitis.

ABNORMALITIES THAT PREDISPOSE TO INFECTION

(Table 74-1)

THE LYMPHOID SYSTEM

It is beyond the scope of this chapter to detail how all the immunologic abnormalities that result from cancer or from chemotherapy for cancer lead to infections. Disorders of the immune system are discussed in other sections of this book. As has been noted, patients with antibody deficiency are predisposed to overwhelming infection with encapsulated bacteria (including *S. pneumoniae*, *H. influenzae*, and *N. meningitidis*). Infections that result from the lack of a functional cellular immune system are described in **Chap. 202**. It is worth mentioning, however, that patients undergoing intensive chemotherapy for any form of cancer will have not only defects due to granulocytopenia but also lymphocyte dysfunction, which may be profound. Thus, these patients—especially those receiving glucocorticoid-containing regimens or drugs that inhibit either T-cell activation (calcineurin inhibitors or drugs like fludarabine, which affect lymphocyte function) or cytokine induction—should be given prophylaxis for *Pneumocystis* pneumonia.

Patients receiving treatment that eliminates B cells (e.g., with anti-CD20 antibodies or rituximab) are especially vulnerable to intercurrent viral infections. The incidence of progressive multifocal leukoencephalopathy (caused by JC virus) is elevated among these patients.

THE HEMATOPOIETIC SYSTEM

Initial studies in the 1960s revealed a dramatic increase in the incidence of infections (fatal and nonfatal) among cancer patients with a granulocyte count of <500/μL. The use of prophylactic antibacterial agents has reduced the number of bacterial infections, but 35–78% of febrile neutropenic patients being treated for hematologic malignancies develop infections at some time during chemotherapy. Aerobic pathogens (both gram-positive and gram-negative) predominate in all series, but the exact organisms isolated vary from center to center. Infections with anaerobic organisms are uncommon. Geographic patterns affect the types of fungi isolated. Tuberculosis and malaria are common causes of fever in the developing world and may present in this setting as well.

Neutropenic patients are unusually susceptible to infection with a wide variety of bacteria; thus, antibiotic therapy should be initiated promptly to cover likely pathogens if infection is suspected. Indeed, early initiation of antibacterial agents is mandatory to prevent deaths. Like most immunocompromised patients, neutropenic patients are threatened by their own microbial flora, including gram-positive and gram-negative organisms found commonly on the skin and mucous membranes and in the bowel (Table 74-4). Because treatment with narrow-spectrum agents leads to infection with organisms not covered by the antibiotics used, the initial regimen should target all pathogens likely to be the initial causes of bacterial infection in neutropenic hosts. Studies performed in the 1970s suggested that administration of antimicrobial agents should be continued until neutropenia resolves—that is, the granulocyte count is sustained above 500/μL for at least 2 days. Recent studies have indicated that it is reasonable to stop antibiotics in patients who are afebrile and stable after 72 hours of treatment **(Fig. 74-2)**. Fever may not resolve prior to granulocyte recovery. In some cases, patients remain febrile after resolution of neutropenia. In these instances, the risk of sudden death from overwhelming bacteremia is greatly reduced, and the following diagnoses should be seriously considered: (1) fungal infection, (2) bacterial abscesses or undrained foci of infection, and (3) drug fever (including reactions to antimicrobial agents as well as to chemotherapy or cytokines). In the proper setting, viral infection or graft-versus-host disease should be considered. In clinical practice, antibacterial therapy is usually discontinued when the patient is no longer neutropenic and all evidence of bacterial disease has been eliminated. Antifungal agents are then discontinued if there is no evidence of fungal disease. If the patient remains febrile, a search for viral diseases or unusual pathogens is conducted while unnecessary cytokines and other drugs are systematically eliminated from the regimen.

TREATMENT

Infections in Cancer Patients

ANTIBACTERIAL THERAPY

Hundreds of antibacterial regimens have been tested for use in patients with cancer. The major risk of infection is related to the degree of neutropenia seen as a consequence of either the disease or the therapy. Many of the relevant studies have involved small populations in which the outcomes have generally been good, and most have lacked the statistical power to detect differences among the regimens studied. Each febrile neutropenic patient should be approached as a unique problem, with particular attention given to previous infections and recent antibiotic exposures. Several general guidelines are useful in the initial treatment of neutropenic patients with fever (Fig. 74-2):

1. In the initial regimen, it is necessary to use antibiotics active against both gram-negative and gram-positive bacteria (Table 74-4).
2. Monotherapy with an aminoglycoside or an antibiotic lacking good activity against gram-positive organisms (e.g., ciprofloxacin or aztreonam) is not adequate in this setting.
3. The agents used should reflect both the epidemiology and the antibiotic resistance pattern of the hospital.
4. If the pattern of resistance justifies its use, a single third-generation cephalosporin constitutes an appropriate initial regimen in many hospitals.
5. Most standard regimens are designed for patients who have not previously received prophylactic antibiotics. The development of fever in a patient who has received antibiotics affects the choice of subsequent therapy, which should target resistant organisms and organisms known to cause infections in patients being treated with the antibiotics already administered.

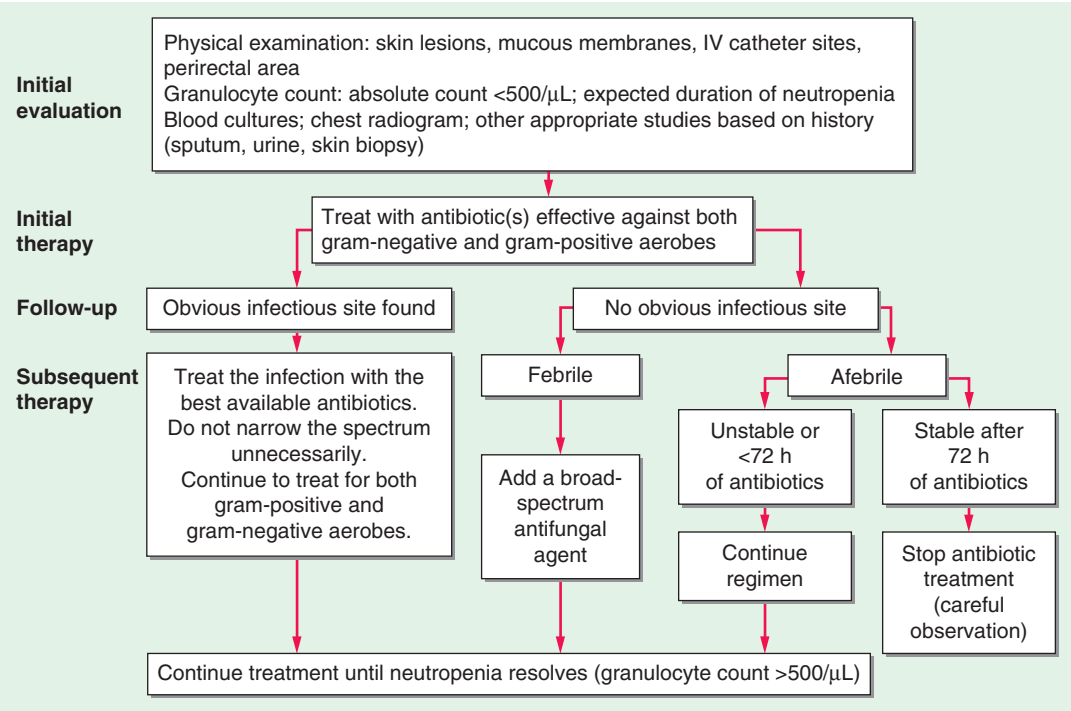

FIGURE 74-2 Algorithm for the diagnosis and treatment of fever and neutropenia.

6. Randomized trials have indicated the safety of oral antibiotic regimens in the treatment of "low-risk" patients with fever and neutropenia. Outpatients who are expected to remain neutropenic for <10 days and who do not have concurrent medical problems (such as hypotension, pulmonary compromise, or abdominal pain) can be classified as low risk and treated with a broad-spectrum oral regimen.
7. Several large-scale studies indicate that prophylaxis with a fluoroquinolone (ciprofloxacin or levofloxacin) decreases morbidity and mortality rates among afebrile patients who are anticipated to have neutropenia of long duration.

Commonly used antibiotic regimens for the treatment of febrile patients in whom prolonged neutropenia (>7 days) is anticipated include (1) ceftazidime or cefepime, (2) piperacillin/tazobactam, or (3) imipenem/cilastatin or meropenem. All three regimens have shown equal efficacy in large trials. All three are active against *P. aeruginosa* and a broad spectrum of aerobic gram-positive and gram-negative organisms. Imipenem/cilastatin has been associated with an elevated rate of *C. difficile* diarrhea, and many centers reserve carbapenem antibiotics for treatment of gram-negative bacteria that produce extended-spectrum β-lactamases; these limitations make carbapenems less attractive as an initial regimen. Despite the frequent involvement of coagulase-negative staphylococci, the initial use of vancomycin or its automatic addition to the initial regimen has not resulted in improved outcomes, and the antibiotic does exert toxic effects. For these reasons, only judicious use of vancomycin is recommended—for example, when there is good reason to suspect the involvement of coagulase-negative staphylococci (e.g., the appearance of erythema at the exit site of a catheter or a positive culture for methicillin-resistant *S. aureus* or coagulase-negative staphylococci). Because the sensitivities of bacteria vary from hospital to hospital, clinicians are advised to check their local sensitivities and to be aware that resistance patterns can change quickly, necessitating a change in the approach to patients with fever and neutropenia. Similarly, infection control services should monitor for basic antibiotic resistance and for fungal infections. The appearance of a large number of *Aspergillus* infections, in particular, suggests the possibility of an environmental source that requires further investigation and remediation.

The initial antibacterial regimen should be refined on the basis of culture results (Fig. 74-2). Blood cultures are the most relevant basis for selection of therapy; surface cultures of skin and mucous membranes may be misleading. In the case of gram-positive bacteremia or another gram-positive infection, it is important that the antibiotic be optimal for the organism isolated. Once treatment with broad-spectrum antibiotics has begun, it is not desirable to discontinue all antibiotics because of the risk of failing to treat a potentially fatal bacterial infection; the addition of more and more antibacterial agents to the regimen is not appropriate unless there is a clinical or microbiologic reason to do so. Planned progressive therapy (the serial, empirical addition of one drug after another without culture data) is not efficacious in most settings and may have unfortunate consequences. Simply adding another antibiotic for fear that a gram-negative infection is present is a dubious practice. The synergy exhibited by β-lactams and aminoglycosides against certain gram-negative organisms (especially *P. aeruginosa*) provides the rationale for using two antibiotics in this setting, but recent analyses suggest that efficacy is not enhanced by the addition of aminoglycosides, while toxicity may be increased. Mere "double coverage," with the addition of a quinolone or another antibiotic that is not likely to exhibit synergy, has not been shown to be beneficial and may cause additional toxicities and side effects. Cephalosporins can cause bone marrow suppression, and vancomycin is associated with neutropenia in some healthy individuals. Furthermore, the addition of multiple cephalosporins may induce β-lactamase production by some organisms; cephalosporins and double β-lactam combinations should probably be avoided altogether in *Enterobacter* infections.

ANTIFUNGAL THERAPY

Fungal infections in cancer patients are most often associated with neutropenia. Neutropenic patients are predisposed to the development of invasive fungal infections, most commonly those due to *Candida* and *Aspergillus* species and occasionally those caused by *Mucor, Rhizopus*, *Fusarium*, *Trichosporon*, *Bipolaris*, and others. Invasive candidal disease is usually caused by *C. albicans* or *C. tropicalis* but can be caused by *C. krusei*, *C. parapsilosis*, and *C. glabrata*. The worldwide spread of *C. auris*, a species that is typically resistant to fluconazole and often resistant to amphotericin B as

well, has further complicated the management of invasive *Candida* infections **(Chap. 216)**.

For decades, it has been common clinical practice to add amphotericin B to antibacterial regimens if a neutropenic patient remains febrile despite 4–7 days of treatment with antibacterial agents. The rationale for this empirical addition is that it is difficult to culture fungi before they cause disseminated disease and that mortality rates from disseminated fungal infections in granulocytopenic patients are high. Before the introduction of newer azoles into clinical practice, amphotericin B was the mainstay of antifungal therapy. The insolubility of amphotericin B has resulted in the marketing of several lipid formulations that are less toxic than the amphotericin B deoxycholate complex. Echinocandins (e.g., caspofungin) are useful in the treatment of infections caused by azole-resistant *Candida* strains as well as in therapy for aspergillosis and have been shown to be equivalent to liposomal amphotericin B for the empirical treatment of patients with prolonged fever and neutropenia. Newer azoles have also been demonstrated to be effective in this setting. Although fluconazole is efficacious in the treatment of infections due to many *Candida* species, its use against serious fungal infections in immunocompromised patients is limited by its narrow spectrum: it has no activity against *Aspergillus* or against several non-*albicans Candida* species. The broad-spectrum azoles (e.g., voriconazole and posaconazole) provide another option for the treatment of *Aspergillus* infections **(Chap. 217)**, including CNS infection. Clinicians should be aware that the spectrum of each azole is somewhat different and that no drug can be assumed to be efficacious against all fungi. *Aspergillus terreus* is resistant to amphotericin B. Although voriconazole is active against *Pseudallescheria boydii*, amphotericin B is not; however, voriconazole has no activity against *Mucor*. Posaconazole, which is administered orally, is useful as a prophylactic agent in patients with prolonged neutropenia. Studies in progress are assessing the use of these agents in combinations. For a full discussion of antifungal therapy, see **Chap. 211**.

ANTIVIRAL THERAPY

The availability of a variety of agents active against herpes-group viruses, including some new agents with a broader spectrum of activity, has heightened focus on the treatment of viral infections, which pose a major problem in cancer patients. Viral diseases caused by the herpes group are prominent. Serious (and sometimes fatal) infections due to HSV and VZV are well documented in patients receiving chemotherapy. CMV may also cause serious disease, but fatalities from CMV infection are more common in hematopoietic stem cell transplant recipients. The roles of human herpesvirus (HHV)-6, HHV-7, and HHV-8 (Kaposi's sarcoma–associated herpesvirus) in cancer patients are still being defined **(Chap. 195)**. EBV lymphoproliferative disease (LPD) can occur in patients receiving chemotherapy but is much more common among transplant recipients **(Chap. 143)**. While clinical experience is most extensive with acyclovir, which can be used therapeutically or prophylactically, a number of derivative drugs offer advantages over this agent **(Chap. 191)**.

In addition to the herpes group, several respiratory viruses (especially RSV) may cause serious disease in cancer patients. Although influenza vaccination is recommended (see below), it may be ineffective in this patient population. The availability of antiviral drugs with activity against influenza viruses gives the clinician additional options for the prophylaxis and treatment of these patients **(Chaps. 191** and **200)**.

The COVID-19 pandemic has affected cancer patients disproportionately. Early analyses suggest that lung cancer patients in particular are more vulnerable to serious infection with SARS-CoV-2.

OTHER THERAPEUTIC MODALITIES

A variety of cytokines, including granulocyte colony-stimulating factor and granulocyte-macrophage colony-stimulating factor, enhance granulocyte recovery after chemotherapy and consequently shorten the period of maximal vulnerability to fatal infections. Most authorities recommend their use only when neutropenia is both severe and prolonged, and they should be used only in the appropriate setting (i.e., when stem cells are likely to be responsive) and not as an adjunct to antimicrobial agents. The cytokines themselves may have adverse effects, including fever, hypoxemia, and pleural effusions or serositis in other areas **(Chap. 349)**.

Once neutropenia has resolved, the risk of infection decreases dramatically. However, depending on what drugs they receive, patients who continue on chemotherapeutic protocols remain at high risk for certain diseases. Any patient receiving more than a maintenance dose of glucocorticoids (e.g., in many treatment regimens for diffuse lymphoma) should also receive prophylactic TMP-SMX because of the risk of *Pneumocystis* infection; those with ALL should receive such prophylaxis for the duration of chemotherapy.

PREVENTION OF INFECTION IN CANCER PATIENTS

EFFECT OF THE ENVIRONMENT

Outbreaks of fatal *Aspergillus* infection have been associated with construction projects and materials in several hospitals. The association between spore counts and risk of infection suggests the need for a high-efficiency air-handling system in hospitals that care for large numbers of neutropenic patients. The use of laminar-flow rooms and prophylactic antibiotics has decreased the number of infectious episodes in severely neutropenic patients. However, because of the expense of such a program and the failure to show that it dramatically affects mortality rates, most centers do not routinely use laminar flow to care for neutropenic patients. Some centers use "reverse isolation," in which health care providers and visitors to a patient who is neutropenic wear gowns and gloves. Since most of the infections these patients develop are due to organisms that colonize the patients' own skin and bowel, the validity of such schemes is dubious, and limited clinical data do not support their use. Hand washing by all staff caring for neutropenic patients should be required to prevent the spread of resistant organisms.

The presence of large numbers of bacteria (particularly *P. aeruginosa*) in certain foods, especially fresh vegetables, has led some authorities to recommend a special "low-bacteria" diet. A diet consisting of cooked and canned food is satisfactory to most neutropenic patients and does not involve elaborate disinfection or sterilization protocols. However, there are no studies to support even this type of dietary restriction. Counseling of patients to avoid leftovers, deli foods, undercooked meat, and unpasteurized dairy products is recommended since these foods have been associated with outbreaks of listerial infection.

PHYSICAL MEASURES

Although few studies address this issue, patients with cancer are predisposed to infections resulting from anatomic compromise (e.g., lymphedema resulting from node dissections after radical mastectomy). Surgeons who specialize in cancer surgery can provide specific guidelines for the care of such patients, and patients benefit from common-sense advice about how to prevent infections in vulnerable areas.

IMMUNOGLOBULIN REPLACEMENT

Many patients with multiple myeloma or CLL have immunoglobulin deficiencies as a result of their disease, and all allogeneic bone marrow transplant recipients are hypogammaglobulinemic for a period after transplantation. However, current recommendations reserve intravenous immunoglobulin replacement therapy for patients with severe, prolonged hypogammaglobulinemia (<400 mg of total IgG/dL) and a history of repeated infections. Antibiotic prophylaxis has been shown to be cheaper and is efficacious in preventing infections in most CLL patients with hypogammaglobulinemia. Routine use of immunoglobulin replacement is not recommended.

SEXUAL PRACTICES

The use of condoms is recommended for severely immunocompromised patients. Any sexual practice that results in oral exposure to feces is not recommended. Neutropenic patients should be advised to avoid any practice that results in trauma, as even microscopic cuts may result in bacterial invasion and fatal sepsis.

ANTIBIOTIC PROPHYLAXIS

Several studies indicate that the use of oral fluoroquinolones prevents infection and decreases mortality rates among severely neutropenic patients. Prophylaxis for *Pneumocystis* is mandatory for patients with ALL and for all cancer patients receiving glucocorticoid-containing chemotherapy regimens.

VACCINATION OF CANCER PATIENTS

In general, patients undergoing chemotherapy respond less well to vaccines than do normal hosts. Their greater need for vaccines thus leads to a dilemma in their management. Purified proteins and inactivated vaccines are almost never contraindicated and should be given to patients even during chemotherapy. For example, all adults should receive diphtheria–tetanus toxoid boosters at the indicated times as well as seasonal influenza vaccine. However, if possible, vaccination should not be undertaken concurrent with cytotoxic chemotherapy. If patients are expected to be receiving chemotherapy for several months and vaccination is indicated (e.g., influenza vaccination in the fall), the vaccine should be given midcycle—as far apart in time as possible from the antimetabolic agents that will prevent an immune response. The meningococcal and pneumococcal polysaccharide vaccines should be given to patients before splenectomy, if possible. The *H. influenzae* type b conjugate vaccine should be administered to all splenectomized patients.

In general, live virus (or live bacterial) vaccines should not be given to patients during intensive chemotherapy because of the risk of disseminated infection. Recommendations on vaccination are summarized in Table 74-2 (see *https://www.cdc.gov/vaccines/hcp/index.html* for updated recommendations).

IN MEMORIAM

Dr. Robert W. Finberg, Richard M. Haidack Distinguished Professor and Chair of Medicine, University of Massachusetts Chan Medical School (2000-2020), Professor of Medicine and Chair of Infectious Diseases, Dana Farber Cancer Institute (1996-1999), passed away on August 30, 2021. In addition to this chapter, he authored Chapter 143, "Infections in Transplant Recipients." Dr. Finberg was an internationally renowned physician-scientist and an academic leader whose career spanned four decades. A brilliant talented researcher focused on viral pathogenesis he was also a consummate clinician who attended at the bedside throughout his career. Dr. Finberg played an important role in the COVID-19 pandemic by leading clinical trials for SARS-CoV-2 vaccines and therapeutics. Warm and generous with a keen wit, he was a beloved family man, colleague and friend. As an educator and mentor he truly cared about training the next generation, as evidenced by the legacy of a very large number of trainees he leaves behind. We are indebted to Dr. Finberg for his outstanding contributions to nine editions of Harrison's Principles of Internal Medicine and to his considerable and significant contributions to the field of human health.

75 Oncologic Emergencies

Rasim Gucalp, Janice P. Dutcher

Emergencies in patients with cancer may be classified into three groups: pressure or obstruction caused by a space-occupying lesion, metabolic or hormonal problems (paraneoplastic syndromes, Chap. 93), and treatment-related complications.

STRUCTURAL-OBSTRUCTIVE ONCOLOGIC EMERGENCIES

SUPERIOR VENA CAVA SYNDROME

Superior vena cava syndrome (SVCS) is the clinical manifestation of superior vena cava (SVC) obstruction, with severe reduction in venous return from the head, neck, and upper extremities. Malignant tumors, such as lung cancer, lymphoma, and metastatic tumors, are responsible for the majority of SVCS cases. With the expanding use of intravascular devices (e.g., permanent central venous access catheters, pacemaker/defibrillator leads), the prevalence of benign causes of SVCS is now increasing, accounting for at least 40% of cases. Lung cancer, particularly of small-cell and squamous cell histologies, accounts for ~85% of all cases of malignant origin. In young adults, malignant lymphoma is a leading cause of SVCS. Hodgkin's lymphoma involves the mediastinum more commonly than other lymphomas but rarely causes SVCS. When SVCS is noted in a young man with a mediastinal mass, the differential diagnosis is lymphoma versus primary mediastinal germ cell tumor. Metastatic cancers to the mediastinal lymph nodes, such as testicular and breast carcinomas, account for a small proportion of cases. Other causes include benign tumors, aortic aneurysm, thyromegaly, thrombosis, and fibrosing mediastinitis from prior irradiation, histoplasmosis, or Behçet's syndrome. SVCS as the initial manifestation of Behçet's syndrome may be due to inflammation of the SVC associated with thrombosis.

Patients with SVCS usually present with neck and facial swelling (especially around the eyes), dyspnea, and cough. Other symptoms include hoarseness, tongue swelling, headaches, nasal congestion, epistaxis, hemoptysis, dysphagia, pain, dizziness, syncope, and lethargy. Bending forward or lying down may aggravate the symptoms. The characteristic physical findings are dilated neck veins; an increased number of collateral veins covering the anterior chest wall; cyanosis; and edema of the face, arms, and chest. Facial swelling and plethora are typically exacerbated when the patient is supine. More severe cases include proptosis, glossal and laryngeal edema, and obtundation. The clinical picture is milder if the obstruction is located above the azygos vein. Symptoms are usually progressive, but in some cases, they may improve as collateral circulation develops.

Signs and symptoms of cerebral and/or laryngeal edema, though rare, are associated with a poorer prognosis and require urgent evaluation. Seizures are more likely related to brain metastases than to cerebral edema from venous occlusion. Patients with small-cell lung cancer and SVCS have a higher incidence of brain metastases than those without SVCS.

Cardiorespiratory symptoms at rest, particularly with positional changes, suggest significant airway and vascular obstruction and limited physiologic reserve. Cardiac arrest or respiratory failure can occur, particularly in patients receiving sedatives or undergoing general anesthesia.

Rarely, esophageal varices may develop, particularly in the setting of SVC syndrome due to hemodialysis catheter. These are "downhill" varices based on the direction of blood flow from cephalad to caudad (in contrast to "uphill" varices associated with caudad to cephalad flow from portal hypertension). If the obstruction to the SVC is proximal to the azygous vein, varices develop in the upper one-third of the esophagus. If the obstruction involves or is distal to the azygous vein, varices occur in the entire length of the esophagus. Variceal bleeding may be a late complication of chronic SVCS.

SVC obstruction may lead to bilateral breast edema with bilateral enlarged breasts. Unilateral breast dilation may be seen as a consequence of axillary or subclavian vein blockage.

The diagnosis of SVCS is a clinical one. The most significant chest radiographic finding is widening of the superior mediastinum, most commonly on the right side. Pleural effusion occurs in only 25% of patients, often on the right side. The majority of these effusions are exudative and occasionally chylous. However, a normal chest radiograph is still compatible with the diagnosis if other characteristic findings are present. Computed tomography (CT) provides the most reliable view of the mediastinal anatomy. The diagnosis of SVCS requires diminished or absent opacification of central venous structures with prominent collateral venous circulation. Magnetic resonance imaging (MRI) is increasingly being used to diagnose SVC obstruction with a 100% sensitivity and specificity, but dyspneic SVCS patients may have difficulty remaining supine for the entire imaging process. Invasive procedures, including bronchoscopy, percutaneous needle biopsy, mediastinoscopy, and even thoracotomy, can be performed by a skilled clinician without any major risk of bleeding. Endobronchial or esophageal ultrasound-guided needle aspiration may establish the diagnosis safely. For patients with a known cancer, a detailed workup usually is not necessary, and appropriate treatment may be started after obtaining a CT scan of the thorax. For those with no history of malignancy, a detailed evaluation is essential to rule out benign causes and determine a specific diagnosis to direct the appropriate therapy.

TREATMENT

Superior Vena Cava Syndrome

The one potentially life-threatening complication of a superior mediastinal mass is tracheal obstruction. Upper airway obstruction demands emergent therapy. Diuretics with a low-salt diet, head elevation, and oxygen may produce temporary symptomatic relief. Glucocorticoids have a limited role except in the setting of mediastinal lymphoma masses.

Radiation therapy is the primary treatment for SVCS caused by non-small-cell lung cancer and other metastatic solid tumors. Chemotherapy is effective when the underlying cancer is small-cell carcinoma of the lung, lymphoma, or germ cell tumor. SVCS recurs in 10–30% of patients; it may be palliated with the use of intravascular self-expanding stents **(Fig. 75-1)**. Endovascular therapy is more frequently used first, to provide rapid relief of clinical symptoms with reduced complications. Early stenting may be necessary in patients with severe symptoms; however, the prompt increase in venous return after stenting may precipitate heart failure and pulmonary edema. Other complications of stent placement include hematoma at the insertion site, SVC perforation, stent migration in the right ventricle, stent fracture, and pulmonary embolism.

Clinical improvement occurs in most patients, although this improvement may be due to the development of adequate collateral circulation. The mortality associated with SVCS does not relate to caval obstruction but rather to the underlying cause.

SVCS AND CENTRAL VENOUS CATHETERS IN ADULTS

The use of long-term central venous catheters has become common practice in patients with cancer. Major vessel thrombosis may occur. In these cases, catheter removal should be combined with anticoagulation to prevent embolization. SVCS in this setting, if detected early, can be treated by fibrinolytic therapy without sacrificing the catheter. When managing patients with transvenous lead-related SVC syndrome, anticoagulation, local and systemic thrombolytic therapy, and surgical intervention can be effective therapy in select patients. Endovascular stenting has also been shown to be safe and promising, with minimal procedural or clinical complications. The role of anticoagulation after SVC stent placement is controversial.

PERICARDIAL EFFUSION/TAMPONADE

Malignant pericardial disease is found at autopsy in 5–10% of patients with cancer, most frequently with lung cancer, breast cancer, leukemias,

C

FIGURE 75-1 Superior vena cava syndrome (SVCS). ***A.*** Chest radiographs of a 59-year-old man with recurrent SVCS caused by non-small-cell lung cancer showing right paratracheal mass with right pleural effusion. ***B.*** Computed tomography of same patient demonstrating obstruction of the superior vena cava with thrombosis (*arrow*) by the lung cancer (*square*) and collaterals (*arrowheads*). ***C.*** Balloon angioplasty (*arrowhead*) with Wallstent (*arrow*) in same patient.

and lymphomas. Cardiac tamponade as the initial presentation of extrathoracic malignancy is rare. The origin is not malignancy in ~50% of cancer patients with symptomatic pericardial disease, but it can be related to irradiation; drug-induced pericarditis, including chemotherapeutic agents such as all-trans retinoic acid, arsenic trioxide, imatinib, and other abl kinase inhibitors; hypothyroidism; idiopathic pericarditis; infection; or autoimmune diseases. Pericardial disease has been associated with immune checkpoint inhibitors specifically in patients with advanced non-small-cell lung cancer. Two types of radiation pericarditis occur: an acute inflammatory, effusive pericarditis occurring within months of irradiation, which usually resolves spontaneously, and a chronic effusive pericarditis that may appear up to 20 years after radiation therapy and is accompanied by a thickened pericardium.

Most patients with pericardial metastasis are asymptomatic. However, the common symptoms are dyspnea, cough, chest pain, orthopnea, and weakness. Pleural effusion, sinus tachycardia, jugular venous distention, hepatomegaly, peripheral edema, and cyanosis are the most frequent physical findings. Relatively specific diagnostic findings, such as paradoxical pulse, diminished heart sounds, pulsus alternans (pulse waves alternating between those of greater and lesser amplitude with successive beats), and friction rub are less common than with nonmalignant pericardial disease. Chest radiographs and electrocardiogram (ECG) reveal abnormalities in 90% of patients, but half of these abnormalities are nonspecific. Echocardiography is the most helpful diagnostic test. Pericardial fluid may be serous, serosanguineous, or hemorrhagic, and cytologic examination of pericardial fluid is diagnostic in most patients. Measurements of tumor markers in the pericardial fluid are not helpful in the diagnosis of malignant pericardial fluid. Pericardioscopy with targeted pericardial and epicardial biopsy may differentiate neoplastic and benign pericardial disease. A combination of cytology, pericardial and epicardial biopsy, and guided pericardioscopy gives the best diagnostic yield. CT scan of chest may also reveal the presence of a concomitant thoracic neoplasm. Cancer patients with pericardial effusion containing malignant cells on cytology have a very poor survival, ~7 weeks.

TREATMENT

Pericardial Effusion/Tamponade

Pericardiocentesis with or without the introduction of sclerosing agents, the creation of a pericardial window, complete pericardial stripping, cardiac irradiation, or systemic chemotherapy are effective treatments. Acute pericardial tamponade with life-threatening hemodynamic instability requires immediate drainage of fluid. This can be quickly achieved by pericardiocentesis. The recurrence rate after percutaneous catheter drainage is ~20%. Sclerotherapy (pericardial instillation of bleomycin, mitomycin C, or tetracycline) may decrease recurrences. Alternatively, subxiphoid pericardiotomy can be performed in 45 min under local anesthesia. Thoracoscopic pericardial fenestration can be employed for benign causes; however, 60% of malignant pericardial effusions recur after this procedure. In a subset of patients, drainage of the pericardial effusion is paradoxically followed by worsening hemodynamic instability. This so-called "postoperative low cardiac output syndrome" occurs in up to 10% of patients undergoing surgical drainage and carries poor short-term survival.

INTESTINAL OBSTRUCTION

Intestinal obstruction and reobstruction are common problems in patients with advanced cancer, particularly colorectal or ovarian carcinoma. However, other cancers, such as lung or breast cancer and melanoma, can metastasize within the abdomen, leading to intestinal obstruction. Metastatic disease from colorectal, ovarian, pancreatic, gastric, and occasionally breast cancer can lead to peritoneal carcinomatosis, with infiltration of the omentum and peritoneal surface, thus limiting bowel motility. Typically, obstruction occurs at multiple sites in peritoneal carcinomatosis. Melanoma has a predilection to involve the small bowel; this involvement may be isolated, and resection may result in prolonged survival. Intestinal pseudoobstruction is caused by infiltration of the mesentery or bowel muscle by tumor, involvement of the celiac plexus, or paraneoplastic neuropathy in patients with small-cell lung cancer. Paraneoplastic neuropathy is associated with IgG antibodies reactive to neurons of the myenteric and submucosal plexuses of the jejunum and stomach. Ovarian cancer can lead to authentic luminal obstruction or to pseudoobstruction that results when circumferential invasion of a bowel segment arrests the forward progression of peristaltic contractions.

The onset of obstruction is usually insidious. Pain is the most common symptom and is usually colicky in nature. Pain can also be due to abdominal distention, tumor masses, or hepatomegaly. Vomiting can be intermittent or continuous. Patients with complete obstruction usually have constipation. Physical examination may reveal abdominal distention with tympany, ascites, visible peristalsis, high-pitched bowel sounds, and tumor masses. Erect plain abdominal films may reveal multiple air-fluid levels and dilation of the small or large bowel. Acute cecal dilation to >12–14 cm is considered a surgical emergency because of the high likelihood of rupture. CT scan is useful in defining the extent of disease and the exact nature of the obstruction and differentiating benign from malignant causes of obstruction in patients who have undergone surgery for malignancy. Malignant obstruction is suggested by a mass at the site of obstruction or prior surgery, adenopathy, or an abrupt transition zone and irregular bowel thickening at the obstruction site. Benign obstruction is more likely when CT shows mesenteric vascular changes, a large volume of ascites, or a smooth transition zone and smooth bowel thickening at the obstruction site. In challenging patients with obstructive symptoms, particularly low-grade small-bowel obstruction (SBO), CT enteroclysis often can help establish the diagnosis by providing distention of small-bowel loops. In this technique, water-soluble contrast is infused through a nasoenteric tube into the duodenum or proximal small bowel followed by CT images. The prognosis for the patient with cancer who develops intestinal obstruction is poor; median survival is 3–4 months. About 25–30% of patients are found to have intestinal obstruction due to causes other than cancer. Adhesions from previous operations are a common benign cause. Ileus induced by vinca alkaloids, narcotics, or other drugs is another reversible cause.

TREATMENT

Intestinal Obstruction

The management of intestinal obstruction in patients with advanced malignancy depends on the extent of the underlying malignancy, options for further antineoplastic therapy, estimated life expectancy, the functional status of the major organs, and the extent of the obstruction. The initial management should include surgical evaluation. Operation is not always successful and may lead to further complications with a substantial mortality rate (10–20%). Laparoscopy can diagnose and treat malignant bowel obstruction in some cases. Self-expanding metal stents placed in the gastric outlet, duodenum, proximal jejunum, colon, or rectum may palliate obstructive symptoms at those sites without major surgery. Patients known to have advanced intraabdominal malignancy should receive a prolonged course of conservative management, including nasogastric decompression. Percutaneous endoscopic or surgical gastrostomy tube placement is an option for palliation of nausea and vomiting, the so-called "venting gastrostomy." Treatment with antiemetics, antispasmodics, and analgesics may allow patients to remain outside the hospital. Octreotide may relieve obstructive symptoms through its inhibitory effect on gastrointestinal secretion. Glucocorticoids have anti-inflammatory effects and may help the resolution of bowel obstruction. They also have antiemetic effects.

URINARY OBSTRUCTION

Urinary obstruction may occur in patients with prostatic or gynecologic malignancies, particularly cervical carcinoma; metastatic disease

from other primary sites such as carcinomas of the breast, stomach, lung, colon, and pancreas; or lymphomas. Radiation therapy to pelvic tumors may cause fibrosis and subsequent ureteral obstruction. Bladder outlet obstruction is usually due to prostate and cervical cancers and may lead to bilateral hydronephrosis and renal failure.

Flank pain is the most common symptom. Persistent urinary tract infection, persistent proteinuria, or hematuria in patients with cancer should raise suspicion of ureteral obstruction. Total anuria and/or anuria alternating with polyuria may occur. A slow, continuous rise in the serum creatinine level necessitates immediate evaluation. Renal ultrasound is the safest and cheapest way to identify hydronephrosis. The function of an obstructed kidney can be evaluated by a nuclear scan. CT scan can reveal the point of obstruction and identify a retroperitoneal mass or adenopathy.

TREATMENT

Urinary Obstruction

Obstruction associated with flank pain, sepsis, or fistula formation is an indication for immediate palliative urinary diversion. Internal ureteral stents can be placed under local anesthesia. Percutaneous nephrostomy offers an alternative approach for drainage. The placement of a nephrostomy is associated with a significant rate of pyelonephritis. In the case of bladder outlet obstruction due to malignancy, a suprapubic cystostomy can be used for urinary drainage. An aggressive intervention with invasive approaches to improve the obstruction should be weighed against the likelihood of antitumor response, and the ability to reverse renal insufficiency should be evaluated.

MALIGNANT BILIARY OBSTRUCTION

This common clinical problem can be caused by a primary carcinoma arising in the pancreas, ampulla of Vater, bile duct, or liver or by metastatic disease to the periductal lymph nodes or liver parenchyma. The most common metastatic tumors causing biliary obstruction are gastric, colon, breast, and lung cancers. Jaundice, light-colored stools, dark urine, pruritus, and weight loss due to malabsorption are usual symptoms. Pain and secondary infection are uncommon in malignant biliary obstruction. Ultrasound, CT scan, or percutaneous transhepatic or endoscopic retrograde cholangiography will identify the site and nature of the biliary obstruction.

TREATMENT

Malignant Biliary Obstruction

Palliative intervention is indicated only in patients with disabling pruritus resistant to medical treatment, severe malabsorption, or infection. Stenting under radiographic control, surgical bypass, or radiation therapy with or without chemotherapy may alleviate the obstruction. The choice of therapy should be based on the site of obstruction (proximal vs distal), the type of tumor (sensitive to radiotherapy, chemotherapy, or neither), and the general condition of the patient. Stenting under radiographic or endoscopic control, surgical bypass, or radiation therapy with or without chemotherapy may alleviate the obstruction. Photodynamic therapy and radiofrequency ablation are promising endoscopic therapies for malignant biliary obstruction.

Endoscopic ultrasonography-guided biliary drainage is an evolving method of biliary drainage in patients with malignant biliary obstruction, particularly in patients whom standard endoscopic retrograde cholangiopancreatography failed.

SPINAL CORD COMPRESSION

Malignant spinal cord compression (MSCC) is defined as compression of the spinal cord and/or cauda equina by an extradural tumor mass. The minimum radiologic evidence for cord compression is indentation of the theca at the level of clinical features. Spinal cord compression (SCC) occurs in 5–10% of patients with cancer. Epidural tumor is the first manifestation of malignancy in ~10% of patients. The underlying cancer is usually identified during the initial evaluation; lung cancer is the most common cause of MSCC.

Metastatic tumor involves the vertebral column more often than any other part of the bony skeleton. Lung, breast, and prostate cancers are the most frequent offenders. Multiple myeloma also has a high incidence of spine involvement. Lymphomas, melanoma, renal cell cancer, and genitourinary cancers also cause cord compression. The thoracic spine is the most common site (70%), followed by the lumbosacral spine (20%) and the cervical spine (10%). Involvement of multiple sites is most frequent in patients with breast and prostate carcinoma. Cord injury develops when metastases to the vertebral body or pedicle enlarge and compress the underlying dura. Another cause of cord compression is direct extension of a paravertebral lesion through the intervertebral foramen. These cases usually involve a lymphoma, myeloma, or pediatric neoplasm. Parenchymal spinal cord metastasis due to hematogenous spread is rare. Intramedullary metastases can be seen in lung cancer, breast cancer, renal cancer, melanoma, and lymphoma, and are frequently associated with brain metastases and leptomeningeal disease.

Expanding extradural tumors induce injury through several mechanisms. Expanding extradural tumors induce mechanical injury to axons and myelin. Compression compromises blood flow, leading to ischemia and/or infarction.

The most common initial symptom in patients with SCC is localized back pain and tenderness due to involvement of vertebrae by tumor. Pain is usually present for days or months before other neurologic findings appear. It is exacerbated by movement and by coughing or sneezing. It can be differentiated from the pain of disk disease by the fact that it worsens when the patient is supine. Radicular pain is less common than localized back pain and usually develops later. Radicular pain in the cervical or lumbosacral areas may be unilateral or bilateral. Radicular pain from the thoracic roots is often bilateral and is described by patients as a feeling of tight, band-like constriction around the thorax and abdomen. Typical cervical radicular pain radiates down the arm; in the lumbar region, the radiation is down the legs. *Lhermitte's sign*, a tingling or electric sensation down the back and upper and lower limbs upon flexing or extending the neck, may be an early sign of cord compression. Loss of bowel or bladder control may be the presenting symptom but usually occurs late in the course. Occasionally, patients present with ataxia of gait without motor and sensory involvement due to involvement of the spinocerebellar tract.

On physical examination, pain induced by straight leg raising, neck flexion, or vertebral percussion may help to determine the level of cord compression. Patients develop numbness and paresthesias in the extremities or trunk. Loss of sensibility to pinprick is as common as loss of sensibility to vibration or position. The upper limit of the zone of sensory loss is often one or two vertebrae below the site of compression. Motor findings include weakness, spasticity, and abnormal muscle stretching. An extensor plantar reflex reflects significant compression. Deep tendon reflexes may be brisk. Motor and sensory loss usually precedes sphincter disturbance. Patients with autonomic dysfunction may present with decreased anal tonus, decreased perineal sensibility, and a distended bladder. The absence of the anal wink reflex or the bulbocavernosus reflex confirms cord involvement. In doubtful cases, evaluation of postvoiding urinary residual volume can be helpful. A residual volume of >150 mL suggests bladder dysfunction. Autonomic dysfunction is an unfavorable prognostic factor. Patients with progressive neurologic symptoms should have frequent neurologic examinations and rapid therapeutic intervention. Other illnesses that may mimic cord compression include osteoporotic vertebral collapse, disk disease, pyogenic abscess or vertebral tuberculosis, radiation myelopathy, neoplastic leptomeningitis, benign tumors, epidural hematoma, and spinal lipomatosis.

Cauda equina syndrome is characterized by low back pain; diminished sensation over the buttocks, posterior-superior thighs, and perineal area in a saddle distribution; rectal and bladder dysfunction; sexual impotence; absent bulbocavernous, patellar, and Achilles'

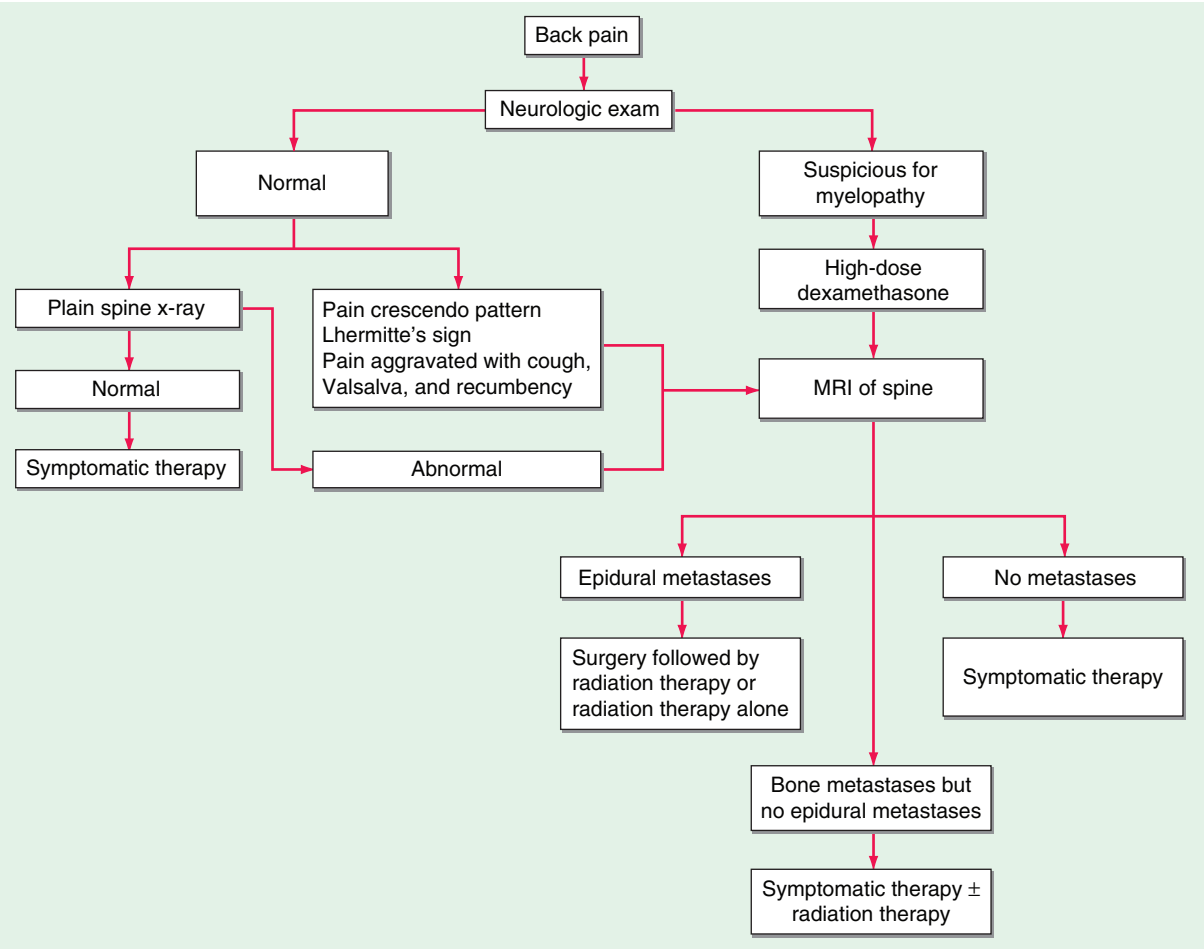

FIGURE 75-2 Management of cancer patients with back pain.

reflexes; and variable amount of lower-extremity weakness. This reflects compression of nerve roots as they form the cauda equina after leaving the spinal cord. The majority of cauda equina tumors are primary tumors of glial or nerve sheath origin; metastases are very rare.

Patients with cancer who develop back pain should be evaluated for SCC as quickly as possible (Fig. 75-2). Treatment is more often successful in patients who are ambulatory and still have sphincter control at the time treatment is initiated. Patients should have a neurologic examination and plain films of the spine. Those whose physical examination suggests cord compression should receive dexamethasone starting immediately and undergo MRI imaging.

Erosion of the pedicles (the "winking owl" sign) is the earliest radiologic finding of vertebral tumor in plain films; however, plain films are insensitive. Other radiographic changes include increased intrapedicular distance, vertebral destruction, lytic or sclerotic lesions, scalloped vertebral bodies, and vertebral body collapse. Vertebral collapse is not a reliable indicator of the presence of tumor; ~20% of cases of vertebral collapse, particularly those in older patients and postmenopausal women, are due not to cancer but to osteoporosis. Also, a normal appearance on plain films of the spine does not exclude the diagnosis of cancer. The role of bone scans in the detection of cord compression is not clear; this method is sensitive but less specific than spinal radiography.

The full-length image of the cord provided by MRI is the imaging procedure of choice. Multiple epidural metastases are noted in 25% of patients with cord compression, and their presence influences treatment plans. On T1-weighted images, good contrast is noted between the cord, cerebrospinal fluid (CSF), and extradural lesions. Owing to its sensitivity in demonstrating the replacement of bone marrow by tumor, MRI can show which parts of a vertebra are involved by tumor. MRI also visualizes intraspinal extradural masses compressing the cord. T2-weighted images are most useful for the demonstration of intramedullary pathology. Gadolinium-enhanced MRI can help to delineate intramedullary disease. MRI is as good as or better than myelography plus postmyelogram CT scan in detecting metastatic epidural disease with cord compression. Myelography should be reserved for patients who have poor MRIs or who cannot undergo MRI promptly. CT scan in conjunction with myelography enhances the detection of small areas of spinal destruction.

In patients with cord compression and an unknown primary tumor, a simple workup including chest radiography, mammography, measurement of prostate-specific antigen, and abdominal CT usually reveals the underlying malignancy.

TREATMENT

Spinal Cord Compression

The treatment of patients with SCC is aimed at relief of pain and restoration/preservation of neurologic function (Fig. 75-2). Management of MSCC requires a multidisciplinary approach.

Radiation therapy plus glucocorticoids is generally the initial treatment of choice for most patients with SCC. The management decision of SCC involves assessment of neurologic (N), oncologic (O), mechanical (M), and systemic factors (S). NOMS was developed by Memorial Sloan Kettering Cancer Center (MSKCC) researchers to provide an algorithm for management of SCC. The neurologic assessment is based on the degree of epidural SCC, myelopathy, and/or functional radiculopathy. Oncologic assessment involves the radiosensitivity of the tumor type. In patients with radioresistant tumors, stereotactic body radiotherapy (SBRT) is the preferred approach if radiation is appropriate. Safe delivery

of SBRT requires a 2- to 3-mm margin away from the spinal cord. Separation surgery followed by SBRT is necessary in patients with high-grade SCC due to radioresistant tumors. Separation surgery is the circumferential excision of epidural tumor to reconstitute the thecal sac and provide a 2-mm margin for safe delivery of an ablative radiation dose. In patients with mechanical instability or retropulsion of bone fragments into the spinal canal or cord, a surgical approach is the treatment of choice. Systemic factors that need to be considered are the extent of disease and medical comorbidities that determine the patient's ability to tolerate planned therapy. Chemotherapy may have a role in patients with chemosensitive tumors who have had prior radiotherapy to the same region and who are not candidates for surgery. Patients who previously received radiotherapy for MSCC with an in-field tumor progression can be treated with reirradiation with spine stereotactic radiosurgery (SRS) if they are not surgical candidates.

Patients with painful pathologic compression fractures without spinal instability may benefit from percutaneous vertebroplasty or kyphoplasty, the injection of acrylic cement into a collapsed vertebra to stabilize the fracture. Pain palliation is common, and local antitumor effects have been noted. Cement leakage may cause symptoms in ~10% of patients. Bisphosphonates and/or denosumab may be helpful in prevention of SCC in patients with bony involvement.

The histology of the tumor is an important determinant of both recovery and survival. Rapid onset and progression of signs and symptoms are poor prognostic features.

INCREASED INTRACRANIAL PRESSURE

About 25% of patients with cancer die with intracranial metastases. The cancers that most often metastasize to the brain are lung and breast cancers and melanoma. Brain metastases often occur in the presence of systemic disease, and they frequently cause major symptoms, disability, and early death. The initial presentation of brain metastases from a previously unknown primary cancer is common. Lung cancer is most commonly the primary malignancy. CT scans of the chest/abdomen and MRI of the brain as the initial diagnostic studies can identify a biopsy site in most patients.

The signs and symptoms of a metastatic brain tumor are similar to those of other intracranial expanding lesions: headache, nausea, vomiting, behavioral changes, seizures, and focal, progressive neurologic changes. Occasionally the onset is abrupt, resembling a stroke, with the sudden appearance of headache, nausea, vomiting, and neurologic deficits. This picture is usually due to hemorrhage into the metastasis. Melanoma, germ cell tumors, and renal cell cancers have a particularly high incidence of intracranial bleeding. The tumor mass and surrounding edema may cause obstruction of the circulation of CSF, with resulting hydrocephalus. Patients with increased intracranial pressure may have papilledema with visual disturbances and neck stiffness. As the mass enlarges, brain tissue may be displaced through the fixed cranial openings, producing various herniation syndromes.

MRI is superior to CT scan. Gadolinium-enhanced MRI is more sensitive than CT at revealing meningeal involvement and small lesions, particularly in the brainstem or cerebellum. The MRI of the brain shows brain metastases as multiple enhancing lesions of various sizes with surrounding areas of low-density edema.

Intracranial hypertension ("pseudotumor cerebri") secondary to tretinoin therapy for acute promyelocytic leukemia has been reported as another cause of intracranial pressure in the setting of a malignancy.

TREATMENT

Increased Intracranial Pressure

Dexamethasone is the best initial treatment for all symptomatic patients with brain metastases. The current success of immunotherapy approaches for primary and metastatic brain tumors may preclude or limit glucocorticoid use since it may decrease antitumor response. Bevacizumab should be considered in patients who are unable to wean completely off of steroids as well as those who have symptomatic brain edema and are on immunotherapy. Patients with multiple lesions should usually receive whole-brain radiation. Patients with a single brain metastasis and with controlled extracranial disease may be treated with surgical excision followed by whole-brain radiation therapy, especially if they are aged <60 years. Radioresistant tumors should be resected if possible. Stereotactic radiosurgery (SRS) is recommended in patients with a limited number of brain metastases (one to four) who have stable, systemic disease or reasonable systemic treatment options and in patients who have a small number of metastatic lesions in whom whole-brain radiation therapy has failed. With a gamma knife or linear accelerator, multiple small, well-collimated beams of ionizing radiation destroy lesions seen on MRI. Some patients with increased intracranial pressure associated with hydrocephalus may benefit from shunt placement. If neurologic deterioration is not reversed with medical therapy, ventriculotomy to remove CSF or craniotomy to remove tumors or hematomas may be necessary.

Targeted agents and checkpoint inhibitors have significant activity in brain metastases from non-small-cell lung cancer, breast cancer, renal cancer, and melanoma.

NEOPLASTIC MENINGITIS

Tumor involving the leptomeninges is a complication of both primary central nervous system (CNS) tumors and tumors that metastasize to the CNS. The incidence is estimated at 3–8% of patients with cancer. Melanoma, breast and lung cancer, lymphoma (including AIDS-associated), and acute leukemia are the most common causes. The lobular or triple-negative subtypes of breast cancer, as well as tumors with expression of the mutant epidermal growth factor receptor (EGFR) or the anaplastic lymphoma kinase (ALK) rearrangement in non-small-cell lung cancer (NSCLC), are more likely to have CNS involvement including neoplastic meningitis and brain metastases. Synchronous intraparenchymal brain metastases are evident in 11–31% of patients with neoplastic meningitis. Leptomeningeal seeding is frequent in patients undergoing resection of brain metastases or receiving stereotactic radiotherapy for brain metastases.

Patients typically present with multifocal neurologic signs and symptoms, including headache, gait abnormality, mental changes, nausea, vomiting, seizures, back or radicular pain, and limb weakness. Signs include cranial nerve palsies, extremity weakness, paresthesia, and decreased deep tendon reflexes.

Diagnosis is made by demonstrating malignant cells in the CSF; however, up to 40% of patients may have false-negative CSF cytology. An elevated CSF protein level is nearly always present (except in HTLV-1–associated adult T-cell leukemia). Patients with neurologic signs and symptoms consistent with neoplastic meningitis who have a negative CSF cytology should have the spinal tap repeated at least one more time for cytologic examination. MRI findings suggestive of neoplastic meningitis include leptomeningeal, subependymal, dural, or cranial nerve enhancement; superficial cerebral lesions; intradural nodules; and communicating hydrocephalus. Spinal cord imaging by MRI is a necessary component of the evaluation of nonleukemia neoplastic meningitis because ~20% of patients have cord abnormalities, including intradural enhancing nodules that are diagnostic for leptomeningeal involvement. Cauda equina lesions are common, but lesions may be seen anywhere in the spinal canal. The value of MRI for the diagnosis of leptomeningeal disease is limited in patients with hematopoietic malignancy. Radiolabeled CSF flow studies are abnormal in up to 70% of patients with neoplastic meningitis; ventricular outlet obstruction, abnormal flow in the spinal canal, or impaired flow over the cerebral convexities may affect distribution of intrathecal chemotherapy, resulting in decreased efficacy or increased toxicity. Radiation therapy may correct CSF flow abnormalities before use of intrathecal chemotherapy. Neoplastic meningitis can also lead to intracranial hypertension and hydrocephalus. Placement of a ventriculoperitoneal shunt may effectively palliate symptoms in these patients.

The development of neoplastic meningitis usually occurs in the setting of uncontrolled cancer outside the CNS; thus, prognosis is poor

(median survival 10–12 weeks). However, treatment of the neoplastic meningitis may successfully alleviate symptoms and control the CNS spread.

TREATMENT

Neoplastic Meningitis

Chemotherapy provided by either intrathecal injection or systemic routes is used to control leptomeningeal disease throughout the entire neuroaxis. Intrathecal chemotherapy, usually methotrexate, cytarabine, or thiotepa, is delivered by lumbar puncture or by an intraventricular reservoir (Ommaya). Among solid tumors, breast cancer responds best to therapy. Focal radiotherapy may have a role in bulky disease and in symptomatic or obstructive lesions. Targeted therapy such as systemically administered EGFR tyrosine kinase inhibitors (TKIs) in non-small-cell lung cancer may lead to improvement in some patients with leptomeningeal spread. Patients with neoplastic meningitis from either acute leukemia or lymphoma may be cured of their CNS disease if the systemic disease can be eliminated.

SEIZURES

Seizures occurring in a patient with cancer can be caused by the tumor itself, by metabolic disturbances, by radiation injury, by cerebral infarctions, by chemotherapy-related encephalopathies, or by CNS infections. Metastatic disease to the CNS is the most common cause of seizures in patients with cancer. However, seizures occur more frequently in primary brain tumors than in metastatic brain lesions. Seizures are a presenting symptom of CNS metastasis in 6–29% of cases. Approximately 10% of patients with CNS metastasis eventually develop seizures. Tumors that affect the frontal, temporal, and parietal lobes are more commonly associated with seizures than are occipital lesions. Both early and late seizures are uncommon in patients with posterior fossa and sellar lesions. Seizures are common in patients with CNS metastases from melanoma and low-grade primary brain tumors. Very rarely, cytotoxic drugs such as etoposide, busulfan, ifosfamide, and chlorambucil cause seizures. Treatment with bispecific antibodies and chimeric antigen receptor (CAR) T cells may also cause CNS toxicity including seizures and encephalopathy. Another cause of seizures related to drug therapy is reversible posterior leukoencephalopathy syndrome (RPLS). Chemotherapy, targeted therapy, and immunotherapies have been associated with the development of RPLS. RPLS occurs in patients undergoing allogeneic bone marrow or solid-organ transplantation. RPLS is characterized by headache, altered consciousness, generalized seizures, visual disturbances, hypertension, and symmetric posterior cerebral white matter vasogenic edema on CT/MRI. Seizures may begin focally but are typically generalized.

TREATMENT

Seizures

Patients in whom seizures due to CNS metastases have been demonstrated should receive anticonvulsive treatment with phenytoin or levetiracetam. If this is not effective, valproic acid can be added. Prophylactic anticonvulsant therapy is not recommended. In postcraniotomy patients, prophylactic antiepileptic drugs should be withdrawn during the first week after surgery. Most antiseizure medications including phenytoin induce cytochrome P450 (CYP450), which alters the metabolism of many antitumor agents, including irinotecan, taxanes, and etoposide as well as molecular targeted agents, including imatinib, gefitinib, erlotinib, tipifarnib, sorafenib, sunitinib, temsirolimus, everolimus, and vemurafenib. Levetiracetam and topiramate are anticonvulsant agents not metabolized by the hepatic CYP450 system and do not alter the metabolism of antitumor agents. They have become the preferred drugs. Surgical resection and other antitumor treatments such as radiotherapy and chemotherapy may improve seizure control.

PULMONARY AND INTRACEREBRAL LEUKOSTASIS

Hyperleukocytosis and the leukostasis syndrome associated with it are potentially fatal complications of acute leukemia (particularly myeloid leukemia) that can occur when the peripheral blast cell count is >100,000/mL. The frequency of hyperleukocytosis is 5–13% in acute myeloid leukemia (AML) and 10–30% in acute lymphoid leukemia; however, leukostasis is rare in lymphoid leukemia. At such high blast cell counts, blood viscosity is increased, blood flow is slowed by aggregates of tumor cells, and the primitive myeloid leukemic cells are capable of invading through the endothelium and causing hemorrhage. Brain and lung are most commonly affected. Patients with brain leukostasis may experience stupor, headache, dizziness, tinnitus, visual disturbances, ataxia, confusion, coma, or sudden death. On examination, papilledema, retinal vein distension, retinal hemorrhages, and focal deficit may be present. Pulmonary leukostasis may present as respiratory distress and hypoxemia and progress to respiratory failure. Chest radiographs may be normal but usually show interstitial or alveolar infiltrates. Hyperleukocytosis rarely may cause acute leg ischemia, renal vein thrombosis, myocardial ischemia, bowel infraction, and priapism. Arterial blood gas results should be interpreted cautiously. Rapid consumption of plasma oxygen by the markedly increased number of white blood cells can cause spuriously low arterial oxygen tension. Pulse oximetry is the most accurate way of assessing oxygenation in patients with hyperleukocytosis. Hydroxyurea can rapidly reduce a high blast cell count while the diagnostic workup is in progress. After the diagnosis is established, the patient should start quickly with effective induction chemotherapy. Leukapheresis should be used in patients with symptoms of hyperleukocytosis. Patients with hyperleukocytosis are also at the risk for disseminated intravascular coagulation and tumor lysis syndrome. The clinician should monitor the patient for these complications and take preventive and therapeutic actions during induction therapy. Intravascular volume depletion and unnecessary blood transfusions may increase blood viscosity and worsen the leukostasis syndrome. Leukostasis is very rarely a feature of the high white cell counts associated with chronic lymphoid or chronic myeloid leukemia.

When acute promyelocytic leukemia is treated with differentiating agents like tretinoin and arsenic trioxide, cerebral or pulmonary leukostasis may occur as tumor cells differentiate into mature neutrophils. This complication can be largely avoided by using cytotoxic chemotherapy together with the differentiating agents.

HEMOPTYSIS

Hemoptysis may be caused by nonmalignant conditions, but lung cancer accounts for a large proportion of cases. Up to 20% of patients with lung cancer have hemoptysis some time in their course. Endobronchial metastases from carcinoid tumors, breast cancer, colon cancer, kidney cancer, and melanoma may also cause hemoptysis. The volume of bleeding is often difficult to gauge. Massive hemoptysis is defined as >200–600 mL of blood produced in 24 h. However, any hemoptysis should be considered massive if it threatens life. When respiratory difficulty occurs, hemoptysis should be treated emergently. The first priorities are to maintain the airway, optimize oxygenation, and stabilize the hemodynamic status. If the bleeding side is known, the patient should be placed in a lateral decubitus position, with the bleeding side down to prevent aspiration into the unaffected lung, and given supplemental oxygen. If large-volume bleeding continues or the airway is compromised, the patient should be intubated and undergo emergency bronchoscopy. If the site of bleeding is detected, either the patient undergoes a definitive surgical procedure or the lesion is treated with a neodymium:yttrium-aluminum-garnet (Nd:YAG) laser, argon plasma coagulation, or electrocautery. In stable patients, multidetector CT angiography delineates bronchial and nonbronchial systemic arteries and identifies the source of bleeding and underlying pathology with high sensitivity. Massive hemoptysis usually originates from the high-pressure bronchial circulation. Bronchial artery embolization is considered a first-line definitive procedure for managing hemoptysis. Bronchial artery embolization may control brisk bleeding in 75–90% of

patients, permitting the definitive surgical procedure to be done more safely if it is appropriate.

Embolization without definitive surgery is associated with rebleeding in 20–50% of patients. Recurrent hemoptysis usually responds to a second embolization procedure. A postembolization syndrome characterized by pleuritic pain, fever, dysphagia, and leukocytosis may occur; it lasts 5–7 days and resolves with symptomatic treatment. Bronchial or esophageal wall necrosis, myocardial infarction, and spinal cord infarction are rare complications. Surgery, as a salvage strategy, is indicated after failure of embolization and is associated with better survival when performed in a nonurgent setting.

Pulmonary hemorrhage with or without hemoptysis in hematologic malignancies is often associated with fungal infections, particularly *Aspergillus* spp. After granulocytopenia resolves, the lung infiltrates in aspergillosis may cavitate and cause massive hemoptysis. Thrombocytopenia and coagulation defects should be corrected, if possible. Surgical evaluation is recommended in patients with aspergillosis-related cavitary lesions.

Bevacizumab, an antibody to vascular endothelial growth factor (VEGF) that inhibits angiogenesis, has been associated with life-threatening hemoptysis in patients with non-small-cell lung cancer, particularly of squamous cell histology. Non-small-cell lung cancer patients with cavitary lesions or previous hemoptysis (≥2.5 mL) within the past 3 months have higher risk for pulmonary hemorrhage.

AIRWAY OBSTRUCTION

Airway obstruction refers to a blockage at the level of the mainstem bronchi or above. It may result either from intraluminal tumor growth or from extrinsic compression of the airway. The most common cause of malignant upper airway obstruction is invasion from an adjacent primary tumor, most commonly lung cancer, followed by esophageal, thyroid, and mediastinal malignancies including lymphomas. Extrathoracic primary tumors such as renal, colon, or breast cancer can cause airway obstruction through endobronchial and/or mediastinal lymph node metastases. Patients may present with dyspnea, hemoptysis, stridor, wheezing, intractable cough, postobstructive pneumonia, or hoarseness. Chest radiographs usually demonstrate obstructing lesions. CT scans reveal the extent of tumor. Cool, humidified oxygen, glucocorticoids, and ventilation with a mixture of helium and oxygen (Heliox) may provide temporary relief. If the obstruction is proximal to the larynx, a tracheostomy may be lifesaving. For more distal obstructions, particularly intrinsic lesions incompletely obstructing the airway, bronchoscopy with mechanical debulking and dilation or ablational treatments including laser treatment, photodynamic therapy, argon plasma coagulation, electrocautery, or stenting can produce immediate relief in most patients **(Fig. 75-3)**. However, radiation therapy (either external-beam irradiation or brachytherapy) given together with glucocorticoids may also open the airway. Symptomatic extrinsic compression may be palliated by stenting. Patients with primary airway tumors such as squamous cell carcinoma, carcinoid tumor, adenocystic carcinoma, or non-small-cell lung cancer, if resectable, should have surgery.

METABOLIC EMERGENCIES

HYPERCALCEMIA

Hypercalcemia is the most common paraneoplastic syndrome. Its pathogenesis and management are discussed fully in **Chaps. 93** and **410**.

SYNDROME OF INAPPROPRIATE SECRETION OF ANTIDIURETIC HORMONE

Hyponatremia is a common electrolyte abnormality in cancer patients, and syndrome of inappropriate secretion of antidiuretic hormone (SIADH) is the most common cause among patients with cancer. SIADH is discussed fully in **Chaps. 93** and **381**.

LACTIC ACIDOSIS

Lactic acidosis is a rare and potentially fatal metabolic complication of cancer. Lactic acidosis associated with sepsis and circulatory failure is a common preterminal event in many malignancies. Lactic acidosis in the absence of hypoxemia may occur in patients with leukemia, lymphoma, or solid tumors. In some cases, hypoglycemia also is present. Extensive involvement of the liver by tumor is often present. In most cases, decreased metabolism and increased production by the tumor both contribute to lactate accumulation. Tumor cell overexpression of certain glycolytic enzymes and mitochondrial dysfunction can contribute to its increased lactate production. HIV-infected patients have an increased risk of aggressive lymphoma; lactic acidosis that occurs in such patients may be related either to the rapid growth of the tumor or from toxicity of nucleoside reverse transcriptase inhibitors. Symptoms of lactic acidosis include tachypnea, tachycardia, change of mental status, and hepatomegaly. The serum level of lactic acid may reach 10–20 mmol/L (90–180 mg/dL). Treatment is aimed at the underlying disease. *The danger from lactic acidosis is from the acidosis, not the lactate.* Sodium bicarbonate should be added if acidosis is very severe or if hydrogen ion production is very rapid and uncontrolled. Other treatment options include renal replacement therapy, such as hemodialysis, and thiamine replacement. The prognosis is poor regardless of the treatment offered.

HYPOGLYCEMIA

Persistent hypoglycemia is occasionally associated with tumors other than pancreatic islet cell tumors. Usually these tumors are large; tumors of mesenchymal origin, hepatomas, or adrenocortical tumors may cause hypoglycemia. Mesenchymal tumors are usually located in the retroperitoneum or thorax. Obtundation, confusion, and behavioral aberrations occur in the postabsorptive period and may precede the diagnosis of the tumor. These tumors often secrete incompletely processed insulin-like growth factor II (IGF-II), a hormone capable

of activating insulin receptors and causing hypoglycemia. Tumors secreting incompletely processed big IGF-II are characterized by an increased IGF-II to IGF-I ratio, suppressed insulin and C-peptide level, and inappropriately low growth hormone and β-hydroxybutyrate concentrations. Rarely, hypoglycemia is due to insulin secretion by a non–islet cell carcinoma. The development of hepatic dysfunction from liver metastases and increased glucose consumption by the tumor can contribute to hypoglycemia. If the tumor cannot be resected, hypoglycemia symptoms may be relieved by the administration of glucose, glucocorticoids, recombinant growth hormone, or glucagon.

Hypoglycemia can be artifactual; hyperleukocytosis from leukemia, myeloproliferative diseases, leukemoid reactions, or colony-stimulating factor treatment can increase glucose consumption in the test tube after blood is drawn, leading to pseudohypoglycemia.

ADRENAL INSUFFICIENCY

In patients with cancer, adrenal insufficiency may go unrecognized because the symptoms, such as nausea, vomiting, anorexia, and orthostatic hypotension, are nonspecific and may be mistakenly attributed to progressive cancer or to therapy. Primary adrenal insufficiency may develop owing to replacement of both glands by metastases (lung, breast, colon, or kidney cancer; lymphoma), to removal of both glands, or to hemorrhagic necrosis in association with sepsis or anticoagulation. Impaired adrenal steroid synthesis occurs in patients being treated for cancer with mitotane, ketoconazole, or aminoglutethimide or undergoing rapid reduction in glucocorticoid therapy. Megestrol acetate, used to manage cancer and HIV-related cachexia, may suppress plasma levels of cortisol and adrenocorticotropic hormone (ACTH). Patients taking megestrol may develop adrenal insufficiency, and even those whose adrenal dysfunction is not symptomatic may have inadequate adrenal reserve if they become seriously ill. Paradoxically, some patients may develop Cushing's syndrome and/or hyperglycemia because of the glucocorticoid-like activity of megestrol acetate. Ipilimumab, an anti-CTLA-4 antibody used for treatment of malignant melanoma, may cause autoimmunity including autoimmune-like enterocolitis, hypophysitis (leading to secondary adrenal insufficiency), hepatitis, and, rarely, primary adrenal insufficiency. Autoimmune hypophysitis may present with headache, visual field defects, and pituitary hormone deficiencies manifesting as hypopituitarism, adrenal insufficiency (including adrenal crisis), or hypothyroidism. Ipilimumab-associated hypophysitis symptoms occur at an average of 6–12 weeks after initiation of therapy. An MRI usually shows homogenous enhancement of pituitary gland. Early glucocorticoid treatment and hormone replacement are the initial treatment. The role of high-dose glucocorticoids in the treatment of hypophysitis is not clear. High-dose glucocorticoids may not improve the frequency of pituitary function recovery. Autoimmune adrenalitis can also be observed with anti-CTLA-4 antibody. Pituitary dysfunction is usually permanent, requiring long-term hormone replacement therapy. Other checkpoint inhibitors, such as monoclonal antibodies targeting programmed cell death-1 (PD-1), an inhibitory receptor expressed by T cells or one of its ligands (PD-L1), may cause hypophysitis infrequently (~1%). Autoimmune adrenalitis is more frequent with use of PD-1/PD-L1 than with CTLA-4 inhibitors, but incidence is low. Cranial irradiation for childhood brain tumors may affect the hypothalamus-pituitary-adrenal axis, resulting in secondary adrenal insufficiency. Rarely, metastatic replacement causes primary adrenal insufficiency as the first manifestation of an occult malignancy. Metastasis to the pituitary or hypothalamus is found at autopsy in up to 5% of patients with cancer, but associated secondary adrenal insufficiency is rare.

Acute adrenal insufficiency is potentially lethal. Treatment of suspected adrenal crisis is initiated after the sampling of serum cortisol and ACTH levels **(Chap. 386)**.

TREATMENT-RELATED EMERGENCIES

TUMOR LYSIS SYNDROME

Tumor lysis syndrome (TLS) is characterized by hyperuricemia, hyperkalemia, hyperphosphatemia, and hypocalcemia and is caused by the destruction of a large number of rapidly proliferating neoplastic cells. Acidosis may also develop. Acute renal failure occurs frequently.

TLS is most often associated with the treatment of Burkitt's lymphoma, acute lymphoblastic leukemia, and other rapidly proliferating lymphomas, but it also may be seen with chronic leukemias and, rarely, with solid tumors. This syndrome has been seen in patients with chronic lymphocytic leukemia after treatment with nucleosides like fludarabine and is increased in frequency in lymphoid neoplasms treated with venetoclax, a bcl-2 antagonist. TLS has been observed with administration of glucocorticoids, hormonal agents such as letrozole and tamoxifen, and monoclonal antibodies such as rituximab, obinutuzumab, ofatumumab, and gemtuzumab. TLS usually occurs during or shortly (1–5 days) after chemotherapy. Rarely, spontaneous necrosis of malignancies causes TLS.

Hyperuricemia may be present at the time of chemotherapy. Effective treatment kills malignant cells and leads to increased serum uric acid levels from the turnover of nucleic acids. Owing to the acidic local environment, uric acid can precipitate in the tubules, medulla, and collecting ducts of the kidney, leading to renal failure. Lactic acidosis and dehydration may contribute to the precipitation of uric acid in the renal tubules. The finding of uric acid crystals in the urine is strong evidence for uric acid nephropathy. The ratio of urinary uric acid to urinary creatinine is >1 in patients with acute hyperuricemic nephropathy and <1 in patients with renal failure due to other causes. Other events may lead to renal failure in TLS. Calcium phosphate also precipitates in the interstitium and renal microvasculature, leading to nephrocalcinosis. Both types of crystals are toxic to the tubular epithelium, inducing local active inflammatory and pro-oxidative responses. Soluble uric acid may induce hemodynamic changes, with decreased renal blood flow due to vasoconstriction and impaired autoregulation (crystal-independent pathway).

Hyperphosphatemia, which can be caused by the release of intracellular phosphate pools by tumor lysis, produces a reciprocal depression in serum calcium, which causes severe neuromuscular irritability and tetany. Deposition of calcium phosphate in the kidney and hyperphosphatemia may cause renal failure. Potassium is the principal intracellular cation, and massive destruction of malignant cells may lead to hyperkalemia. Hyperkalemia in patients with renal failure may rapidly become life threatening by causing ventricular arrhythmias and sudden death.

The likelihood that TLS will occur in patients with Burkitt's lymphoma is related to the tumor burden and renal function. Hyperuricemia and high serum levels of lactate dehydrogenase (LDH >1500 U/L), both of which correlate with total tumor burden, also correlate with the risk of TLS. In patients at risk for TLS, pretreatment evaluations should include a complete blood count, serum chemistry evaluation, and urine analysis. High leukocyte and platelet counts may artificially elevate potassium levels ("pseudohyperkalemia") due to lysis of these cells after the blood is drawn. In these cases, plasma potassium instead of serum potassium should be followed. In pseudohyperkalemia, no electrocardiographic abnormalities are present. In patients with abnormal baseline renal function, the kidneys and retroperitoneal area should be evaluated by sonography and/or CT to rule out obstructive uropathy. Urine output should be watched closely.

TREATMENT

Tumor Lysis Syndrome

Recognition of risk and prevention are the most important steps in the management of this syndrome **(Fig. 75-4)**. The standard preventive approach consists of allopurinol and aggressive hydration. Urinary alkalization with sodium bicarbonate is no longer recommended. It increases uric acid solubility, but a high pH decreases the solubility of xanthine, hypoxanthine, and calcium phosphate, potentially increasing the likelihood of intratubular crystallization. Intravenous allopurinol may be given in patients who cannot tolerate oral therapy. Febuxostat, a potent nonpurine selective xanthine oxidase inhibitor, is indicated for treatment of hyperuricemia. It

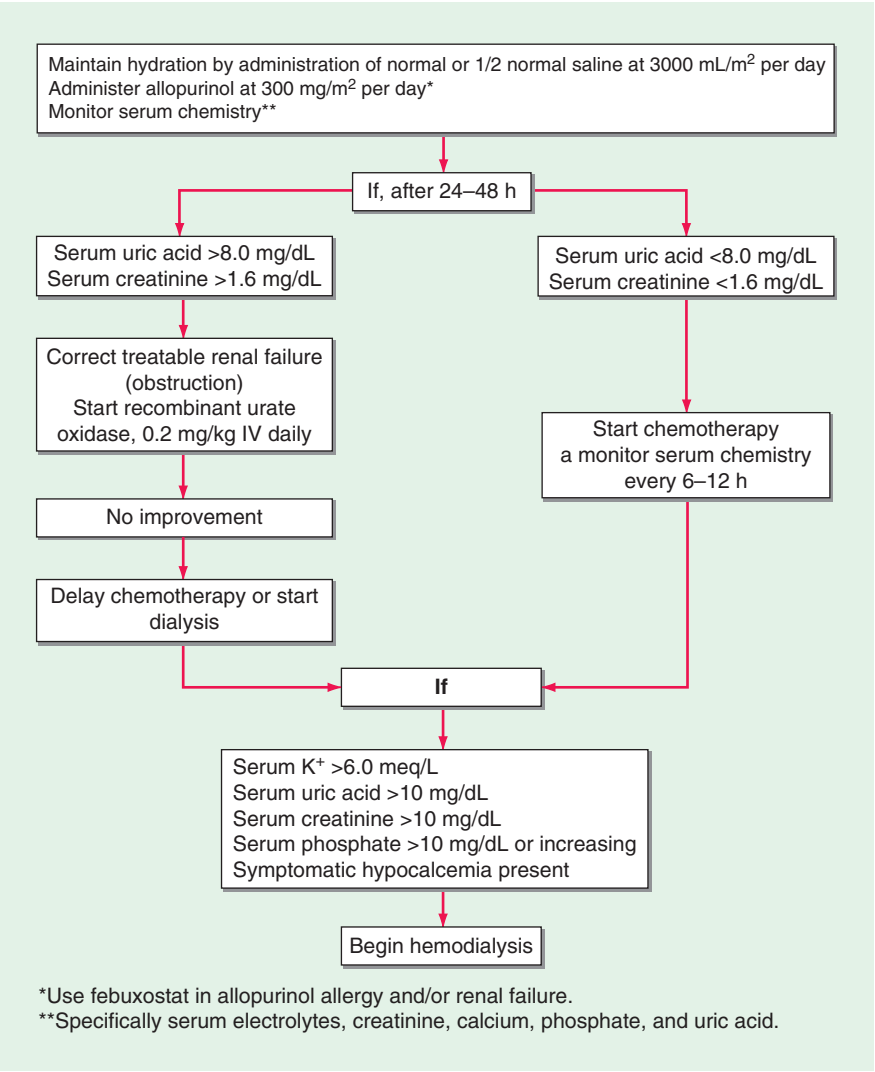

FIGURE 75-4 Management of patients at high risk for the tumor lysis syndrome.

results in fewer hypersensitivity reactions than allopurinol. Febuxostat does not require dosage adjustment in patients with mild to moderate renal impairment. Febuxostat achieved significantly superior serum uric acid control in comparison to allopurinol in patients with hematologic malignancies at intermediate to high TLS risk. In some cases, uric acid levels cannot be lowered sufficiently with the standard preventive approach. Rasburicase (recombinant urate oxidase) can be effective in these instances, particularly when renal failure is present. Urate oxidase is missing from primates and catalyzes the conversion of poorly soluble uric acid to readily soluble allantoin. Rasburicase acts rapidly, decreasing uric acid levels within hours; however, it may cause hypersensitivity reactions such as bronchospasm, hypoxemia, and hypotension. Rasburicase should also be administered to high-risk patients for TLS prophylaxis. Rasburicase is contraindicated in patients with glucose-6-phosphate dehydrogenase deficiency who are unable to break down hydrogen peroxide, an end product of the urate oxidase reaction. Rasburicase is known to cause ex vivo enzymatic degradation of uric acid in test tube at room temperature. This leads to spuriously low uric acid levels during laboratory monitoring of the patient with TLS. Samples must be cooled immediately to deactivate the urate oxidase. Despite aggressive prophylaxis, TLS and/or oliguric or anuric renal failure may occur. Renal replacement therapy is often necessary and should be considered early in the course. Hemodialysis is preferred. Hemofiltration offers a gradual, continuous method of removing cellular by-products and fluid.

HUMAN ANTIBODY INFUSION REACTIONS

The initial infusion of human or humanized antibodies (e.g., rituximab, gemtuzumab, trastuzumab, alemtuzumab, panitumumab, brentuximab vedotin, blinatumomab) is associated with fever, chills, nausea, asthenia, and headache in up to half of treated patients. Bronchospasm and hypotension occur in 1% of patients. Severe manifestations including pulmonary infiltrates, acute respiratory distress syndrome (ARDS), and cardiogenic shock occur rarely. Laboratory manifestations include elevated hepatic aminotransferase levels, thrombocytopenia, and prolongation of prothrombin time. The pathogenesis is thought to be activation of immune effector processes (cells and complement) and release of inflammatory cytokines, such as tumor necrosis factor α, interferon γ, interleukin (IL) 6, and IL-10 (cytokine release syndrome [CRS]). Although its origins are not completely understood, CRS is believed to be due to activation of a variety of cell types including monocytes/macrophages and T and B lymphocytes. Hemophagocytic lymphohistiocytosis (HLH)/macrophage activation syndrome (MAS) can develop as part of CRS and usually is a manifestation of severe CRS.

Severe CRS may require intensive support for ARDS and resistant hypotension. Emerging clinical experience at several institutions has concluded that tocilizumab is an effective treatment for severe or life-threatening CRS. Tocilizumab prevents IL-6 binding to both cell-associated and soluble IL-6 receptors and therefore inhibits both classical and trans-IL-6 signaling. Other cytokine-directed therapies, such as siltuximab, a chimeric anti-IL-6 monoclonal antibody, and anakinra, an IL-1 receptor antagonist, have been used.

Adoptive transfer of CAR-engineered T cells is a promising therapy for cancers. The most common acute toxicity of CAR T cells is CRS. CAR T cell–associated CRS may be associated with cardiac dysfunction and neurotoxicity. The management includes supportive care and tocilizumab.

Severe reactions from rituximab have occurred with high numbers (>50 × 10^9 lymphocytes) of circulating cells bearing the target antigen (CD20) and have been associated with a rapid fall in circulating tumor cells, mild electrolyte evidence of TLS, and, very rarely, death. In addition, increased liver enzymes, D-dimer, and LDH and prolongation of the prothrombin time may occur. Diphenhydramine, hydrocortisone, and acetaminophen can often prevent or suppress the infusion-related symptoms. If they occur, the infusion is stopped and restarted at half the initial infusion rate after the symptoms have abated.

HEMOLYTIC-UREMIC SYNDROME

Hemolytic-uremic syndrome (HUS) and, less commonly, thrombotic thrombocytopenic purpura (TTP) **(Chap. 317)** may rarely occur after treatment with antineoplastic drugs, including mitomycin, gemcitabine, cisplatin, bleomycin, and proteasome inhibitors, and with VEGF inhibitors. Mitomycin and gemcitabine are the most common offenders. Unlike mitomycin, there is no clear-cut relationship between the cumulative dose of gemcitabine and risk of HUS. It occurs most often in patients with gastric, lung, colorectal, pancreatic, and breast carcinoma. In one series, 35% of patients were without evident cancer at the time this syndrome appeared. Secondary HUS/TTP has also been reported as a rare but sometimes fatal complication of bone marrow transplantation.

HUS usually has its onset 4–8 weeks after the last dose of chemotherapy, but it is not rare to detect it several months later. HUS is characterized by microangiopathic hemolytic anemia, thrombocytopenia, and renal failure. Dyspnea, weakness, fatigue, oliguria, and purpura are also common initial symptoms and findings. Systemic hypertension and pulmonary edema frequently occur. Severe hypertension, pulmonary edema, and rapid worsening of hemolysis and renal function may occur after a blood or blood product transfusion. Cardiac findings include atrial arrhythmias, pericardial friction rub, and pericardial effusion. Raynaud's phenomenon is part of the syndrome in patients treated with bleomycin.

Laboratory findings include severe to moderate anemia associated with red blood cell fragmentation and numerous schistocytes on peripheral smear. Reticulocytosis, decreased plasma haptoglobin, and an LDH level document hemolysis. The serum bilirubin level is usually normal or slightly elevated. The Coombs test is negative. The white cell count is usually normal, and thrombocytopenia (<100,000/μL) is almost always present. Most patients have a normal coagulation profile, although some have mild elevations in thrombin time and in levels of fibrin degradation products. The serum creatinine level is elevated at presentation and shows a pattern of subacute worsening within weeks of the initial azotemia. The urinalysis reveals hematuria, proteinuria, and granular or hyaline casts, and circulating immune complexes may be present.

The basic pathologic lesion appears to be deposition of fibrin in the walls of capillaries and arterioles, and these deposits are similar to those seen in HUS due to other causes. These microvascular abnormalities involve mainly the kidneys and rarely occur in other organs. The pathogenesis of cancer treatment–related HUS is not completely understood, but probably the most important factor is endothelial damage. Primary forms of HUS/TTP are related to a decrease in processing of von Willebrand factor by a protease called ADAMTS13.

The case-fatality rate is high; most patients die within a few months. Optimal treatment for chemotherapy-induced HUS is debated. Immunocomplex removal through plasmapheresis, plasma exchange, immunoadsorption, or exchange transfusion, antiplatelet and anticoagulant therapies, and immunosuppression have all been employed with varying degrees of success.

The outcome with plasma exchange is generally poor, as in many other cases of secondary TTP. Rituximab is successfully used in patients with chemotherapy-induced HUS as well as in ADAMTS13-deficient TTP. Eculizumab, a complement inhibitor, is now approved by the U.S. Food and Drug Administration (FDA) and considered first line for the treatment of atypical HUS. Vaccination against *Neisseria meningitis* is mandatory before eculizumab is administered.

NEUTROPENIA AND INFECTION

These remain the most common serious complications of cancer therapy. They are covered in detail in **Chap. 74**.

PULMONARY INFILTRATES

Patients with cancer may present with dyspnea associated with diffuse interstitial infiltrates on chest radiographs. Such infiltrates may be due to progression of the underlying malignancy, treatment-related toxicities, infection, and/or unrelated diseases. The cause may be multifactorial; however, most commonly, they occur as a consequence of treatment. Infiltration of the lung by malignancy has been described in patients with leukemia, lymphoma, and breast and other solid cancers. Pulmonary lymphatics may be involved diffusely by neoplasm (pulmonary lymphangitic carcinomatosis), resulting in a diffuse increase in interstitial markings on chest radiographs. The patient is often mildly dyspneic at the onset, but pulmonary failure develops over a period of weeks. In some patients, dyspnea precedes changes on the chest radiographs and is accompanied by a nonproductive cough. This syndrome is characteristic of solid tumors. In patients with leukemia, diffuse microscopic neoplastic peribronchial and peribronchiolar infiltration is frequent but may be asymptomatic. However, some patients present with diffuse interstitial infiltrates, an alveolar capillary block syndrome, and respiratory distress. Thickening of bronchovascular bundles and prominence of peripheral arteries are CT findings suggestive of leukemic infiltration. In these situations, glucocorticoids can provide symptomatic relief, but specific chemotherapy should always be started promptly.

Several cytotoxic agents, such as bleomycin, methotrexate, busulfan, nitrosoureas, gemcitabine, mitomycin, vinorelbine, docetaxel, paclitaxel, fludarabine, pentostatin, and ifosfamide, may cause pulmonary damage. The most frequent presentations are interstitial pneumonitis, alveolitis, and pulmonary fibrosis. Some cytotoxic agents, including methotrexate and procarbazine, may cause an acute hypersensitivity reaction. Cytosine arabinoside has been associated with noncardiogenic pulmonary edema. Administration of multiple cytotoxic drugs, as well as radiotherapy and preexisting lung disease, may potentiate the pulmonary toxicity. Supplemental oxygen may potentiate the effects of drugs and radiation injury. Patients should always be managed with the lowest F_{IO_2} that is sufficient to maintain hemoglobin saturation.

The onset of symptoms may be insidious, with symptoms including dyspnea, nonproductive cough, and tachycardia. Patients may have bibasilar crepitant rales, end-inspiratory crackles, fever, and cyanosis. The chest radiograph generally shows an interstitial and sometimes an intraalveolar pattern that is strongest at the lung bases and may be symmetric. A small effusion may occur. Hypoxemia with decreased carbon monoxide diffusing capacity is always present. Glucocorticoids may be helpful in patients in whom pulmonary toxicity is related to radiation therapy or to chemotherapy. Treatment is otherwise supportive.

Molecular targeted agents, imatinib, erlotinib, and gefitinib are potent inhibitors of tyrosine kinases. These drugs may cause interstitial lung disease (ILD). In the case of gefitinib, preexisting fibrosis, poor performance status, and prior thoracic irradiation are independent risk factors; this complication has a high fatality rate. In Japan, incidence of ILD associated with gefitinib was ~4.5% compared to 0.5% in the United States. Temsirolimus and everolimus, both esters of rapamycin (sirolimus), are agents that block the effects of mammalian target of rapamycin (mTOR), an enzyme that has an important role in regulating the synthesis of proteins that control cell division. These agents may cause ground-glass opacities (GGO) in the lung with or without diffuse interstitial disease and lung parenchymal consolidation. Patients may be asymptomatic with only radiologic findings or may be symptomatic. Symptoms include cough, dyspnea, and/or hypoxemia, and sometimes patients present with systemic symptoms such as fever and fatigue. The incidence of everolimus-induced ILD also appears to be higher in

Japanese patients. Treatment includes dose reduction or withdrawal and, in some cases, the addition of glucocorticoids.

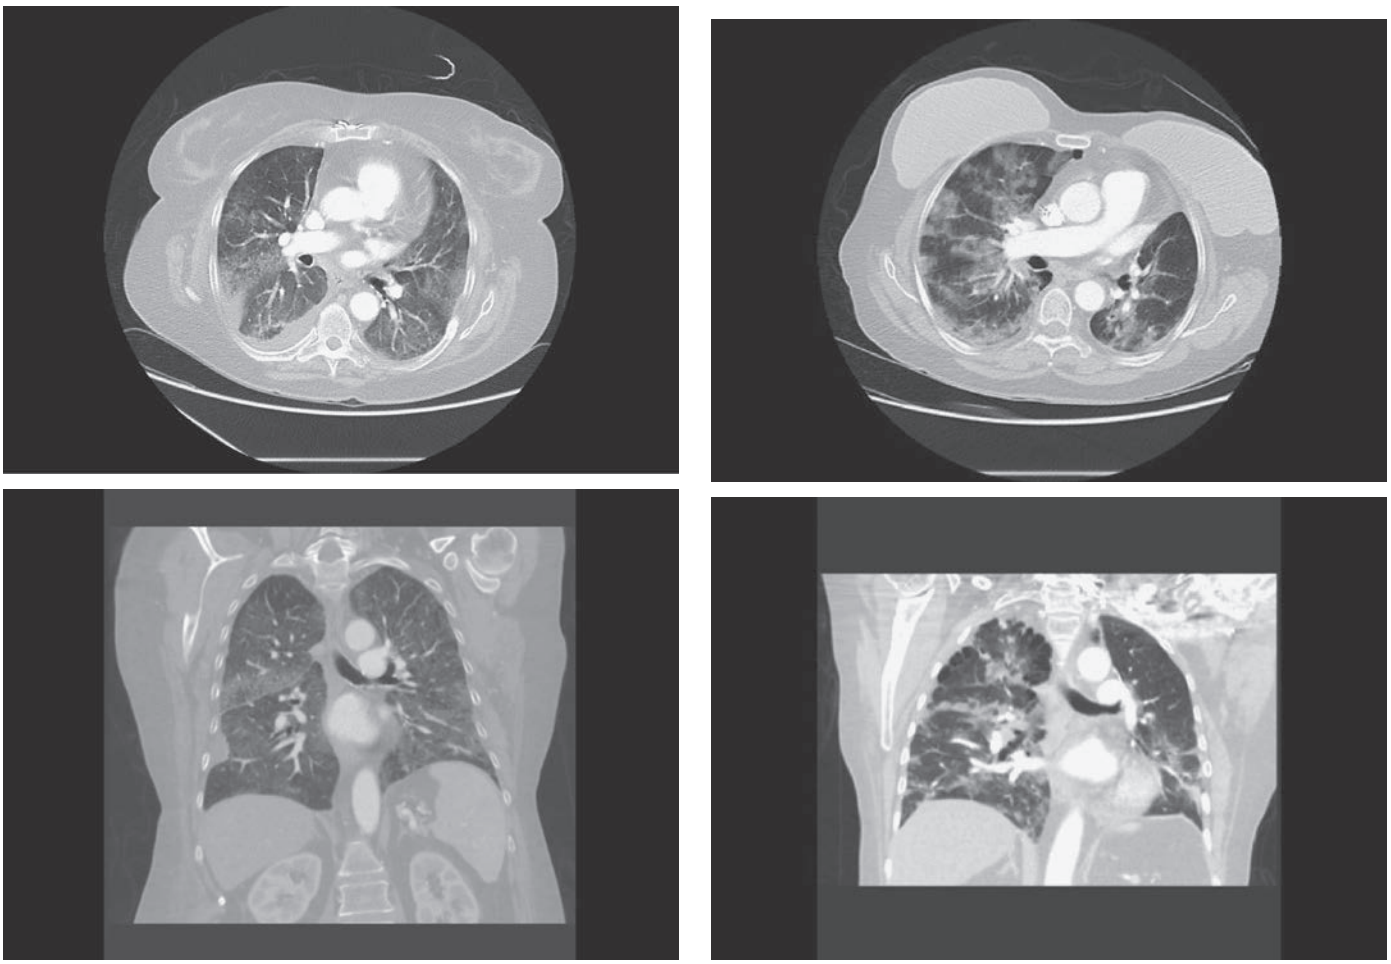
The FDA-approved immune checkpoint inhibitors (ICI) of the PD-1 and PD-L1 pathway, including nivolumab, pembrolizumab, durvalumab, avelumab, atezolizumab, and cemiplimab, enhance antitumor activity by blocking negative regulators of T-cell function. Immune-mediated pneumonitis is rare (10%) but may be a life-threatening complication of these drugs. Pneumonitis symptoms include cough, shortness of breath, dyspnea, and fever, and often involve only asymptomatic radiographic changes. Pneumonitis shows ground-glass patchy lesions and/or disseminated nodular infiltrates, predominantly in the lower lobes. Identifying the exact cause of a pneumonitis in a patient treated with ICIs could be challenging during the current COVID-19 outbreak **(Fig. 75-5A)**. Chest CT manifestations of COVID-19 include an imaging pattern of pure GGO, consolidation, nodules, fibrous stripes, and mixed patterns, with the distribution slightly predominant in the lower lobe and peripheral areas of the lung. Treatment of immune-mediated pneumonitis includes temporary or permanent withdrawal of drug and the addition of high-dose glucocorticoids **(Fig. 75-5B)**.

Radiation pneumonitis and/or fibrosis are relatively frequent side effects of thoracic radiation therapy. It may be acute or chronic. Radiation-induced lung toxicity is a function of the irradiated lung volume, dose per fraction, and radiation dose. The larger the irradiated lung field, the higher is the risk for radiation pneumonitis. The use of concurrent chemoradiation, particularly regimens including paclitaxel, increases pulmonary toxicity. Radiation pneumonitis usually develops 2–6 months after completion of radiotherapy. The clinical syndrome, which varies in severity, consists of dyspnea, cough with scanty sputum, low-grade fever, and an initial hazy infiltrate on chest radiographs. The infiltrate and tissue damage usually are confined to the radiation field. The CT scan may show GGOs, consolidation, fibrosis, atelectatic cicatrization, pleural volume loss, or pleural thickening. The patients subsequently may develop a patchy alveolar infiltrate and air bronchograms, which may progress to acute respiratory failure that is sometimes fatal. A lung biopsy may be necessary to make the diagnosis. Asymptomatic infiltrates found incidentally after radiation therapy need not be treated. However, prednisone should be administered to patients with fever or other symptoms. The dosage should be tapered slowly after the resolution of radiation pneumonitis, because abrupt withdrawal of glucocorticoids may cause an exacerbation of pneumonia. Delayed radiation fibrosis may occur years after radiation therapy and is signaled by dyspnea on exertion. Often it is mild, but it can progress to chronic respiratory failure. Therapy is supportive.

Classic radiation pneumonitis that leads to pulmonary fibrosis is due to radiation-induced production of local cytokines such as platelet-derived growth factor β, tumor necrosis factor, interleukins, and transforming growth factor β in the radiation field.

SBRT is a radiotherapy treatment method that has been applied to the treatment of stage I lung cancers in medically inoperable patients. SBRT accurately delivers a high dose of irradiation in one or few treatment fractions to an image-defined lung mass. Most of the acute changes after SBRT occur later than 3 months after treatment, and the shape of the SBRT-induced injury conforms more tightly to the tumor.

Pneumonia is a common problem in patients undergoing treatment for cancer **(Chap 74)**. In patients with pulmonary infiltrates who are



A ***B***

afebrile, heart failure and multiple pulmonary emboli are in the differential diagnosis.

NEUTROPENIC ENTEROCOLITIS

Neutropenic enterocolitis (typhlitis) is the inflammation and necrosis of the cecum and surrounding tissues that may complicate the treatment of acute leukemia. Nevertheless, it may involve any segment of the gastrointestinal tract including small intestine, appendix, and colon. This complication has also been seen in patients with other forms of cancer treated with taxanes, 5-fluorouracil, irinotecan, vinorelbine, cisplatin, carboplatin, and high-dose chemotherapy **(Fig. 75-6)**. It also has been reported in patients with AIDS, aplastic anemia, cyclic neutropenia, idiosyncratic drug reactions involving antibiotics, and immunosuppressive therapies. The patient develops right lower quadrant abdominal pain, often with rebound tenderness and a tense, distended abdomen, in a setting of fever and neutropenia. Watery diarrhea (often containing sloughed mucosa) and bacteremia are common, and bleeding may occur. Plain abdominal films are generally of little value in the diagnosis; CT scan may show marked bowel wall thickening, particularly in the cecum, with bowel wall edema, mesenteric stranding, and ascites, and may help to differentiate neutropenic colitis from other abdominal disorders such as appendicitis, diverticulitis, and *Clostridium difficile*–associated colitis in this high-risk population. Patients with bowel wall thickness >10 mm on ultrasonogram have higher mortality rates. However, bowel wall thickening is significantly more prominent in patients with *C. difficile* colitis. Pneumatosis intestinalis is a more specific finding, seen only in those with neutropenic enterocolitis and ischemia. The combined involvement of the small and large bowel suggests a diagnosis of neutropenic enterocolitis. Rapid institution of broad-spectrum antibiotics, bowel rest, and nasogastric suction may reverse the process. Use of myeloid growth factors improved outcome significantly. Surgical intervention is reserved for severe cases of neutropenic enterocolitis with evidence of perforation, peritonitis, gangrenous bowel, or gastrointestinal hemorrhage despite correction of any coagulopathy.

C. difficile colitis is increasing in incidence. Newer strains of *C. difficile* produce ~20 times more of toxins A and B compared to previously studied strains. *C. difficile* risk is also increased with chemotherapy. Antibiotic coverage for *C. difficile* should be added if pseudomembranous colitis cannot be excluded.

HEMORRHAGIC CYSTITIS

Hemorrhagic cystitis is characterized by diffuse bladder mucosal bleeding that develops secondary to chemotherapy (mostly cyclophosphamide or ifosfamide), radiation therapy, bone marrow transplantation (BMT), and/or opportunistic infections. Both cyclophosphamide and ifosfamide are metabolized to acrolein, which is a strong chemical irritant that is excreted in the urine. Prolonged contact or high concentrations may lead to bladder irritation and hemorrhage. Symptoms include gross hematuria, frequency, dysuria, burning, urgency, incontinence, and nocturia. The best management is prevention. Maintaining a high rate of urine flow minimizes exposure. In addition, 2-mercaptoethanesulfonate (mesna) detoxifies the metabolites and can be coadministered with the instigating drugs. Mesna usually is given three times on the day of ifosfamide administration in doses that are each 20% of the total ifosfamide dose. If hemorrhagic cystitis develops, the maintenance of a high urine flow may be sufficient supportive care. If conservative management is not effective, irrigation of the bladder with a 0.37–0.74% formalin solution for 10 min stops the bleeding in most cases. *N*-Acetylcysteine may also be an effective irrigant. Prostaglandin (carboprost) can inhibit the process. In extreme cases, ligation of the hypogastric arteries, urinary diversion, or cystectomy may be necessary.

In the BMT setting, early-onset hemorrhagic cystitis is related to drugs in the treatment regimen (e.g., cyclophosphamide), and late-onset hemorrhagic cystitis is usually due to the polyoma virus BKV or adenovirus type 11. BKV load in urine alone or in combination with acute graft-versus-host disease correlates with development of hemorrhagic cystitis. Viral causes are usually detected by polymerase chain reaction (PCR)–based diagnostic tests. Treatment of viral hemorrhagic cystitis is largely supportive, with reduction in doses of immunosuppressive agents, if possible. No antiviral therapy is approved, although cidofovir was reported to be effective in a small series. Hyperbaric oxygen therapy has been used successfully in patients with BKV-associated and cyclophosphamide-induced hemorrhagic cystitis during hematopoietic stem cell transplantation, as well as in hemorrhagic radiation cystitis that occurs in up to 5% of patients after pelvic radiation.

HYPERSENSITIVITY REACTIONS TO ANTINEOPLASTIC DRUGS

Many antineoplastic drugs may cause hypersensitivity reaction. These reactions are unpredictable and potentially life threatening. Most reactions occur during or within hours of parenteral drug administration. Taxanes, platinum compounds, asparaginase, etoposide, procarbazine, and biologic agents, including rituximab, bevacizumab, trastuzumab, gemtuzumab, cetuximab, and alemtuzumab, are more commonly associated with acute hypersensitivity reactions than are other agents. Hypersensitivity reactions to some drugs, such as taxanes, occur during the first or second dose administered. Hypersensitivity to platinum compounds occurs after prolonged exposure. Skin testing may identify patients with high risk for hypersensitivity after carboplatin exposure. Premedication with histamine H_1 and H_2 receptor antagonists and glucocorticoids reduces the incidence of hypersensitivity reaction to

taxanes, particularly paclitaxel. Despite premedication, hypersensitivity reactions may still occur. In these cases, rapid desensitization in the intensive care unit setting or re-treatment may be attempted with care, but the use of alternative agents may be required. Skin testing is used to assess the involvement of IgE in the reaction. Tryptase levels measured at the time of the reaction help to explain the mechanism of the reaction and its severity. Increased tryptase levels indicate underlying mast cell activation. Candidate patients for desensitization include those who have mild to severe hypersensitivity type I, with mast cell–mediated and IgE-dependent reactions occurring during a chemotherapy infusion or shortly thereafter.

MELANOMA

Pigmented lesions are among the most common findings on skin examination. The challenge for the physician is to distinguish benign lesions from cutaneous melanomas and nonmelanoma skin cancers (NMSCs). Both melanoma and NMSC are increasing in frequency, and melanoma accounts for over half of the deaths resulting from skin cancer. Melanoma is an aggressive malignancy of melanocytes, pigment-producing cells that originate from the neural crest and migrate to the skin, meninges, mucous membranes, upper esophagus, and eyes. Melanocytes in each of these locations have the potential for malignant transformation, but the vast majority of melanomas arise in the skin, often permitting detection at a time when complete surgical excision leads to cure. Cutaneous melanoma can occur in people of all ages and all colors. Examples of malignant melanoma of the skin, mucosa, eye, and nail are shown in Fig. 76-1.

RISK FACTORS AND EPIDEMIOLOGY

The epidemiologic patterns seen in melanoma reflect the genetic and biologic features of melanocytes and their response to environmental ultraviolet radiation (UVR). Clinical features that confer an increased risk for melanoma include: (1) vulnerability to sun damage (light/red coloration of skin, hair, or eyes; photodamaged skin; history of exposure to natural or artificial UVR; prior history of skin cancers of any type); (2) abnormal growth of melanocytes (increased absolute number of nevi, increased size of nevi, or atypical features of moles such as multiple colors, speckles, or shapes); and (3) immunosuppression (innate, functional, or drug-induced). Table 76-1 summarizes melanoma risk factors and the relative risk associated with these factors.

The incidence and mortality rates are strongly influenced by ethnic and geographic/environmental factors, which superimpose substantial variability on melanoma rates. Specifically, the incidence of melanoma is 1/100,000 per year in populations with high skin eumelanin content and up to 27/100,000 per year in populations with low skin eumelanin. Men are affected slightly more than women (1.3:1), and the median age at diagnosis is the late fifties. Melanoma is one of the few cancer types with increasing incidence in the United States and is now the fifth leading cancer in men (60,190 new cases estimated in 2020; probability 1:28) and the sixth leading cancer in women (40,160 new cases estimated in 2020; probability 1:41). Although these rankings are based on the total number of new invasive melanoma cases (100,350 in 2020), an additional 95,710 cases of melanoma in situ are expected to occur in 2020. Given the stable or decreasing mortality (see below), it seems likely that new cases include some that represent overdiagnosis of cancers that would not progress to fatal disease.

Mortality rates begin to rise at age 55, with the greatest mortality in men age >65 years. In contrast to the increasing incidence, the mortality rates for melanoma are decreasing, though this trend appears less dramatic outside of the United States. The reasons for the decrease are not entirely clear but have been attributed in part to the recent success of melanoma therapeutics on survival. After U.S. Food and Drug Administration (FDA) approval of ipilimumab and vemurafenib in 2011, the 1-year relative survival rate increased from 42% (2008–2010) to 55% (2013–2015). The mortality rate from 2013 to 2017 dropped annually by 7% in those aged 20–64 years old and dropped 5–6% per year for individuals aged ≥65 years.

GLOBAL CONSIDERATIONS

The incidence of both nonmelanoma and melanoma skin cancers around the world has been increasing. Every year, between 2 and 3 million people develop NMSC, and in 2018, there were 300,000 cases of melanoma. A disproportionate number of cases and deaths occur in North America, Europe, Australia, and New Zealand. The highly variable incidence rates of melanoma in different populations are due to the interplay between risk factors, including host genetics and environmental factors, that distribute risk unevenly across these populations and account for the absolute risk in different ethnic groups and geographic areas.

Dark-skinned populations (such as those of India and Puerto Rico), blacks, and East Asians also develop melanoma but at rates 10–20 times lower than those in whites. Cutaneous melanomas in dark-skinned populations are more often diagnosed at a higher stage, and patients tend to have worse outcomes. Surveillance, Epidemiology, and End Results (SEER) data (2000–2004) reveal that whites have the highest incidence of melanoma at 27.2/100,000 and that the incidence drops substantially in Hispanics (4.5/100,000), Native Americans (4.1/100,000), Asians/Pacific Islanders (1.7/100,000), and blacks (1.1/100,000). In nonwhite populations, the frequency of acral (subungual, plantar, palmar) and mucosal melanomas is much higher; the incidence of melanoma in black and Hispanic populations is not associated with ultraviolet (UV) exposure. In China, about 20,000 new melanomas are reported each year, and in contrast to the United States, mortality is increasing. This may be due to the fact that in Asians and dark-skinned populations, more melanomas arise from acral and mucosal areas, which have a different biology and carry a poorer

prognosis than cutaneous melanomas. Little is yet known about the effects of mixed ethnicity on melanoma risk.

GENETIC SUSCEPTIBILITY TO MELANOMA

Approximately 20–40% of hereditary melanomas (0.2–2% of all melanomas) are due to germline mutations in the cell cycle regulatory gene cyclin-dependent kinase inhibitor 2A (*CDKN2A*). In fact, 70% of all cutaneous melanomas have mutations or deletions affecting the *CDKN2A* locus on chromosome 9p21. This locus encodes two distinct tumor-suppressor proteins from alternate reading frames: p16 and ARF ($p14^{ARF}$). The p16 protein inhibits CDK4/6-mediated phosphorylation and inactivation of the retinoblastoma (RB) protein, whereas ARF inhibits MDM2 ubiquitin-mediated degradation of p53. The loss of *CDKN2A* results in inactivation of two critical tumor-suppressor pathways, RB and p53, which control entry of cells into the cell cycle. Several studies have shown an increased risk of pancreatic cancer among melanoma-prone families with *CDKN2A* mutations. A second high-risk locus for melanoma susceptibility, *CDK4*, is located on chromosome 12q13 and encodes the cyclin-dependent kinase inhibited by p16. *CDK4* mutations, which also inactivate the RB pathway, are much rarer than *CDKN2A* mutations. Germline mutations in the melanoma lineage-specific oncogene microphthalmia-associated transcription factor (*MITF*), BRCA1-associated protein 1 (*BAP-1*), protection of telomeres 1 (*POT-1*), and telomerase reverse transcriptase (*TERT*) also predispose to familial melanoma with a not yet quantified high penetrance, based on families that have been tested.

The melanocortin-1 receptor (*MC1R*) gene is a moderate-risk inherited melanoma susceptibility factor. UVR stimulates the production of melanocortin (α-melanocyte-stimulating hormone [α-MSH]), the ligand for *MC1R*, which is a G-protein-coupled receptor that signals via cyclic AMP and regulates the amount and type of pigment produced by melanocytes. *MC1R* is highly polymorphic, and many among its ~80 variants result in partial or full loss of signaling and lead to the production of non-photoprotective red/yellow pheomelanins, rather than photoprotective brown/black eumelanins. The red hair color (RHC) phenotype produced by *MC1R* mutations includes lightly colored skin, red hair, freckles, increased sun sensitivity, and increased risk of melanoma. In addition to its weak UV-shielding capacity relative to eumelanin, increased pheomelanin production in patients with inactivating polymorphisms of *MC1R* also provides a UV-independent carcinogenic contribution to melanomagenesis via oxidative damage and reduced DNA damage repair.

TABLE 76-1 Melanoma Risk Factors and Relative Risk

RISK LEVEL	RISK FACTOR	RELATIVE RISK
Elevated	1 atypical nevus versus 0	1.5
	Total common nevi, 16+ versus <15	1.5
	Blue eye color versus dark	1.5
	Hazel eye color versus dark	1.5
	Green eye color versus dark	1.6
	Light brown hair versus dark	1.6
	Indoor tanning in any gender versus never	1.7
	Fitzpatrick II versus IV	1.8
	Fitzpatrick III versus IV	1.8
	History of sunburn versus no sunburn	2.0
	Blond hair versus dark	2.0
	2 atypical nevi versus 0	2.1
	Fitzpatrick I versus IV	2.1
	High density of freckles versus none	2.1
	Total common nevi 41–60 versus <15	2.2
Moderately elevated	Family history of melanoma in 1 or more first-degree relatives	1.7–3.0
	3 atypical nevi versus 0	3.0
	Total common nevi 61–80 versus <15	3.3
	Red hair versus dark	3.6
	Chronic lymphocytic leukemia	3.9
	History of actinic keratoses and/or keratinocyte carcinoma versus not	4.3
	Indoor tanning in women aged 30–39 versus never	4.3
	4 atypical nevi versus 0	4.4
High	Transplant recipient versus not	2.2–4.6
	Indoor tanning in women aged <30 versus never	6.0
	5 atypical nevi versus 0	6.4
	Total common nevi 81–120 versus <15	6.9
	Personal history of melanoma	8.2–13.4
	CDK2NA mutation carrier	14–28

Other more common, low-penetrance polymorphisms in genes related to pigmentation, nevus count, immune responses, DNA repair, metabolism, and the vitamin D receptor have small effects on melanoma susceptibility. In sum, ~50–60% of the genetic risk for hereditary melanoma can be attributed to known melanoma predisposition genes, with ~40% of the known genetic risk attributable to *CDKN2A*. The other components of inherited risk are most likely due to the presence of additional modifier genes and/or shared environmental exposures of the host.

PREVENTION AND EARLY DETECTION

Primary prevention of melanoma and NMSC is based on protection from the sun. Public health initiatives, such as the SunSmart program that started in Australia and is now operative in Europe and the United States, have demonstrated that behavioral change can decrease the incidence of NMSC and melanoma. Preventive measures should start early in life because damage from UV light begins early despite the fact that cancers develop years later. Early episodes of sun burns may be a greater risk than chronic tanning. Some individuals tan compulsively. There is greater understanding of tanning addiction and the cutaneous-neural connections that may give rise to this behavior. Compulsive tanners exhibit differences in dopamine binding and reactivity in reward pathways in the brain, such as the basal striatum, resulting in cutaneous secretion of β-endorphins after UV exposure. Identifying individuals with tanning addiction may be another prevention method. Regular use of broad-spectrum sunscreens that block UVA and UVB with a sun protection factor (SPF) of at least 30 and protective clothing should be encouraged. Physical blockers such as zinc oxide and titanium dioxide have less likelihood of being absorbed or of generating an allergic reaction than chemical sunscreens. Avoidance of sunburns, tanning beds, and midday sun exposure is recommended.

Secondary prevention comprises education and screening with the goal of early detection and can be individualized based on risk factors. A full-body skin exam is warranted in populations at higher risk for melanoma such as patients with clinically atypical moles (dysplastic nevi) and those with a personal history of melanoma. Surveillance in high-risk patients should be performed by a dermatologist and include total-body photography and dermoscopy where appropriate. Individuals with three or more primary melanomas and families with at least one invasive melanoma and two or more cases of melanoma and/or pancreatic cancer among first- or second-degree relatives on the same side of the family may benefit from genetic testing. Severely atypical nevi and melanoma in situ should be removed. Early detection of small lesions allows the use of simpler treatment modalities with higher cure rates and lower morbidity. Monthly self-screening augments provider-based screening. Patients should be taught to recognize the clinical features of melanoma and advised to report any change in a pigmented lesion. There is evidence supporting the ability of media campaigns to reduce cancer mortality in lung cancer, and results from Australia's skin cancer campaigns demonstrate improvement in attitude and behavior and a reduction in melanoma incidence. A benefit/cost analysis in Australia showed a return of $3.85 for every $1 invested. Although the U.S. Preventive Services Task Force states that there is insufficient evidence to recommend skin screening for the general population, additional research is anticipated to find best practices for skin cancer detection and prevention.

DIAGNOSIS

The goal is to identify a melanoma before it becomes invasive and life-threatening metastases have occurred. Early detection may be facilitated by applying the ABCDEs: *a*symmetry (benign lesions are usually symmetric); *b*order irregularity (most nevi have clear-cut borders); *c*olor variegation (benign lesions usually have uniform light or dark pigment); *d*iameter >6 mm (the size of a pencil eraser); and *e*volving (any change in size, shape, color, or elevation or new symptoms such as bleeding, itching, and crusting). In addition, any nevus that appears atypical and different from the rest of the nevi on that individual (an "ugly duckling") should be considered suspicious.

The entire skin surface, including the scalp and mucous membranes, as well as the nails should be examined in each patient. Bright room illumination is important, and a hand lens or dermatoscope is helpful for evaluating variation in pigment pattern. Any suspicious lesions should be biopsied, evaluated by a specialist, or recorded by chart and/or photography for follow-up. Dermoscopy employs low-level magnification of the epidermis with polarized light or water interface and permits a more precise visualization of patterns of pigmentation than is possible with the naked eye **(Fig. 76-2)**.

Biopsy Any pigmented cutaneous lesion that has changed in size or shape or has other features suggestive of malignant melanoma is a candidate for biopsy. An excisional biopsy with 1- to 3-mm margins (narrow-margin excision) is suggested. This facilitates histologic assessment of the lesion, permits accurate measurement of thickness if the lesion is melanoma, and constitutes definitive treatment if the lesion is benign. For lesions that are large or on anatomic sites where excisional biopsy may not be feasible (such as the face, hands, and feet), an incisional biopsy (partial biopsy) through the most nodular or darkest area of the lesion is acceptable. Incisional biopsy does not appear to facilitate the spread of melanoma. For suspicious lesions, every attempt should be made to preserve the ability to assess the deep and peripheral margins and to perform immunohistochemistry. Shave, saucerization, or punch biopsies are an acceptable alternative, particularly if the suspicion of malignancy is low. They should be deep enough to include the deepest component of the entire lesion, and any pigment at the base of the lesion should be removed and included with the biopsy specimen.

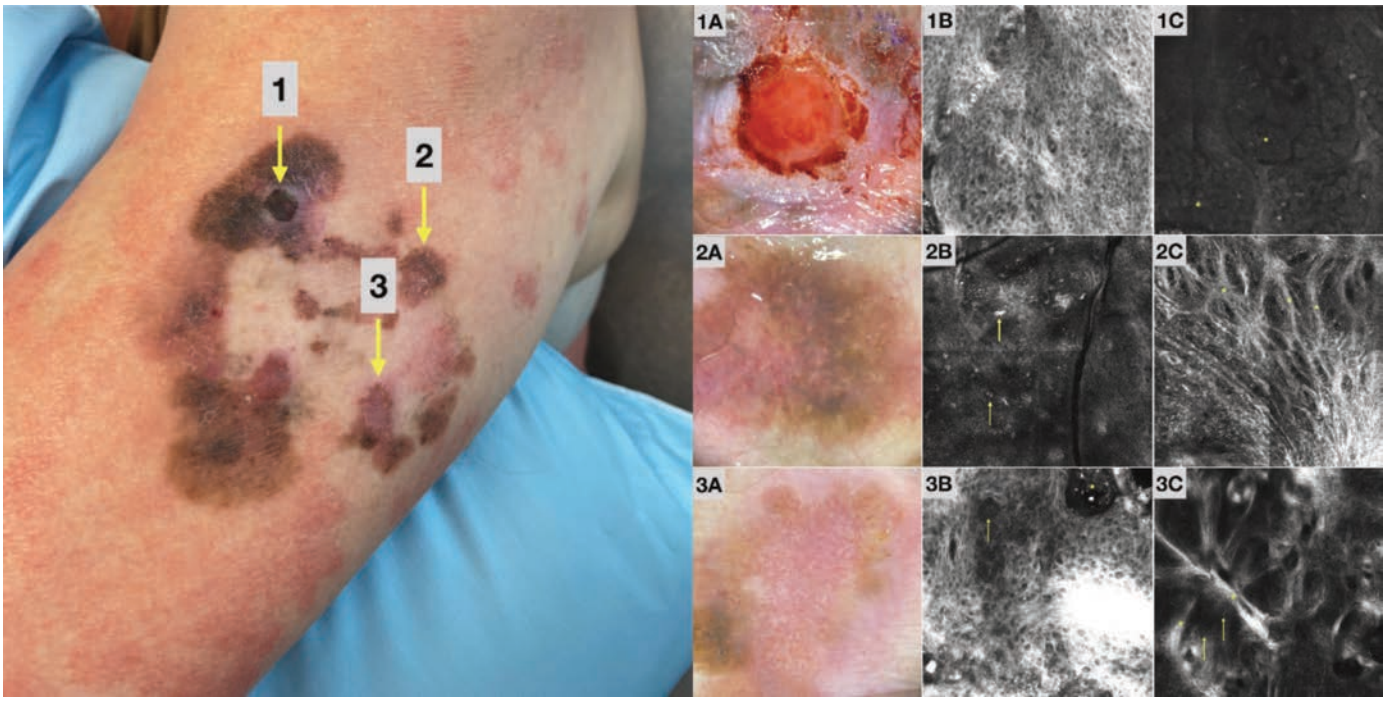

FIGURE 76-2 Clinical and confocal diagnostic findings of melanoma. ***Left panel:*** A clinical image of a large melanoma of a 60-year-old woman used to illustrate classic features of nodular melanoma (1), superficial spreading melanoma (2), and amelanotic melanoma (3). Panels ***1A***, ***2A***, and ***3A*** correspond to the dermoscopy images taken at sites 1, 2, and 3, respectively (Sklip Dermatoscope, Sklip LLC, Las Vegas, NV). Panels ***1B***, ***1C***, ***2B***, ***2C***, ***3B***, and ***3C*** are reflectance confocal microscopy images of the epidermis and upper dermis taken at sites 1, 2, and 3, respectively (Vivascope 1500 Gen 4, Caliber I.D., Rochester, NY). ***1A.*** Site 1 dermoscopy shows a pink nodule with polymorphous vessels and ulceration with active bleeding consistent with malignancy. ***1B.*** Site 1 reflectance confocal microscopy of the epidermis shows an atypical enlarged honeycombed pattern frequently seen in melanoma. ***1C.*** Site 1 reflectance confocal microscopy of the upper dermis shows cerebriform nests (*) seen in nodular melanoma. ***2A.*** Site 2 dermoscopy shows a pigmented area with an atypical, thickened network, blue-gray structures, and polymorphous vessels. ***2B.*** Site 2 reflectance confocal microscopy of the epidermis shows an irregular honeycombed pattern and pagetoid cells with nuclei (↑) typically seen in a superficial spreading melanoma. ***2C.*** Site 2 reflectance confocal microscopy of the dermoepidermal junction shows thickened junctional nests with bright reflective linear dendritic cells (*). ***3A.*** Site 3 dermoscopy shows an amelanotic area within the melanoma with milky red areas, polymorphous vessels, atypical network, and blue-gray structures classic for an amelanotic melanoma. ***3B.*** Site 3 reflectance confocal microscopy of the epidermis shows an irregular enlarged honeycombed pattern, dermal nests protruding upward into the epidermis (↑), and artefacts (*). ***3C.*** Site 3 reflectance confocal microscopy image of the dermoepidermal junction shows thickened collagen bundles (*) with atypical polymorphous vessels (↑).

Punch biopsies are more likely to clear the deep margin but more likely to be positive at the radial margins; the opposite is true for shave biopsies. The choice of biopsy type should be guided by which is most likely to remove the entire lesion for histologic evaluation.

The biopsy should be read by a pathologist experienced in pigmented lesions, and the report should include Breslow thickness, mitotic rate, presence or absence of ulceration, lymphatic invasion, regression, microsatellitosis, and the status of the peripheral and deep margins. Breslow thickness is the greatest thickness of a primary cutaneous melanoma measured on the slide from the top of the epidermal granular layer, or from the ulcer base, to the bottom of the tumor. To distinguish melanomas from benign nevi in challenging cases, fluorescence in situ hybridization with multiple probes or comparative genomic hybridization can be helpful. Gene expression profile (GEP) assays have been developed to determine prognosis and are commercially available.

CLASSIFICATION AND PATHOGENESIS

Clinical Five major types of cutaneous melanoma are described in Table 76-2. In *superficial spreading melanoma*, *lentigo maligna melanoma*, and *acral lentiginous melanoma*, the lesion has a period of

TABLE 76-2 Major Histologic Subtypes of Malignant Melanoma

TYPE	SITE	APPEARANCE	ASSOCIATED MUTATIONS
Lentigo maligna	Sun-exposed surfaces, particularly malar region and temple	In flat portions, brown and tan predominate, but whitish gray sometimes present; in nodules, reddish brown, bluish gray, bluish black.	*BRAF* 28% *NRAS* 15%
Superficial spreading	Any (more common on upper back and, in women, lower legs)	Brown mixed with bluish red, bluish black, reddish brown, and often whitish pink. The lesion border is often visibly and/or palpably raised.	*BRAF* 57% *NRAS* 18%
Nodular	Any	Reddish blue, purple, or bluish black; can be uniform or mixed with brown and black.	*BRAF* 47% *NRAS* 33%
Acral lentiginous	Palm, sole, nail bed, mucous membrane	In flat portions, dark brown; in raised lesions (plaques), brown-black or blue-black.	*NRAS* 25% *c-KIT* 5-10% *BRAF* 10%
Desmoplastic	Any (more common on head and neck)	Highly variable; pigmentation is frequently absent. Can mimic nodular basal cell carcinoma.	*MAPK* and *PI3K* 73% High tumor mutational burden, *BRAF* and *NRAS* uncommon

Driver Mutations
BRAF: 10%
NRAS: 10%
C-KIT: 5–10%
NF1: 48% of BRAF and NRAS WT melanoma in older patients
BRAF: 50%
NRAS: 20%
C-KIT: 0%

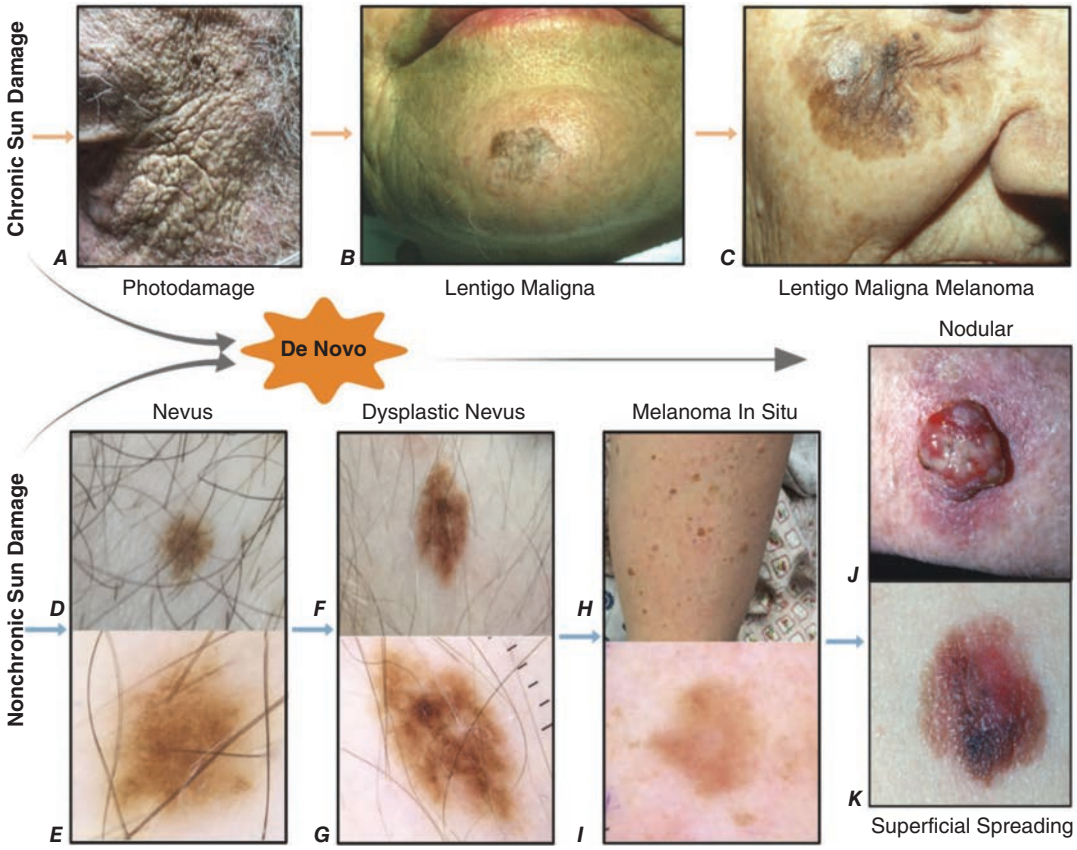

FIGURE 76-3 Cutaneous melanoma development and associated driver mutations. Chronic sun damage (***A***) predisposes to a lentigo maligna (in situ) (***B***), which can evolve into lentigo maligna melanoma (invasive) (***C***). Similarly, nonchronic sun damage can initiate melanoma de novo or in nevomelanocytes, where clinical and histologic changes of atypia may be seen prior to complete transformation. Nevi (***D, E***) can evolve into atypical lesions (***F, G***), in situ melanoma (***H, I***), and eventually invasive nodular (***J***) or superficial spreading melanomas (***K***).

superficial (radial) growth during which it increases in surface area but does not penetrate deeply and is most capable of being cured by surgical excision. Melanomas with a radial growth phase are characterized by irregular and sometimes notched borders, variation in pigment pattern, and variation in color. *Nodular melanoma* does not have a radial growth phase but usually presents with penetration deep into the skin (vertical growth phase). *Desmoplastic melanoma* is associated with a fibrotic response, neural invasion, and a greater tendency for local recurrence. Occasionally, melanomas appear clinically to be amelanotic (not pigmented), in which case the diagnosis is established microscopically after biopsy.

Although these subtypes are clinically distinct, they are primarily of historical interest because this classification has minimal prognostic value and is not part of American Joint Committee on Cancer (AJCC) staging. Characterizing the genomic and mutational profiles of melanoma has become increasingly common, informs prognosis, reflects the mechanisms of tumorigenesis, and may influence surveillance strategies and treatment.

Genomic The advent of next-generation sequencing has led to whole exome sequencing of hundreds of cutaneous melanomas derived from nonglabrous skin. This has revealed very complex genomic changes resulting from both germline (see "Genetic Susceptibility to Melanoma" above) and somatic mutations. Cutaneous melanomas have one of the highest somatic mutation rates (>10 mutations/Mb) among all cancers; the majority (76% of primary tumors and 84% of metastatic melanomas) exhibit mutations indicative of UVR exposure. The mutation rate varies based on body site; melanomas arising in chronic sun-damaged skin harbor substantially more mutations than melanomas from non-sun-damaged skin.

Melanomas can harbor thousands of mutations, but only a few are "driver" mutations that promote cell proliferation or inhibit normal pathways of apoptosis or DNA repair and confer a growth advantage to the neoplastic cell. Some of the driver mutations for cutaneous melanoma are depicted in Fig. 76-3 along with the clinical evolution of melanoma lesions. Driver mutations are often found in combination with mutations to germline susceptibility genes such as *p16*, which affect cell cycle arrest, and *ARF*, which result in defective apoptotic responses to genotoxic damage. The altered melanocytes accumulate DNA damage and develop the malignant phenotype characterized by invasion, metastasis, and angiogenesis.

A genomic classification of cutaneous melanoma has been proposed based on the pattern of the most prevalent mutated genes, *BRAF*, *RAS*, and *NF1*, along with a triple wild-type (WT) in which no mutations in these three genes are found. The pattern of DNA mutations can vary with the site of origin and is independent of the histologic subtype of the tumor. An important aspect of this classification is that the mutational profile can guide therapy. The proliferative pathways affected by the mutations include the mitogen-activated protein (MAP) kinase and phosphatidylinositol 3′ kinase/AKT pathways. *RAS* and *BRAF*, members of the MAP kinase pathway, which mediate the transcription of genes involved in cell proliferation and survival, undergo somatic mutation in melanoma and thereby generate potential therapeutic targets. *NRAS* is mutated in ~20% of melanomas, and somatic activating *BRAF* mutations are found in most benign nevi and 40–50% of cutaneous melanomas. Neither mutation by itself appears to be sufficient to cause melanoma; thus, they often are accompanied by other mutations, such as *TERT*. The *BRAF* mutation is most commonly a T→A point mutation that results in a valine-to-glutamate amino acid substitution (V600E). V600E *BRAF* mutations are more common in younger patients and are present in most melanomas that arise on sites with intermittent sun exposure and are less common in melanomas from chronically sun-damaged skin (i.e., those of older patients).

Melanomas may harbor mutations in *AKT* (primarily in *AKT3*) and *PTEN* (phosphatase and tensin homolog). *AKT* can be amplified, and

PTEN may be deleted or undergo epigenetic silencing that leads to constitutive activation of the PI3K/AKT pathway and enhanced cell survival by antagonizing the intrinsic pathway of apoptosis. A loss-of-function mutation in *NF1*, which can affect both the MAP kinase and PI3K/AKT pathways, has been described in 10–15% of melanomas. In melanoma, these two signaling pathways (MAP kinase and PI3K/AKT) enhance tumorigenesis, chemoresistance, migration, and cell cycle dysregulation.

PROGNOSTIC FACTORS

The most important prognostic factors for a newly diagnosed patient are incorporated in the staging classification. The best predictor of recurrence is Breslow thickness, followed by ulceration, which together make up the T stage of the AJCC system for melanoma. The anatomic site of the primary tumor is also prognostic; favorable sites are the forearm and leg, and unfavorable sites include the scalp, hands, feet, and mucous membranes. Women with stage I or II disease have better survival than men, perhaps in part because of earlier diagnosis; women frequently have melanomas on the lower leg, where self-recognition is more likely and the prognosis is better.

Older individuals, especially men >60, have a tendency toward delayed diagnosis (and thus thicker tumors), have more head and neck and acral melanomas (which tend to have earlier vertical growth and distant metastases), and are more likely to develop melanomas in chronically UVR-damaged skin (which are more often *BRAF* wild type, with fewer options for therapy). Other important adverse factors include high mitotic rate, microscopic evidence of regression, and lymphatic/vascular invasion. Clinical features such as microsatellite lesions and/or in-transit metastases, evidence of nodal involvement, elevated serum lactate dehydrogenase (LDH), and presence and site of distant metastases all portend a higher stage and worse prognosis.

GEPs and machine-learning algorithms that associate genomic changes with clinical outcomes have been used to estimate the prognosis of melanoma. A commercially available 31-gene GEP is available that predicts for all-site (particularly distant) relapse and incorporates the increased and decreased expression, as well as the dysregulation, of genes involved in many of the cellular processes leading to melanoma progression described earlier. Although this 31-gene GEP can estimate the probability of distant relapse, it has not supplanted the prognostic estimates derived from surgical staging. It is anticipated that GEPs will be incorporated into future cutaneous melanoma management guidelines, as they have been for uveal melanoma, breast cancer, thyroid cancer, and other malignancies.

STAGING

Once the diagnosis of melanoma has been made, the tumor is staged to determine the prognosis and aid in treatment selection. The current melanoma staging criteria and estimated 10-year survival by stage are depicted in **Table 76-3**. The clinical stage is determined after the microscopic evaluation of the melanoma skin lesion and clinical and radiologic assessment. The pathologic stage also includes microscopic examination of clinically negative regional lymph nodes obtained at sentinel lymph node biopsy (SLNB), any enlarged nodes found on exam or imaging, and any suspected metastases amenable to open or image-guided biopsy.

All patients should have a complete history, with attention to symptoms that suggest metastatic disease, such as new palpable masses, malaise, weight loss, headaches, changes in vision or bowel habits, hemoptysis, and pain. The provider should look for persistent disease at the biopsy site, dermal or subcutaneous nodules that could represent satellite or in-transit metastases, and lymphadenopathy. A complete blood count, complete metabolic panel, and LDH should be performed. Although these tests rarely help uncover occult metastatic disease, a microcytic anemia would raise the possibility of bowel metastases, elevated liver function tests can suggest liver metastases, and LDH is part of the AJCC system for stage IV disease. Abnormal test results should prompt a more extensive evaluation, including computed tomography (CT) scan or a positron emission tomography (PET) scan (or CT/PET combined).

TABLE 76-3 Staging and Survival

STAGE	TNM	10-YEAR MELANOMA-SPECIFIC SURVIVAL ESTIMATE
0	TisN0M0	>99%
IA	T1aN0M0, T1bN0M0	98–96%
IB	T2aN0M0	92%
IIA	T2b-T3aN0M0	88%
IIB	T3b-T4aN0M0	81–83%
IIC	T4bN0M0	75%
IIIA	T1a-T2aN1a-2aM0	88%
IIIB	T2b-T3aN1a-N2bM0	77%
IIIC	T3b-4bN1a-N3cM0	60%
IIID	T4bN3a-N3cM0	24%
IV M1a	Any T, any N, skin, soft tissue, or distant nodal sites	50% at 5 years
IV M1b	Any T, any N, lung + any M1a sites	35–50% at 5 years
IV M1c	Any T, any N, skin, non-CNS visceral disease, any M1a or M1b sites	~25% at 5 years
IV M1d	Any T, any N, CNS metastasis + any M1a,b,c sites	<5% at 5 years

Abbreviations: CNS, central nervous system; TNM, tumor-node-metastasis.

Despite all the above considerations, >80% of patients at presentation will have disease confined to the skin and a negative history and physical examination, in which case imaging is not indicated. Although controversial, an exception is sometimes made for very-high-risk primaries (e.g., >4 mm with ulceration) in which the chance for occult distant metastases is higher than that for a positive SLNB.

TREATMENT

Melanoma

MANAGEMENT OF CLINICALLY LOCALIZED MELANOMA (STAGE I, II)

For a newly diagnosed cutaneous melanoma, wide surgical excision of the lesion with a margin of normal skin is necessary to remove all malignant cells and minimize the probability of local recurrence. The National Comprehensive Cancer Network (NCCN), based on data from six randomized trials, recommends the following radial margins for a primary melanoma: in situ, 0.5–1.0 cm; invasive up to 1 mm thick, 1 cm; >1.01–2 mm, 1–2 cm; and >2 mm, 2 cm. Smaller margins may be used for special locations such as the face, hands, feet, and genitalia due to the higher likelihood of morbidity in these regions. In all instances, however, inclusion of subcutaneous fat in the surgical specimen facilitates adequate thickness measurement and assessment of surgical margins by the pathologist. When feasible, excision should go down to fascia, with fascial resection for thick (T4) lesions. Topical imiquimod can be used to treat lentigo maligna in cosmetically sensitive locations with narrow resection margins by promoting local immune response resulting in decreased local recurrence.

SLNB is a valuable staging tool providing prognostic information to identify patients at high risk for relapse who may be candidates for adjuvant therapy. The first (sentinel) draining node(s) from the primary site is (are) located by injecting a blue dye and a gamma-emitting radioisotope around the primary site. The sentinel node(s) then is (are) identified using a handheld gamma detector brought sterilely into the operative field. The surgeon makes an incision of the area of uptake and looks for the blue-stained, "hot" node(s), which is (are) removed and subjected to histopathologic analysis with serial sectioning using hematoxylin and eosin and immunohistochemical stains (e.g., S100, HMB45, MART-1, and MelanA) to identify melanocytes.

NCCN guidelines recommend SLNB to patients with a 10% or greater chance of having tumor in the node. This includes patients

with tumors >1 mm thick (T2) or T1 tumors that have ulceration (T1b). Patients with a 5–10% risk of node positivity, such as those with tumors measuring between 0.75 and 1.0 mm, transected tumors, regressed tumors, or lymphovascular invasion, should also be considered for SLNB. The NCCN does not recommend SLNB for patients with a risk of a positive SLNB ≤5% such as those with melanomas ≤0.75 mm thick and no high-risk features. In these patients, wide excision alone is the usual definitive therapy.

Patients whose SLNB is negative can either be followed or considered for a clinical trial if the primary lesion is considered high risk (i.e., stages IIB and IIC). Patients with a positive sentinel lymph node should undergo imaging (CT or PET scanning) to rule out distant metastatic disease, and if none is found (i.e., stage III), adjuvant therapy on or off a clinical study should be offered (see next section). Complete lymphadenectomy for a positive sentinel lymph node has been shown to improve relapse-free but not overall survival, and therefore, it is no longer offered routinely. This avoids the morbidity of regional node dissection in most patients. However, patients not undergoing immediate completion node dissection should have nodal bed surveillance with physical examination and ultrasound at 4- to 6-month intervals for approximately 3 years to rule out isolated nodal bed progression. Complete node dissection is therefore still offered to patients who cannot comply with follow-up and/or forgo adjuvant therapy.

MANAGEMENT OF REGIONALLY METASTATIC MELANOMA (STAGE III)

Patients with a positive sentinel lymph node, resected regional nodal macrometastases, or resected locoregional disease (e.g., recurrences in the wide excision site, within 2 cm of the site ["satellite metastases"], or >2 cm from the site ["in-transit metastases"]) are all considered as having stage III disease. Even after complete resection of stage III disease, the risk for progression to distant metastases (stage IV) may be high, and adjuvant systemic therapy should be offered. Melanomas may recur at the edge of the incision or graft, as satellite metastases, in-transit metastases, or most commonly, regional spread to a draining lymph node basin. Each of these presentations is managed surgically and, increasingly, with postsurgical adjuvant immunotherapy or targeted therapy, after which there is the possibility of long-term disease-free survival. Topical therapy with imiquimod has been useful for patients with low-volume dermal lesions. Talimogene laherparepvec is an engineered, oncolytic herpes simplex virus type 1 that is FDA approved for injection of primary or recurrent melanomas including cutaneous and subcutaneous lesions or lymph node deposits that cannot be completely removed by surgery.

Stage III patients rendered free of disease after surgery are at risk for local or distant recurrence and should be offered adjuvant therapy. Radiotherapy can reduce the risk of local recurrence after lymphadenectomy but does not influence overall survival. Patients with large nodes (>3–4 cm), four or more involved lymph nodes, or extranodal spread on microscopic examination should be considered for radiation. Systemic adjuvant therapy is indicated primarily for patients with stage III disease, but high-risk, node-negative patients (>4 mm thick or ulcerated lesions) and patients with completely resected stage IV disease also may benefit.

Current options for adjuvant therapy include anti-PD-1 (nivolumab or pembrolizumab) or targeted therapy in melanomas that express a *BRAF* V600 mutation. Both anti-PD-1 and targeted therapy have been shown to confer disease-free and overall survival benefits in stage III and stage IV melanoma (see below for further discussion). Other agents such as ipilimumab and interferon α2b (IFN-α2b) have been used in the adjuvant setting, but due to a higher percentage of immune-mediated side effects in the case of ipilimumab and limited efficacy in the case of interferon, they have been supplanted by better alternatives. Ongoing clinical trials are comparing systemic therapy before surgery (neoadjuvant) with adjuvant treatment, the optimal sequence of immunotherapy and targeted therapies, and the utility of anti-PD-1 in high-risk stage II melanoma. GEP may help to identify patients with stage II or III melanoma who are at lower risk of recurrence and could avoid the toxicity and expense of adjuvant therapy.

TREATMENT

Metastatic Disease

At diagnosis, 84% patients with melanoma will have stage I or II disease and 4% will present with metastases. Many others will develop metastases after initial therapy for locoregional disease. The probability of recurrence is related to initial stage, ranging from <5% with stage IA to >90% for subsets of patients with stage IIID disease at presentation. Patients with a history of melanoma who develop signs or symptoms suggesting recurrent disease should undergo restaging as described earlier. Distant metastases (stage IV) commonly involve skin and lymph nodes as well as viscera, bone, or the brain. The prognosis is better for patients with skin and subcutaneous metastases (M1a) than for lung (M1b) and worst for those with metastases to bone or other visceral organs (M1c) or brain (M1d). An elevated serum LDH is a poor prognostic factor and places the patient in stage M1c regardless of the metastatic sites. The 15-year survival of patients with melanoma was <10% before 2010; however, the development of targeted therapy and immunotherapy has improved disease-free and overall survival, especially for patients with M1a and M1b disease, such that currently the 15-year survival exceeds 25%. Even patients with M1c disease may have prolonged survival, and those who are progression-free for >2 years after immunotherapy or targeted therapy have a high probability of living >5 years from the onset of metastasis.

FDA-approved agents since 2011 include three immune T-cell checkpoint inhibitors (ipilimumab, nivolumab, and pembrolizumab), combination immunotherapy (ipilimumab plus nivolumab), six oral agents that target the MAP kinase pathway (the BRAF inhibitors vemurafenib, dabrafenib, and encorafenib, and the MEK inhibitors trametinib, cobimetinib, and binimetinib), and the oncolytic virus talimogene laherparepvec **(Table 76-4)**.

Local modalities, such as surgery and stereotactic radiosurgery, should be considered for patients with oligometastatic disease because they may experience long-term disease-free survival after metastasectomy or ablative high-dose-per-fraction radiation. Patients with solitary metastases are the best candidates, but local modalities can also be used for patients with metastases at more than one site if a complete resection or treatment of all sites can be achieved with reasonable side effects. Patients rendered free of disease can be considered for adjuvant therapy or a clinical trial because their risk of developing additional metastases remains high. Surgery can also be used as an adjunct to systemic therapy when, for example, a few of many metastatic lesions prove resistant to

TABLE 76-4 Treatment Options for Metastatic Melanoma

Immunotherapy
Immune checkpoint blockade
Anti-PD-1: pembrolizumab or nivolumab
Anti-CTLA-4: ipilimumab
Combined ipilimumab and nivolumab
Cytokine-based immunotherapy
High-dose interleukin 2
Oncolytic virus
Talimogene laherparepvec
Targeted therapies
BRAF inhibitors: vemurafenib, dabrafenib, encorafenib
MEK inhibitors: trametinib, cobimetinib, binimetinib
Local modalities
Surgery
Stereotactic radiation

immunotherapy; it may also be helpful to obtain tumor to establish the mutational profile of the recurrent melanoma.

IMMUNOTHERAPY

Checkpoint Blockade Immunotherapies are based on an understanding of the control mechanisms of the normal immune response. Inhibitory receptors or checkpoints, including CTLA-4 and PD-1, are upregulated on T cells after engagement of the T-cell receptor by cognate tumor antigen in the context of the appropriate class I or II HLA molecules during the interaction between a T cell and antigen-presenting cell. Immune checkpoints are an absolute requirement to ensure proper regulation of a normal immune response; however, the continued expression of inhibitory receptors during chronic infection (hepatitis, HIV) and in cancer patients leads to exhausted T cells with limited potential for proliferation, cytokine production, or cytotoxicity. Checkpoint blockade with an antagonistic monoclonal antibody results in improved T-cell function and eradication of tumor cells in preclinical animal models. Ipilimumab, a fully human IgG1 antibody that binds CTLA-4 and blocks inhibitory signals, was the first drug shown in a randomized trial to improve survival in patients with metastatic melanoma. Although response rates are low (about 10%), overall survival is improved. Anti-CTLA-4 monotherapy has been supplanted by combination anti-CTLA-4 plus anti-PD-1 or anti-PD-1 monotherapy due to enhanced survival and, in the case of anti-PD-1 monotherapy, better patient tolerance, as detailed below.

Chronic T-cell activation also leads to induction of PD-1 on the surface of T cells. Expression of one of its ligands, PD-L1, on tumor cells can protect them from immune destruction. Blockade of the PD-1:PD-L1 axis by intravenous (IV) administration of anti-PD-1 or anti-PD-L1 has substantial clinical activity, including cure, in some patients with advanced melanoma and other solid tumors with significantly less toxicity than ipilimumab. The PD-1 blockers, nivolumab and pembrolizumab, have been approved to treat patients with advanced melanoma. Combination T-cell checkpoint therapy, blocking both inhibitory pathways with ipilimumab and nivolumab, leads to superior antitumor activity compared to treatment with either agent alone. Combined therapy with IV ipilimumab and nivolumab is administered in the outpatient setting every 3 weeks for four doses (induction), followed by nivolumab given every 2–4 weeks (maintenance) for up to 1 year, and is associated with an objective response rate of 56% and enhanced survival compared to ipilimumab monotherapy. There may be subsets of patients, specifically those who have >5% expression of PD-1 on T cells in a melanoma biopsy sample, who derive a similar level of clinical benefit from nivolumab monotherapy, although using PD-1 expression to select therapy remains problematic as some patients whose melanoma has no detectable PD-1 expression can still respond to immunotherapy.

T-cell checkpoint antibodies can also interfere with normal immune regulatory mechanisms, which may produce a novel spectrum of side effects. The most common immune-related adverse events were skin rash and diarrhea (sometimes severe, life-threatening colitis), but toxicity can involve almost any organ (e.g., thyroiditis, hypophysitis, hepatitis, nephritis, pneumonitis, myocarditis, neuritis). The severity and frequency of toxicity are greatest with combination T-cell checkpoint antibody therapy, followed by anti-CTLA-4 and then anti-PD-1 monotherapies. Vigilance, interruption of therapy, and early intervention with steroids or other immunosuppressive agents, such as anti–tumor necrosis factor antibodies or mycophenolate mofetil, can mitigate toxicity and prevent permanent organ damage. The management of drug-induced toxicity with immunosuppressive agents does not appear to interfere with antitumor activity, and benefit is manifest even in patients who have to discontinue immunotherapy due to immune-mediated toxicity. The use of T-cell checkpoint antibodies for metastatic melanoma has become commonplace, but there is controversy about whether all patients need combined anti-CTLA-4 and anti-PD-1, whether biomarkers can be used to select patients who may benefit from anti-PD-1 alone, and the best sequence of targeted therapy and immunotherapy in patients whose melanomas have a *BRAF* mutation. There is also a significant economic impact with any anticancer therapy, which must be placed in the context of the survival benefit.

TARGETED THERAPY

The RAS-RAF-MEK-ERK pathway delivers proliferation and survival signals from the cell surface to the cytoplasm and nucleus and is mutated in approximately 50% of melanomas. Inhibitors of BRAF and MEK can induce regression of melanomas that harbor a *BRAF* mutation. Three BRAF inhibitors, vemurafenib, dabrafenib, and encorafenib, have been approved for the treatment of patients whose stage IV melanomas harbor a mutation at position 600 in *BRAF*. Monotherapy with BRAF inhibitors has been supplanted with combined BRAF and MEK inhibition to address the rapid adaptation of the majority of melanomas that use MAP kinase pathway reactivation to facilitate growth when BRAF is inhibited. Combined therapy with BRAF and MEK inhibitors (dabrafenib and trametinib, vemurafenib with cobimetinib, or encorafenib and binimetinib) improved progression-free and overall survival compared to monotherapy with a BRAF inhibitor. Long-term results of inhibition of the MAP kinase pathway confirm that some patients achieve long intervals of disease control, yet the major limitation of both monotherapy and combined therapy appears to be the acquisition of resistance; the majority of patients relapse and eventually die. The mechanisms of resistance are diverse and reflect the genomic heterogeneity of melanoma; however, most instances involve reactivation of the MAPK pathway, often through *RAS* mutations or mutant *BRAF* amplification. Patients who develop resistance to BRAF and MEK inhibition are candidates for immunotherapy or clinical trials.

Targeted therapy is accompanied by manageable side effects that differ from those experienced during immunotherapy or chemotherapy. A class-specific side effect of BRAF inhibitor monotherapy is the development of hyperproliferative skin lesions, some of which are well-differentiated squamous cell skin cancers (SCCs) occurring in up to 25% of patients. Paradoxical activation of the MAP kinase pathway occurs from BRAF inhibitor–mediated changes in *BRAF* wild-type cells, and the activation is blocked by MEK inhibitor, which explains why these lesions occur much less frequently during combined therapy. Metastases of the treatment-induced SCCs have not been reported, and BRAF and MEK inhibitors can be continued safely following simple excision of the SCCs. Cardiac and ocular toxicities, although infrequent, can occur with BRAF and MEK inhibitors and require medical evaluation, management, and usually discontinuation of targeted therapy.

Activating mutations in the c-kit receptor tyrosine kinase are found in a minority of cutaneous melanomas with chronic sun damage but are more common in mucosal and acral lentiginous subtypes. Overall, the number of patients with *c-kit* mutations is small, but when present, they are similar to those found in gastrointestinal stromal tumors and melanomas with activating *c-kit* mutations and can have clinically meaningful responses to imatinib. The probability of objective response in patients whose melanomas harbor a *c-kit* mutation is 29%. *N-RAS* mutations occur in 15–20% of melanomas. At present, there are no effective targeted agents for these patients, but *N-RAS* inhibitors are being investigated in clinical trials.

Other systemic therapies used to treat stage IV melanoma patients include high-dose interleukin 2, which is also associated with durable remissions in some patients. Chemotherapy with dacarbazine or taxanes is infrequently used, and clinical trials remain an important option for patients with advanced melanoma.

INITIAL APPROACH TO PATIENT WITH METASTATIC DISEASE

Upon diagnosis of stage IV disease, a sample of the patient's tumor should be submitted for molecular testing to determine whether a *BRAF* or *c-kit* mutation is present. Analysis of a metastatic lesion biopsy (if possible) is preferred, but any sample will suffice because

there is little discordance between primary and metastatic lesions. Treatment algorithms start with the tumor's *BRAF* status. For *BRAF* wild-type tumors, immunotherapy is recommended. For patients whose tumors harbor a *BRAF* mutation, initial therapy with either combination BRAF and MEK inhibitors or immunotherapy is acceptable. Combined therapy with BRAF and MEK inhibitors is recommended for patients with rapidly growing and symptomatic disease when a *BRAF* mutation is present. The sequence of immunotherapy and targeted therapy that confers the greatest survival benefit in patients with minimally symptomatic melanoma is not yet known, but ongoing randomized phase III trials should answer this important question. Despite improvements in therapy, the majority of patients with metastatic melanoma will not be cured, so enrollment in a clinical trial is always an important consideration, even for previously untreated patients.

Clinical trials should be considered for patients with stage IV disease who experience tumor progression despite current therapy. Many will be poor candidates for therapy because of extensive disease burden, poor performance status, or concomitant illness; thus, the timely integration of palliative care and hospice remains an important element of care.

FOLLOW-UP

Skin examination and surveillance at least once a year are recommended for all patients with melanoma. Routine blood work and imaging for patients with stage IA–IIA disease is not recommended unless symptoms are present. Surveillance diagnostic imaging can be considered in patients with stage III high-risk disease but is mainly reserved for patients with signs or symptoms of recurrent disease or to follow response to therapy. For stage-specific recommendations, please consult the NCCN guidelines (see "Further Reading").

NONMELANOMA SKIN CANCERS

NMSCs (mostly SCCs and basal cell cancer [BCC]) are the most common cancers in the United States. Although tumor registries do not routinely gather data on the incidence of NMSCs, it is estimated that the annual incidence is more than 5.3 million cases in the United States; SCCs and BCCs account for 80% and 18%, respectively. While less common, the incidence of Merkel cell carcinoma (MCC) has tripled over the past 20 years. There are now an estimated 1600 cases per year with an annual increase in incidence of 8%. While all forms of NMSCs can metastasize, MCCs do this most commonly, with sentinel lymph node positivity rates of 25% (compared to 12–19% for melanoma) and mortality rates approaching 33% at 3 years. SCCs, particularly those with high-risk features, can also metastasize and account for 2400 deaths annually.

PATHOPHYSIOLOGY AND ETIOLOGY

Similar to melanoma, the most significant cause of NMSCs is UVR, with a dose-response relationship between tanning bed use and the incidence of NMSC. As few as four tanning bed visits per year confers a 15% increase in BCC and an 11% increase in SCC. The risk of lip or oral SCC is increased with cigarette smoking and, like SCC of the ear, has a worse prognosis than that seen on other body sites. Human papillomaviruses and UVR may act as co-carcinogens. Inherited disorders of DNA repair, such as xeroderma pigmentosum, are associated with a greatly increased incidence of skin cancer and help to establish the link between UV-induced DNA damage, inadequate DNA repair, and skin cancer.

The genes damaged most commonly by UV in SCC include *p53* and *N-RAS*, whereas BCC is associated with damage to hedgehog signaling pathway (Hh) genes, which lead to basal cell proliferation. This is usually the result of loss of function of the tumor-suppressor patched homolog 1 (*PTCH1*), which normally inhibits the signaling of smoothened homolog (*SMO*). Two oral SMO inhibitors, vismodegib and sonidegib, have been approved by the FDA to treat advanced inoperable or metastatic BCC and locally advanced BCC that has recurred following surgery or radiotherapy, respectively. Vismodegib also reduces the incidence of BCC in patients with basal cell nevus syndrome who have *PTCH1* mutations, affirming the importance of Hh in the onset of BCC.

Immunosuppression has also been associated with the development of NMSCs; chronically immunosuppressed solid organ transplant recipients have a 65-fold increase in SCC and a 10-fold increase in BCC. The frequency of skin cancer is proportional to the level and duration of immunosuppression and the extent of sun exposure before and after transplantation. SCCs in this population are particularly aggressive, demonstrating higher rates of local recurrence, metastasis, and mortality. Tumor necrosis factor (TNF) antagonist therapy of inflammatory bowel disease and autoimmune disorders, such as rheumatoid and psoriatic arthritis, may also confer an increased risk of NMSC.

Other risk factors for NMSCs include HIV infection, ionizing radiation, thermal burn scars, *BRAF* inhibitor monotherapy, and chronic ulcerations. Albinism, xeroderma pigmentosum, Muir-Torre syndrome, Rombo's syndrome, Bazex-Dupré-Christol syndrome, dyskeratosis congenita, and basal cell nevus syndrome (Gorlin syndrome) also increase the incidence of NMSC.

Although MCC is also clearly related to UV exposure, age, and immunosuppression, this neural crest–derived cancer also appears to have a viral etiology; an oncogenic Merkel cell polyomavirus (MCPyV) is present in 80% of tumors. In patients with MCPyV-positive tumors, there is inactivation of tumor-suppressor genes, specifically the *p53* transcription factor and retinoblastoma protein (*Rb*). In addition, the viral large T antigen is expressed on tumor cells, and many patients have detectable cellular or humoral immune responses to polyoma viral proteins, although this immune response is insufficient to eradicate the malignancy.

CLINICAL PRESENTATION

Basal Cell Carcinoma BCC arises from epidermal basal cells. The least invasive of BCC subtypes, superficial BCC, consists of often subtle, erythematous scaling plaques that slowly enlarge and are most commonly seen on the trunk and proximal extremities **(Fig. 76-4)**. This subtype may be confused with benign inflammatory dermatoses, especially nummular eczema and psoriasis or premalignant actinic keratoses. BCC also can present as a small, slowly growing, pearly nodule, often with tortuous telangiectatic vessels on its surface, rolled borders, and a central crust (nodular BCC). The occasional presence of melanin in this variant of nodular BCC (pigmented BCC) may lead to confusion with melanoma. Morpheaform (fibrosing), infiltrative, and micronodular BCC, the most invasive and potentially aggressive subtypes, manifest as solitary, flat or slightly depressed, indurated whitish, yellowish, or pink scar-like plaques. Borders are typically indistinct, and lesions can be subtle; thus, delay in treatment is common, and tumors can be more extensive than expected clinically. An archaic name for this tumor is "rodent ulcer."

Squamous Cell Carcinoma Primary *cutaneous SCC* is a malignant neoplasm of keratinizing epidermal cells that has a variable clinical course, ranging from indolent to rapid growth, with the potential to metastasize to regional and distant sites. Commonly, SCC appears as an ulcerated erythematous nodule or superficial erosion on sun-exposed skin of the head, neck, trunk, and extremities **(Fig. 76-5)**. It may also appear as a banal, firm, dome-shaped papule or rough textured plaque. It is commonly mistaken for a wart or callous when the inflammatory response to the lesion is minimal. Dotted or coiled vessels are a hallmark of SCC when viewed through a dermatoscope. The margins of this tumor may be ill defined, and fixation to underlying structures may occur ("tethering").

A very rapidly growing low-grade form of SCC, called keratoacanthoma (KA), typically appears as a large dome-shaped papule with a central keratotic crater. Some KAs regress spontaneously without therapy, but because progression to metastatic SCC has been documented, KAs should be treated in the same manner as other types of cutaneous SCC. KAs occur in 15–25% of patients receiving monotherapy with a BRAF inhibitor.

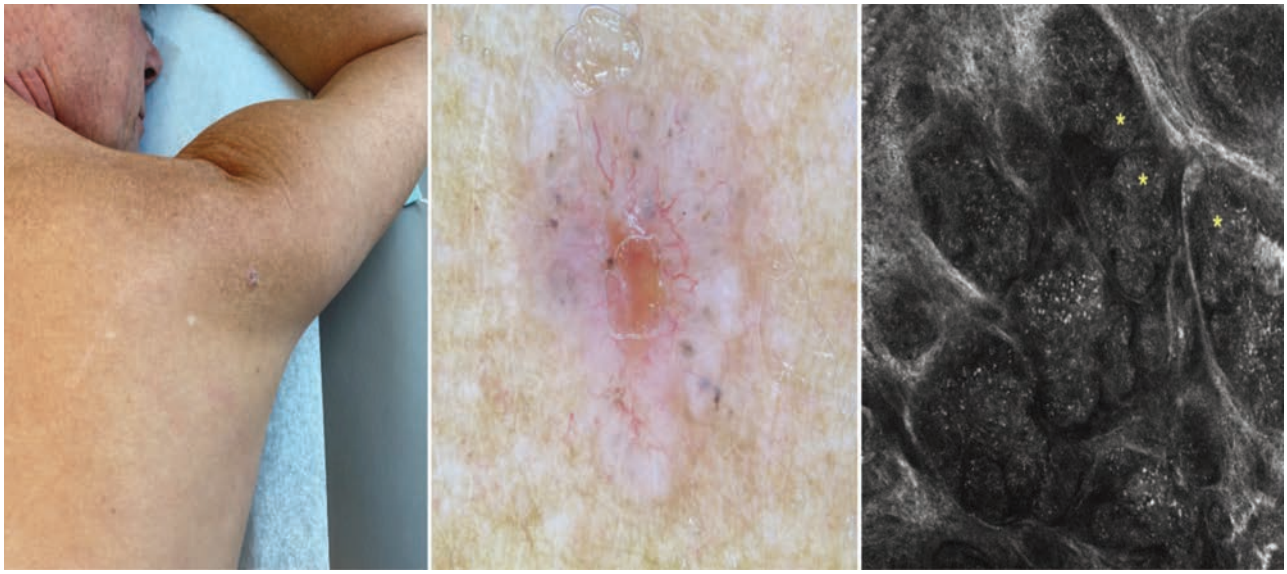

FIGURE 76-4 Clinical and confocal diagnostic findings of basal cell carcinoma. ***A.*** Typical basal cell carcinoma with skin-colored, slightly translucent rolled borders and a small central erosion on chronically sun-damaged skin of the lateral posterior shoulder. ***B.*** Dermoscopic image of the same lesion as in panel ***A*** clearly revealing the central erosion and classic gray, nonreticular globular structures of melanophages that characterize BCC. ***C.*** In vivo reflectance confocal microscopy of the same lesion as in panel ***A*** showing typical nests of dermal basaloid cells (*) with classic cleft formation around the nests.

Actinic keratoses and *cheilitis* (actinic keratoses on the lip), both premalignant forms of SCC, present as hyperkeratotic papules on sun-exposed areas. Malignant transformation occurs in 0.25–20% of untreated lesions. SCC in situ, also called *Bowen's disease*, is the intraepidermal form of SCC and usually presents as a scaling, erythematous plaque. SCC in situ most commonly arises on sun-damaged skin but can occur anywhere on the body. Bowen's disease occurring secondary to infection with human papillomavirus can arise on skin with minimal or no prior sun exposure, such as the buttock or posterior thigh. Treatment of premalignant and in situ lesions reduces the subsequent risk of invasive disease.

Merkel Cell Carcinoma MCC, also known as cutaneous apudoma, primary neuroendocrine carcinoma of the skin, primary small cell carcinoma of the skin, and trabecular carcinoma of the skin, arises from Merkel cells, which are neuroendocrine skin cells that act as

FIGURE 76-5 Progression of squamous cell carcinoma (SCC). ***A.*** Actinic keratoses (AKs). ***B.*** Actinic cheilitis (AK of the lip). ***C.*** Bowen's disease (SCC in situ). ***D.*** Keratoacanthoma (well-differentiated SCC). ***E.*** SCC. ***F.*** Metastatic SCC.

pressure receptors. Like other skin cancers, MCCs most commonly arise as visible skin lesions, usually as raised, flesh-colored nodules or masses; they can also be red or blue in color and vary in size from 0. 5 to >5 cm in diameter and may enlarge rapidly. Although MCCs may arise almost anywhere on the body, they are most commonly found in sun-exposed areas such as the head, neck, or extremities. They can also be found around the anus and on eyelids. The common clinical features of MCC can be summarized by the acronym AEIOU: *a*symptomatic/nontender, *e*xpand rapidly, *i*mmune suppression, *o*lder than 50 years, and *u*ltraviolet-exposed site.

NATURAL HISTORY

Basal Cell Carcinoma The natural history of BCC is that of a slowly enlarging, locally invasive neoplasm. The degree of local destruction and risk of recurrence vary with the size, duration, location, and histologic subtype of the tumor. Location on the central face, ears, or scalp may portend a higher risk. Small nodular, pigmented, cystic, or superficial BCCs respond well to most treatments. Large lesions and micronodular, infiltrative, and morpheaform subtypes may be more aggressive. The metastatic potential of BCC is low (0.1%) in immunocompetent patients, but the risk of recurrence or a new primary NMSC is about 40% over 5 years.

Squamous Cell Carcinoma The natural history of SCC depends on tumor and host characteristics. Tumors arising on sun-damaged skin have a lower metastatic potential than do those on non-sun-exposed areas. Cutaneous SCC metastasizes in 0.3–5.2% of individuals, most frequently to regional lymph nodes. Tumors occurring on the lower lip and ear develop regional metastases in 13 and 11% of patients, respectively, whereas the metastatic potential of SCC arising in scars, chronic ulcerations, and genital or mucosal surfaces is higher. Recurrent SCC has a 30% probability for metastatic spread. Large, poorly differentiated, deep tumors with perineural or lymphatic invasion, multifocal tumors, and those arising in immunosuppressed patients often behave aggressively.

Merkel Cell Carcinoma MCCs have clinical features of both skin cancers and neuroendocrine tumors (particularly small cell lung cancer [SCLC]); thus, they can present locally and develop spread to lymph nodes and distant sites. Molecular markers of neuroendocrine origin such as synaptophysin or chromogranin A are useful to diagnose MCC. Unlike other neuroendocrine tumors, MCCs are not associated with measurable hormone secretion or endocrine syndromes.

Survival with MCC depends on extent of disease: 90% of patients with local disease are cured, whereas 52% with nodal involvement and 10% with distant disease survive. MCC has its own tumor-node-metastasis (TNM) staging system, which incorporates tumor size (<2 cm vs. >2 cm), nodal status (which can be determined by SLNB for clinically negative nodes), and the presence of distant metastases.

Independent of stage, the prognosis of MCC is improved if the tumor cells contain virus, RB protein expression, and intratumoral CD8+ T lymphocyte infiltration, whereas p63 expression, lymphovascular infiltrative pattern, and the presence of immunosuppression (e.g., organ transplant, HIV infection, certain cancers) portend a worse prognosis.

TREATMENT

Basal Cell, Squamous Cell, and Merkle Cell Carcinoma

BASAL CELL CARCINOMA

Treatment for BCC includes electrodesiccation and curettage (ED&C), excision, cryosurgery, radiation therapy (RT), laser therapy, Mohs micrographic surgery (MMS), topical 5-fluorouracil, photodynamic therapy (PDT), and topical immunomodulators, such as imiquimod. The choice of therapy depends on tumor characteristics including depth and location, patient age, medical status, and patient preference. ED&C remains the most commonly employed treatment for superficial, minimally invasive nodular BCCs and low-risk tumors (e.g., a small tumor of a less aggressive subtype in a favorable location). Wide local excision with standard margins is usually selected for invasive, ill-defined, and more aggressive subtypes of tumors or for cosmetic reasons. MMS, a specialized type of surgical excision that provides the best method for tumor removal while preserving uninvolved tissue, is associated with cure rates >98%. It is the preferred modality for lesions that are recurrent, in high-risk or cosmetically sensitive locations (including recurrent tumors in these locations), and for which maximal tissue conservation is critical (e.g., the eyelids, lips, ears, nose, and digits). RT can cure patients not considered surgical candidates and can be used as a surgical adjunct in high-risk tumors. Imiquimod can be used to treat superficial and smaller nodular BCCs, although it is not FDA approved for nodular BCC. Topical 5-fluorouracil therapy should be limited to superficial BCC. PDT, which uses selective activation of a photoactive drug by visible light, has been used in patients with numerous tumors. Intralesional therapy (5-fluorouracil or IFN) can also be employed. Like RT, it remains an option for selected patients who cannot or will not undergo surgery. Systemic therapy with an SMO inhibitor, vismodegib or sonidegib, is indicated for patients with metastatic or advanced BCC that has recurred after local therapy and who are not candidates for surgery or RT. Targeted therapy with SMO antagonists does not cure patients with BCC but induces regression in approximately 50% of patients with a median duration of response >9 months.

SQUAMOUS CELL CARCINOMA

The principles for surgical management of SCC are the same as for BCC. Previously, advanced disease was treated with cisplatin-containing chemotherapy, intralesional 5-fluorouracil, or cetuximab. These regimens have been supplanted by cemiplimab, a monoclonal antibody targeting PD-1, which causes tumor regression in 47% of patients with advanced disease. SCC and KAs that develop in patients receiving BRAF-targeted therapy should be excised, after which BRAF therapy can be continued.

MERKEL CELL CARCINOMA

The epidemiology, clinical features, and treatments for MCC overlap those for melanoma and NMSC. Early-stage MCCs may be cured with wide local excision of the primary tumor and nodal staging with SLNB. Like SCLCs, MCC is sensitive to radiation, PD-1-directed immunotherapy, and platinum-based chemotherapy. RT is often used as postoperative adjuvant therapy at both the primary excision and SLNB sites, although its use may be withheld around sensitive areas such as the eyelids and hands and after a negative SLNB. For nonsensitive areas, RT may allow for primary excision margins smaller than the traditionally recommended 2-cm radial margins. Similar to melanoma, completion node dissection is now uncommonly used for a positive sentinel node. Adjuvant RT, close observation, and clinical trials investigating immunotherapy based on anti-PD-1 agents are favored.

For patients with metastatic disease, immunotherapy has supplanted chemotherapy. Avelumab (anti-PD-L1) therapy led to objective responses in 33% of patients with advanced MCC; 82% of the responses were durable.

Follow-up of patients with MCC is based on stage and risk. Routine skin exams by a dermatologist familiar with MCC and regular examinations of the nodal basins are recommended. A serum titer of monoclonal antibody to MCPyV should be obtained in newly diagnosed MCC patients. The test can be used to follow patients for relapse if the titer is elevated at baseline and returns to normal after treatment. Conversely, if the titer is elevated but does not return to normal after treatment, imaging should be obtained to look for occult metastases.

PREVENTION

The principles for prevention are those described for melanoma earlier. Unique strategies for NMSC include active surveillance for patients on immunosuppressive medications or BRAF-targeted therapy.

FIGURE 76-6 Other malignant cutaneous tumors. ***A.*** Patch stage mycosis fungoides (variant of cutaneous T-cell lymphoma). ***B.*** Tumor stage mycosis fungoides. ***C.*** Extramammary Paget's disease. ***D.*** Merkel cell carcinoma. ***E.*** Dermatofibrosarcoma protuberans. ***F.*** Kaposi's sarcoma. ***G.*** Kaposi's sarcoma.

Chemoprophylaxis using synthetic retinoids and immunosuppression reduction when possible may be useful in controlling new lesions and managing patients with multiple tumors. Field therapy with topical 5-fluorouracil, ingenol mebutate, or imiquimod can reduce transformation to SCC in patients with severely sun-damaged skin and numerous premalignant actinic keratoses. Older, immunosuppressed patients should be managed with the lowest doses of immunosuppression possible and encouraged to be particularly careful to minimize UV exposure. Earlier biopsy of unusual-appearing skin lesions may lead to better control of aggressive lesions.

OTHER NONMELANOMA CUTANEOUS MALIGNANCIES

Neoplasms of cutaneous adnexae and sarcomas of fibrous, mesenchymal, fatty, and vascular tissues make up the remaining 1–2% of NMSCs (Fig. 76-6). Lymphomas of B- or T-cell origin can also manifest in the skin and can mimic benign conditions such as psoriasis and eczema.

Extramammary Paget's disease is an uncommon apocrine malignancy arising from stem cells of the epidermis that is characterized histologically by the presence of Paget cells. These tumors present as moist erythematous patches on anogenital or axillary skin of the elderly.

Outcomes are generally good with surgery, and 5-year disease-specific survival is 95% with localized disease. Advanced age and extensive disease at presentation confer poorer prognosis. RT or topical imiquimod can be considered for more extensive disease. Local management may be challenging because these tumors often extend far beyond clinical margins; surgical excision with MMS has the highest cure rates. Similarly, MMS is the treatment of choice in other rare cutaneous tumors with extensive subclinical extension such as *dermatofibrosarcoma protuberans*.

Kaposi's sarcoma (KS) is a soft tissue sarcoma of vascular origin that is induced by the human herpesvirus 8. The incidence of KS increased dramatically during the AIDS epidemic, but has now decreased tenfold with the institution of highly active antiretroviral therapy.

77 Head and Neck Cancer

Everett E. Vokes

Epithelial carcinomas of the head and neck arise from the mucosal surfaces in the head and neck and typically are squamous cell in origin. This category includes tumors of the paranasal sinuses, the oral cavity, and the nasopharynx, oropharynx, hypopharynx, and larynx. Tumors of the salivary glands differ from the more common carcinomas of the head and neck in etiology, histopathology, clinical presentation, and therapy. They are rare and histologically highly heterogeneous. Thyroid malignancies are described in **Chap. 385**.

INCIDENCE AND EPIDEMIOLOGY

The number of new cases of head and neck cancers (oral cavity, pharynx, and larynx) in the United States was estimated at 65,630 in 2020, accounting for about 4% of adult malignancies; estimated deaths were 14,500. The worldwide incidence exceeds half a million cases annually. In North America and Europe, the tumors usually arise from the oral cavity, oropharynx, or larynx. The incidence of oropharyngeal cancers is increasing in recent years, especially in Western countries. Nasopharyngeal cancer is more commonly seen in the Mediterranean countries and in the Far East, where it is endemic in some areas.

ETIOLOGY AND GENETICS

Alcohol and tobacco use are the most significant environmental risk factors for head and neck cancer, and when used together, they act synergistically. Smokeless tobacco is an etiologic agent for oral cancers. Other potential carcinogens include marijuana and occupational exposures such as nickel refining, exposure to textile fibers, and woodworking.

Some head and neck cancers have a viral etiology. Epstein-Barr virus (EBV) infection is frequently associated with nasopharyngeal cancer, especially in endemic areas of the Mediterranean and Far East. EBV antibody titers can be measured to screen high-risk populations and are under investigation to monitor treatment response. Nasopharyngeal cancer has also been associated with consumption of salted fish and indoor pollution.

In Western countries, the human papillomavirus (HPV) is associated with a rising incidence of tumors arising from the oropharynx, that is, the tonsillar bed and base of tongue. Over 50% of oropharyngeal tumors are caused by HPV in the United States, and in many urban centers, this proportion is higher. HPV 16 is the dominant viral subtype, although HPV 18 and other oncogenic subtypes are seen as well. Alcohol- and tobacco-related cancers, on the other hand, have decreased in incidence. HPV-related oropharyngeal cancer frequently occurs in a younger patient population and is associated with increased numbers of sexual partners and oral sexual practices. It is associated with a better prognosis, especially for nonsmokers. Vaccination with the nine-valent HPV vaccine may prevent the disease in high-risk populations.

Dietary factors may contribute. The incidence of head and neck cancer is higher in people with the lowest consumption of fruits and vegetables. Certain vitamins, including carotenoids, may be protective if included in a balanced diet. Supplements of retinoids, such as *cis*-retinoic acid, have not been shown to prevent head and neck cancers (or lung cancer) and may increase the risk in active smokers. No specific risk factors or environmental carcinogens have been identified for salivary gland tumors.

HISTOPATHOLOGY, CARCINOGENESIS, AND MOLECULAR BIOLOGY

Squamous cell head and neck cancers are divided into well-differentiated, moderately well-differentiated, and poorly differentiated categories. Poorly differentiated tumors have a worse prognosis than well-differentiated tumors. For nasopharyngeal cancers, the less common differentiated squamous cell carcinoma is distinguished from nonkeratinizing and undifferentiated carcinoma (lymphoepithelioma) that contains infiltrating lymphocytes and is commonly associated with EBV.

Salivary gland tumors can arise from the major (parotid, submandibular, sublingual) or minor salivary glands (located in the submucosa of the upper aerodigestive tract). Most parotid tumors are benign, but half of submandibular and sublingual gland tumors and most minor salivary gland tumors are malignant. Malignant tumors include mucoepidermoid and adenoid cystic carcinomas and adenocarcinomas.

The mucosal surface of the entire pharynx is exposed to alcohol- and tobacco-related carcinogens and is at risk for the development of a premalignant or malignant lesion. Erythroplakia (a red patch) or leukoplakia (a white patch) can be histopathologically classified as hyperplasia, dysplasia, carcinoma in situ, or carcinoma. However, most head and neck cancer patients do not present with a known history of premalignant lesions. Multiple synchronous or metachronous cancers can also be observed. In fact, over time, patients with treated early-stage tobacco- and alcohol-related head and neck cancer are at greater risk of dying from a second malignancy than from a recurrence of the primary disease.

Second head and neck malignancies are usually not therapy induced; they reflect the exposure of the upper aerodigestive mucosa to the same carcinogens that caused the first cancer. These second primaries develop in the head and neck area, the lung, or the esophagus. Thus, computed tomography (CT) screening for lung cancer in heavy smokers who have already developed a head and neck cancer is recommended. Rarely, patients can develop a radiation therapy–induced sarcoma after having undergone prior radiotherapy for a head and neck cancer.

Much progress has been made in describing the molecular features of head and neck cancer. These features have allowed investigators to describe the genetic and epigenetic alterations and the mutational spectrum of these tumors. Early reports demonstrated frequent overexpression of the epidermal growth factor receptor (EGFR). Overexpression was shown to correlate with poor prognosis. However, it has not proved to be a good predictor of tumor response to EGFR inhibitors, which are active in only about 10–15% of patients as single agents. Complex genetic analyses, including those by The Cancer Genome Atlas project, have been performed. *p53* mutations are found frequently with other major affected oncogenic driver pathways including the mitotic signaling and Notch pathways and cell cycle regulation in HPV-negative tumors. HPV oncogenes act through direct inhibition of the *p53* and *RB* tumor-suppressor genes, thereby initiating the carcinogenic process. *HRAS* appears to be emerging as a potentially targetable mutation in a small patient subset. While overall mutation rates are similar in HPV-positive and carcinogen-induced tumors, the specific mutational signature of HPV-positive tumors differs, with frequent alteration of the PI3K pathway and occasional mutations in *KRAS*. Overall, these alterations affect mitogenic signaling, genetic stability, cellular proliferation, and differentiation.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Most tobacco-related head and neck cancers occur in patients older than age 60 years. HPV-related malignancies are frequently diagnosed in younger patients, usually in their forties or fifties, whereas EBV-related nasopharyngeal cancer can occur at all ages, including in teenagers. The manifestations vary according to the stage and primary site of the tumor. Patients with nonspecific signs and symptoms in the head and neck area should be evaluated with a thorough otolaryngologic examination, particularly if symptoms persist longer than 2–4 weeks. Males are more frequently affected than women by head and neck cancers, including HPV-positive tumors.

Cancer of the nasopharynx typically does not cause early symptoms. However, it may cause unilateral serous otitis media due to obstruction of the eustachian tube, unilateral or bilateral nasal obstruction, or epistaxis. Advanced nasopharyngeal carcinoma causes neuropathies of the cranial nerves due to skull base involvement.

Carcinomas of the oral cavity present as nonhealing ulcers, changes in the fit of dentures, or painful lesions and masses. Tumors of the tongue base or oropharynx can cause decreased tongue mobility and alterations in speech. Cancers of the oropharynx or hypopharynx rarely cause early symptoms, but they may cause sore throat and/or otalgia. HPV-related tumors frequently present with neck lymphadenopathy as the first sign.

Hoarseness may be an early symptom of laryngeal cancer, and persistent hoarseness requires referral to a specialist for indirect laryngoscopy and/or radiographic studies. If a head and neck lesion treated initially with antibiotics does not resolve in a short period, further workup is indicated; to simply continue the antibiotic treatment may be to lose the chance of early diagnosis of a malignancy.

Advanced head and neck cancers in any location can cause severe pain, otalgia, airway obstruction, cranial neuropathies, trismus, odynophagia, dysphagia, decreased tongue mobility, fistulas, skin involvement, and massive cervical lymphadenopathy, which may be unilateral or bilateral. Some patients have enlarged lymph nodes even though no primary lesion can be detected by endoscopy or biopsy; these patients are considered to have carcinoma of unknown primary (Fig. 77-1). Tonsillectomy and directed biopsies of the base of tongue can frequently identify a small primary tumor that frequently will be HPV related. If the enlarged nodes are located in the upper neck and the tumor cells are of squamous cell histology, the malignancy probably arose from a mucosal surface in the head or neck. Tumor cells in supraclavicular lymph nodes may also arise from a primary site in the chest or abdomen.

The physical examination should include inspection of all visible mucosal surfaces and palpation of the floor of the mouth and of the tongue and neck. In addition to tumors themselves, leukoplakia (a white mucosal patch) or erythroplakia (a red mucosal patch) may be observed; these "premalignant" lesions can represent hyperplasia, dysplasia, or carcinoma in situ and require biopsy. Further examination should be performed by a specialist. Additional staging procedures include CT or MRI of the head and neck to identify the extent of the disease. Patients with lymph node involvement should have CT scan of the chest and upper abdomen to screen for distant metastases. In heavy smokers, the CT scan of the chest can also serve as a screening tool to rule out a second lung primary tumor. A positron emission tomography (PET) scan can help to identify or exclude distant metastases. CT and PET scans may also be useful in evaluating response to therapy. The definitive staging procedure is an endoscopic examination under anesthesia, which may include laryngoscopy, esophagoscopy, and bronchoscopy; during this procedure, multiple biopsy samples are obtained to establish a primary diagnosis, define the extent of primary disease, and identify any additional premalignant lesions or second primaries.

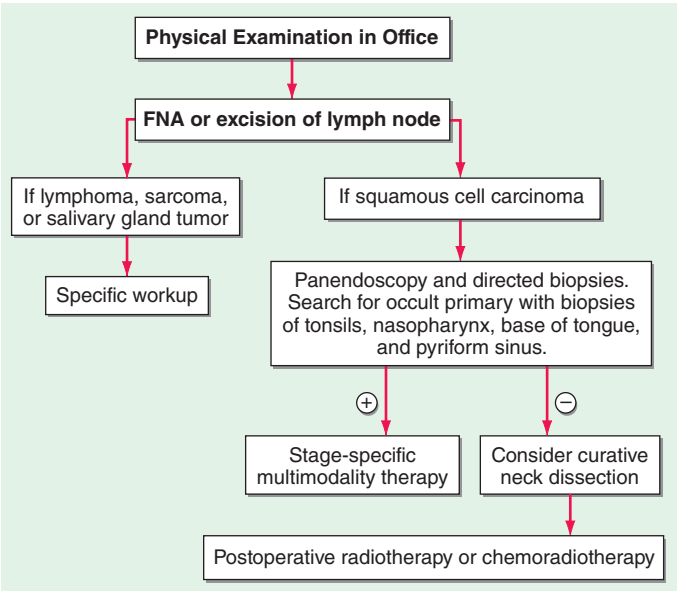

FIGURE 77-1 Evaluation of a patient with cervical adenopathy without a primary mucosal lesion; a diagnostic workup. FNA, fine-needle aspiration.

Head and neck tumors are classified according to the tumor-node-metastasis (TNM) system of the American Joint Committee on Cancer (AJCC) (Fig. 77-2). This classification varies according to the specific anatomic subsite. In general, primary tumors are classified as T1 to T3 by increasing size, whereas T4 usually represents invasion of another structure such as bone, muscle, or root of tongue. Lymph nodes are staged by size, number, and location (ipsilateral vs contralateral to the primary). Distant metastases are found in <10% of patients at initial diagnosis and are more common in patients with advanced lymph node stage; microscopic involvement of the lungs, bones, or liver is more common, particularly in patients with advanced neck lymph node disease. Modern imaging techniques may increase the number of patients with clinically detectable distant metastases in the future. HPV-related oropharyngeal malignancies have consistently been shown to have a better prognosis, and in the eighth edition of the AJCC staging manual, a separate staging system that takes into account the more favorable outlook of these patients will be included. According to this system, patients with advanced nodal stage can still be considered to have an overall early stage (and associated good prognosis), especially if the patient is a nonsmoker or has limited lifelong tobacco exposure.

In patients with lymph node involvement and no visible primary, the diagnosis should be made by lymph node excision (Fig. 77-1). If the results indicate squamous cell carcinoma, a panendoscopy should be performed, with biopsy of all suspicious-appearing areas and directed biopsies of common primary sites, such as the nasopharynx, tonsil, tongue base, and pyriform sinus. HPV-positive tumors especially can have small primary tumors that spread early to locoregional lymph nodes.

TREATMENT

Head and Neck Cancer

Patients with head and neck cancer can be grossly categorized into three clinical groups: those with localized disease, those with locally or regionally advanced disease (lymph node positive), and those with recurrent and/or metastatic disease below the neck. Comorbidities associated with tobacco and alcohol abuse can affect treatment outcome and define long-term risks for patients who are cured of their disease.

LOCALIZED DISEASE

Nearly one-third of patients have localized disease, that is, T1 or T2 (stage I or stage II) lesions without detectable lymph node involvement or distant metastases. These patients are treated with curative intent by either surgery or radiation therapy. The choice of modality differs according to anatomic location and institutional expertise. Radiation therapy is often preferred for laryngeal cancer to preserve voice function, and surgery is preferred for small lesions in the oral cavity to avoid the long-term complications of radiation, such as xerostomia and osteoradionecrosis and dental decay. Randomized data have shown that a prophylactic staging neck dissection should be part of the surgical procedure to eliminate occult nodal metastatic disease. Overall 5-year survival is 60–90%. Most recurrences occur within the first 2 years following diagnosis and are usually local.

LOCALLY OR REGIONALLY ADVANCED DISEASE

Locally or regionally advanced disease—disease with a large primary tumor and/or lymph node metastases—is the stage of presentation for >50% of patients. Such patients can also be treated with curative intent, but not usually with surgery or radiation therapy alone. Combined-modality therapy, including surgery and/or radiation therapy and chemotherapy, is most successful. Chemotherapy can be administered as induction chemotherapy (chemotherapy before surgery and/or radiotherapy) or as concomitant (simultaneous)

DOI = depth of invasion

Definition of TNM			Stage groupings		
Stage I	T1 Tumor ≤2 cm in greatest dimension ≤5 mm depth of invasion (DOI)	N0 N0- No regional lymph node metastasis	T1	N0	M0
Stage II	T2 Tumor ≥2 cm but not more than 4 cm in greatest dimension OR DOI >5 mm and ≤10 mm	N0 N0- No regional lymph node metastasis	T2	N0	M0
Stage III	T3 Tumor ≥4 cm OR DOI >10 mm	N1  ≤3 cm N1- Metastasis in a single ipsilateral lymph node, ≤3 cm in greateast dimension	T3 T1 T2 T3	N0 N1 N1 N1	M0 M0 M0 M0
Stage IVA	T4a Tumor invades skin, mandible, ear canal, fascial nerve, and/or floor of mouth	N2 ≤6 cm N2a- Metastasis in a single ipsilateral lymph node, >3 cm but ≤6 cm N2b- Metastasis in multiple ipsilateral lymph nodes, none >6 cm N2c- Metastasis in bilateral or contralateral lymph nodes, none >6 cm	T4a T4a T1 T2 T3 T4a	N0 N1 N2 N2 N2 N2	M0 M0 M0 M0 M0 M0
Stage IVB	T4b  Tumor invades skull base and/or pterygoid plates and/or encases carotid artery	N3 >6 cm N3- Metastasis in a lymph node >6 cm in greatest dimension or clinically overt extranodal extension	T4b Any T	Any N N3	M0 M0
Stage IVC	M1		Any T	Any N	M1

FIGURE 77-2 Tumor-node-metastasis (TNM) staging system. *(Figure based on the AJCC Cancer Staging Manual, 8th edition.)*

chemotherapy and radiation therapy. The latter is currently most commonly used and supported by the best evidence. Five-year survival rates exceed 50% in many trials, but part of this increased survival may be due to an increasing fraction of study populations with HPV-related tumors who carry a better prognosis. HPV testing of newly diagnosed tumors should be performed for patients with oropharyngeal tumors at the time of diagnosis. Clinical trials for HPV-related tumors are focused on exploring reductions in treatment intensity, especially radiation dose, in order to ameliorate long-term toxicities (fibrosis, swallowing dysfunction).

In patients with intermediate-stage tumors (stage III and early stage IV), concomitant chemoradiotherapy can be administered as a primary treatment for patients with unresectable disease, to pursue an organ-preserving approach especially for patients with laryngeal cancer (omission of surgery), or in the postoperative setting for smaller resectable tumors with adverse prognostic features.

Induction Chemotherapy In this strategy, patients receive chemotherapy (current standard is a three-drug regimen of docetaxel, cisplatin, and fluorouracil [5-FU]) before surgery and radiation therapy. Most patients who receive three cycles show tumor reduction, and the response is clinically "complete" in up to half of patients. This "sequential" multimodality therapy allows for organ preservation in patients with laryngeal and hypopharyngeal cancer and results in higher cure rates compared with radiotherapy alone.

Concomitant Chemoradiotherapy With the concomitant strategy, chemotherapy and radiation therapy are given simultaneously rather than in sequence. Tumor recurrences from head and neck cancer develop most commonly locoregionally (in the head and neck area of the primary and draining lymph nodes). The concomitant approach is aimed at enhancing tumor cell killing by radiation therapy in the presence of chemotherapy (radiation enhancement) and is a conceptually attractive approach for bulky tumors. Toxicity (especially mucositis, grade 3 or 4, in 70–80%) is increased with concomitant chemoradiotherapy. However, meta-analyses of randomized trials document an improvement in 5-year survival of 8% with concomitant chemotherapy and radiation therapy. Cisplatin is preferentially given weekly during a course of daily radiotherapy over a 6- to 7-week course. In addition, concomitant chemoradiotherapy produces better laryngectomy-free survival (organ preservation) than radiation therapy alone in patients with advanced larynx cancer. The use of radiation therapy together with cisplatin produces improved survival in patients with advanced nasopharyngeal cancer. The outcome of HPV-related cancers seems to be especially favorable following cisplatin-based chemoradiotherapy. Trials substituting cisplatin with the EGFR inhibitor cetuximab in that patient population have shown inferior survival.

The success of concomitant chemoradiotherapy in patients with unresectable disease has led to the testing of a similar approach in patients with resected intermediate-stage disease as a postoperative therapy. Concomitant chemoradiotherapy produces a significant improvement over postoperative radiation therapy alone for patients whose tumors demonstrate higher risk features, such as extracapsular spread beyond involved lymph nodes, involvement of multiple lymph nodes, or positive margins at the primary site following surgery.

A monoclonal antibody to EGFR (cetuximab) increases survival rates when administered during radiotherapy. EGFR blockade results in radiation sensitization and has milder systemic side effects than traditional chemotherapy agents, although an acneiform skin rash is commonly observed. Nevertheless, the addition of cetuximab to current standard chemoradiotherapy regimens has failed to show further improvement in survival and is not recommended.

TREATMENT APPROACHES FOR HPV-RELATED HEAD AND NECK CANCERS

Given consistent observations of high survival rates for patients with advanced HPV-related oropharyngeal tumors using combined-modality treatment strategies, de-escalation protocols have attracted widespread interest. The goal here is to decrease the long-term morbidity resulting from high-dose radiation therapy, including extensive neck fibrosis, swallowing problems, and osteoradionecrosis of the jaw. Current studies are investigating the use of lower radiation doses, the use of induction chemotherapy and subsequent omission of chemotherapy or administration of significantly reduced chemoradiation doses in very good responders, and other strategies. In addition, interest has increased in surgical approaches using robotic surgery, which allows better visualization of the base of tongue and tonsil. While technically feasible, this approach remains investigational because a large number of patients with disease involving multiple lymph nodes will still require postoperative chemoradiotherapy, thus negating the goal of treatment de-escalation. It is expected that distinct treatment guidelines from carcinogen-induced tumors will be defined in the coming years.

RECURRENT AND/OR METASTATIC DISEASE

Five to ten percent of patients present with metastatic disease, and 30–50% of patients with locoregionally advanced disease experience recurrence, frequently outside the head and neck region. Patients with recurrent and/or metastatic disease are, with few exceptions, treated with palliative intent. Some patients may require local or regional radiation therapy for pain control, but most are given systemic therapy.

Combination chemotherapy formerly was the first-line systemic therapeutic approach to patients with recurrent disease after prior curative intent surgery and/or chemoradiotherapy or those presenting initially with metastatic disease. In particular, a combination of cisplatin with 5-FU and cetuximab (the EXTREME regimen) was frequently used.

However, immunotherapies have proven to be of value in this setting. In particular, inhibitors of the immunosuppressive lymphocyte surface receptor (PD-1) pathway have shown activity in squamous cell cancers of the head and neck. A randomized trial evaluating the PD-1 inhibitor nivolumab versus traditional chemotherapy in the second-line treatment of patients with recurrent or metastatic disease showed a significant increase in 1-year survival rates with fewer severe treatment-related toxicities. In addition, some responses were of long duration, allowing a cohort of patients to live far beyond the historical median of <1 year. The PD-1 inhibitor pembrolizumab also demonstrated activity in a similarly designed randomized trial.

Following establishment of second-line activity, pembrolizumab was compared as single-agent therapy or in combination with cisplatin and 5-FU with prior standard chemotherapy alone (cisplatin, 5-FU, and cetuximab). In this trial, overall survival was improved with pembrolizumab versus chemotherapy as well as with the combination of chemotherapy plus pembrolizumab. No statistically significant impact on progression-free survival was noted. In addition, expression of PD-L1 in the tumor tissue was shown to be of importance. Patients with tumors high in expression (PD-L1 score >20%; i.e., expression of PD-L1 on 20% of tumor cells) had a marked survival benefit with pembrolizumab as single agent, whereas patients with lower PD-L1 expression had a less impressive but still statistically significant survival benefit. However, for the group expressing lower levels of PD-L1, the combination of pembrolizumab with chemotherapy showed more substantial benefit. Current standard treatment therefore frequently consists of combination chemoimmunotherapy for patients with a low combined positive score (CPS; the fraction of tumor cells expressing PD-L1), whereas those with higher CPS scores can be treated with immunotherapy alone, especially if overall tumor burden is limited. Patients who experience progression after first-line chemoimmunotherapy or immunotherapy can then be treated with additional single-agent or combination chemotherapy.

EGFR-directed therapies, including monoclonal antibodies (e.g., cetuximab) and tyrosine kinase inhibitors (TKIs) of the EGFR signaling pathway (e.g., erlotinib or gefitinib), have single-agent activity of ~10%. Side effects are usually limited to an acneiform rash and diarrhea (for the TKIs). The addition of cetuximab to standard combination chemotherapy with cisplatin or carboplatin and 5-FU results in a significant increase in median survival. Drugs targeting specific mutations are under investigation, and patients with *HRAS* mutations have tumor shrinkage with the farnesyltransferase inhibitor tipifarnib.

COMPLICATIONS

Complications from treatment of head and neck cancer are usually correlated to the extent of surgery and exposure of normal tissue structures to radiation. Currently, the extent of surgery has been limited or completely replaced by chemotherapy and radiation therapy as the primary approach. Acute complications of radiation include mucositis and dysphagia. Long-term complications include xerostomia, loss of taste, decreased tongue mobility, second malignancies, dysphagia, and neck fibrosis. The complications of

chemotherapy vary with the regimen used but usually include myelosuppression, mucositis, nausea and vomiting, and nephrotoxicity (with cisplatin).

The mucosal side effects of therapy can lead to malnutrition and dehydration. Many centers address issues of dentition before starting treatment, and some place feeding tubes to ensure control of hydration and nutrition intake. About 50% of patients develop hypothyroidism from the treatment; thus, thyroid function should be monitored.

SALIVARY GLAND TUMORS

Most benign salivary gland tumors are treated with surgical excision, and patients with invasive salivary gland tumors are treated with surgery and radiation therapy. These tumors may recur regionally; adenoid cystic carcinoma has a tendency to recur along the nerve tracks. Distant metastases may occur as late as 10–20 years after the initial diagnosis. For metastatic disease, therapy is given with palliative intent, usually chemotherapy with doxorubicin and/or cisplatin. Identification of novel agents with activity in these tumors is a high priority. It is hoped that comprehensive genomic characterization of these rare tumors will facilitate these efforts.

78 Neoplasms of the Lung

Leora Horn, Wade T. Iams

Lung cancer, which was rare before 1900 with fewer than 400 cases described in the medical literature, is considered a disease of modern man, killing over three times as many men as prostate cancer and nearly twice as many women as breast cancer. Although lung cancer remains the number one cause of cancer-related mortality, a decline in lung cancer deaths has emerged, attributed to improvements in testing and therapeutic strategies and a decline in tobacco usage. Tobacco consumption is the primary cause of lung cancer, a reality firmly established in the mid-twentieth century and codified with the release of the U.S. Surgeon General's 1964 report on the health effects of tobacco smoking. Following the report, cigarette use started to decline in North America and parts of Europe, and with it, so did the incidence of lung cancer. Although tobacco smoking remains the primary cause of lung cancer worldwide, approximately 60% of new lung cancers in the United States occur in former smokers (smoked ≥100 cigarettes per lifetime, quit ≥1 year), many of whom quit decades ago, or never smokers (smoked <100 cigarettes per lifetime). Moreover, one in five women and one in 12 men diagnosed with lung cancer have never smoked.

EPIDEMIOLOGY

Lung cancer is the most common cause of cancer death among American men and women. Approximately 228,000 individuals will be diagnosed with lung cancer in the United States in 2020, and >135, 000 individuals will die from the disease. Lung cancer is uncommon below age 40, with rates increasing until age 80, after which the rate tapers off. The projected lifetime probability of developing lung cancer is estimated to be ~8% among males and ~6% among females. The incidence of lung cancer varies by racial and ethnic group, with the highest age-adjusted incidence rates among African Americans. The excess in age-adjusted rates among African Americans occurs only among men, but examinations of age-specific rates show that below age 50, mortality from lung cancer is >25% higher among African American than Caucasian women. Incidence and mortality rates among Hispanics and Native and Asian Americans are ~40–50% those of whites.

RISK FACTORS

Cigarette smokers have a 10-fold or greater increased risk of developing lung cancer compared to those who have never smoked. A large-scale genomic study suggested that one genetic mutation is induced for every 15 cigarettes smoked. The risk of lung cancer is lower among persons who quit smoking than among those who continue smoking. The size of the lung cancer risk reduction increases with the length of time the person has quit smoking, although even long-term former smokers have higher risks of lung cancer than those who never smoked. Cigarette smoking has been shown to increase the risk of all major types of lung cancer. Environmental tobacco smoke (ETS) or second-hand smoke is also an established cause of lung cancer. The risk from ETS is less than from active smoking, with about a 20–30% increase in lung cancer observed among never smokers married for many years to smokers, in comparison to the 2000% increase among continuing active smokers. The impact on the development of lung cancer among users of alternate nicotine delivery devices (e-cigarettes or vaping) is undefined. While one large randomized study demonstrated the superiority of e-cigarettes compared to traditional nicotine replacement therapy in aiding smoking cessation, e-cigarette– or vaping-associated lung injury (EVALI) is an emerging phenomenon that poses risks that may counterbalance the potential benefit in helping patients reduce traditional cigarette consumption and lung cancer risk.

Although cigarette smoking is the cause of the majority of lung cancers, several other risk factors have been identified, including occupational exposure to asbestos, arsenic, bischloromethyl ether, hexavalent chromium, mustard gas, nickel (as in certain nickel-refining processes), and polycyclic aromatic hydrocarbons.

Ionizing radiation is also an established lung carcinogen, most convincingly demonstrated from studies showing increased rates of lung cancer among survivors of the atom bombs dropped on Hiroshima and Nagasaki and large excesses among workers exposed to alpha irradiation from radon in underground uranium mining. Prolonged exposure to low-level radon in homes might impart a risk of lung cancer equal to or greater than that of ETS. Prior lung diseases such as chronic bronchitis, emphysema, and tuberculosis have been linked to increased risks of lung cancer as well. The risk of lung cancer appears to be higher among individuals with low fruit and vegetable intake during adulthood. This observation led to hypotheses that specific nutrients, in particular retinoids and carotenoids, might have chemopreventative effects for lung cancer. However, randomized trials failed to validate this hypothesis.

Smoking Cessation Given the undeniable link between cigarette smoking and lung cancer, physicians must promote tobacco abstinence. Stopping tobacco use before middle age avoids >90% of the lung cancer risk attributable to tobacco. Importantly, smoking cessation can even be beneficial in individuals with an established diagnosis of lung cancer, as it is associated with improved survival, fewer side effects from therapy, and an overall improvement in quality of life. Consequently, it is important to promote smoking cessation even *after* the diagnosis of lung cancer is established.

Physicians need to understand the essential elements of smoking cessation therapy. The individual must want to stop smoking and must be willing to work hard to achieve the goal of smoking abstinence. Self-help strategies alone only marginally affect quit rates, whereas individual and combined pharmacotherapies in combination with counseling can significantly increase rates of cessation. Therapy with an antidepressant (e.g., bupropion) and nicotine replacement therapy (varenicline, a $\alpha_4\beta_2$ nicotinic acetylcholine receptor partial agonist) are approved by the U.S. Food and Drug Administration (FDA) as first-line treatments for nicotine dependence. In a randomized trial, varenicline was shown to be more efficacious than bupropion or placebo. Prolonged use of varenicline beyond the initial induction phase proved useful in maintaining smoking abstinence. Clonidine and nortriptyline are recommended as second-line treatments. A role for e-cigarettes has not been definitively established **(Chap. 454)**.

Inherited Predisposition to Lung Cancer Exposure to environmental carcinogens, such as those found in tobacco smoke, induce or facilitate the transformation from bronchoepithelial cells to a malignant phenotype. The contribution of carcinogens to transformation is modulated by polymorphic variations in genes that affect aspects of carcinogen metabolism. Certain genetic polymorphisms of the P450 enzyme system, specifically CYP1A1, and chromosome fragility are associated with the development of lung cancer. These genetic variations occur at relatively high frequency in the population, but their contribution to an individual's lung cancer risk is generally low. However, because of their population frequency, the overall impact on lung cancer risk could be high.

First-degree relatives of lung cancer probands have a two- to threefold excess risk of lung cancer and other cancers, many of which are not smoking-related. These data suggest that specific genes and/or genetic variants may contribute to susceptibility to lung cancer. However, very few such genes have yet been identified. Individuals with inherited mutations in *RB* (patients with retinoblastoma living to adulthood) and *p53* (Li-Fraumeni syndrome) genes may develop lung cancer. Common gene variants involved in lung cancer have identified three separate loci that are associated with lung cancer (5p15, 6p21, and 15q25) and include genes that regulate acetylcholine nicotinic receptors and telomerase production. A rare germline mutation (T790M) involving the epidermal growth factor receptor (EGFR) maybe be linked to lung cancer susceptibility in never smokers. Likewise, a susceptibility locus on chromosome 6q greatly increases lung cancer risk among light and never smokers. Although progress has been made, there is a significant amount of work that remains to be done in identifying heritable risk factors for lung cancer. Currently no molecular criteria are suitable to select patients for more intense screening programs or for specific chemopreventive strategies.

PATHOLOGY

The World Health Organization (WHO) defines lung cancer as tumors arising from the respiratory epithelium (bronchi, bronchioles, and alveoli). The WHO classification system divides epithelial lung cancers into four major cell types: small-cell lung cancer (SCLC), adenocarcinoma, squamous cell carcinoma, and large-cell carcinoma; the latter three types are collectively known as non-small-cell carcinomas (NSCLCs) **(Fig. 78-1)**. Small-cell carcinomas consist of small cells with scant cytoplasm, ill-defined cell borders, finely granular nuclear chromatin, absent or inconspicuous nucleoli, and a high mitotic count. SCLC may be distinguished from NSCLC by the presence of neuroendocrine markers including CD56, neural cell adhesion molecule (NCAM), synaptophysin, and chromogranin. Adenocarcinomas possess glandular differentiation or mucin production and may show acinar, papillary, lepidic, or solid features or a mixture of these patterns. Squamous cell carcinomas of the lung are morphologically identical to extrapulmonary squamous cell carcinomas and cannot be distinguished by immunohistochemistry alone. Squamous cell tumors show keratinization and/or intercellular bridges that arise from bronchial epithelium. The tumor consists of sheets of cells rather than the three-dimensional groups of cells characteristic of adenocarcinomas. Large-cell carcinomas compose <10% of lung carcinomas. These tumors lack the cytologic and architectural features of small-cell carcinoma and glandular or squamous differentiation. Together, these four histologic types account for ~90% of all epithelial lung cancers.

All histologic types of lung cancer can develop in current and former smokers, although squamous and small-cell carcinomas are most commonly associated with tobacco use. With the decline in cigarette consumption, adenocarcinoma has become the most frequent histologic subtype of lung cancer in the United States. In lifetime never smokers or former light smokers (<10 pack-year history), women, and younger adults (<60 years), adenocarcinoma tends to be the most common form of lung cancer.

In addition to distinguishing between SCLC and NSCLC, because these tumors have quite different natural histories and therapeutic approaches (see below), it is necessary to classify whether NSCLC is squamous or nonsquamous. The classification system, developed jointly by the International Association for the Study of Lung Cancer, the American Thoracic Society, and the European Respiratory Society, provides an integrated approach to the classification of lung adenocarcinoma that includes clinical, molecular, radiographic, and pathologic information.

It is recognized that most lung cancers present in an advanced stage and are often diagnosed based on small biopsies or cytologic specimens, rendering clear histologic distinctions difficult, if not impossible. In such cases, particularly in patients with advanced-stage disease, a repeat biopsy is recommended to obtain additional tissue for further clarification. The distinction between squamous and nonsquamous lung cancer is viewed as critical to optimal therapeutic decision making, and a diagnosis of *non-small-cell carcinoma, not otherwise specified* is no longer considered acceptable. This distinction can be achieved using a single marker for adenocarcinoma (thyroid transcription factor-1 or napsin-A) plus a squamous marker (p40 or p63) and/or mucin stains. If tissue is limited and a clear morphologic pattern is evident, a diagnosis can be made without immunohistochemistry staining. In addition to determining histologic subtype, preservation of sufficient specimen material for appropriate molecular testing and PD-L1 testing necessary to help guide therapeutic decision making is recommended (see below).

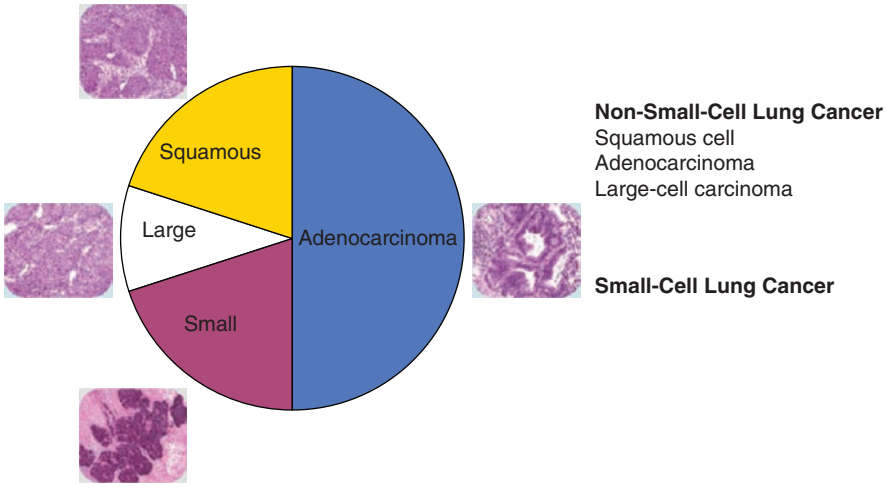

FIGURE 78-1 Histologic subsets of lung cancer.

The terms *adenocarcinoma in situ* and *minimally invasive adenocarcinoma* are now recommended for small solitary adenocarcinomas (≤3 cm) with either pure lepidic growth (term used to describe single-layered growth of atypical cuboidal cells coating the alveolar walls) or predominant lepidic growth with ≤5 mm invasion. Individuals with these entities experience 100% or near 100% 5-year disease-free survival with complete tumor resection. *Invasive adenocarcinomas*, representing more than 70–90% of surgically resected lung adenocarcinomas, are now classified by their predominant pattern: lepidic, acinar, papillary, and solid patterns. Lepidic-predominant subtype has a favorable prognosis, acinar and papillary have an intermediate prognosis, and solid-predominant has a poor prognosis. The terms *signet ring* and *clear cell adenocarcinoma* have been eliminated from the variants of invasive lung adenocarcinoma, whereas the term *micropapillary*, a subtype with a particularly poor prognosis, has been added. Because of prognostic implications, squamous cell carcinoma has also been modified to consist of keratinizing, nonkeratinizing, and basaloid, analogous to head and neck cancers.

IMMUNOHISTOCHEMISTRY

The diagnosis of lung cancer most often rests on the morphologic or cytologic features correlated with clinical and radiographic findings. Immunohistochemistry may be used to verify neuroendocrine differentiation within a tumor, with markers such as neuron-specific enolase (NSE), CD56 or NCAM, synaptophysin, chromogranin, and Leu7. Immunohistochemistry is also helpful in differentiating primary from metastatic adenocarcinomas; thyroid transcription factor-1 (TTF-1), identified in tumors of thyroid and pulmonary origin, is positive in >70% of pulmonary adenocarcinomas and is a reliable indicator of primary lung cancer, provided a thyroid primary has been excluded. A negative TTF-1, however, does not exclude the possibility of a lung primary. TTF-1 is also positive in neuroendocrine tumors of pulmonary and extrapulmonary origin. Napsin-A (Nap-A) is an aspartic protease that plays an important role in maturation of surfactant B7 and is expressed in cytoplasm of type II pneumocytes. In several studies, Nap-A has been reported in >90% of primary lung adenocarcinomas. Notably, a combination of Nap-A and TTF-1 is useful in distinguishing primary lung adenocarcinoma (Nap-A positive, TTF-1 positive) from primary lung squamous cell carcinoma (Nap-A negative, TTF-1 negative) and primary SCLC (Nap-A negative, TTF-1 positive). Cytokeratins 7 and 20 used in combination can help narrow the differential diagnosis; nonsquamous NSCLC, SCLC, and mesothelioma may stain positive for CK7 and negative for CK20, whereas squamous cell lung cancer often will be both CK7 and CK20 negative. p63 is a useful marker for the detection of NSCLCs with squamous differentiation when used in cytologic pulmonary samples. Mesothelioma can be easily identified ultrastructurally, but it has historically been difficult to differentiate from adenocarcinoma through morphology and immunohistochemical staining. Several markers in the past few years have proven to be more helpful including CK5/6, calretinin, and Wilms tumor gene-1 (*WT-1*), all of which show positivity in mesothelioma.

MOLECULAR PATHOGENESIS

As proposed by Hanahan and Weinberg, virtually all cancer cells acquire six hallmark capabilities: self-sufficiency in growth signals, insensitivity to antigrowth signals, evading apoptosis, limitless replicative potential, sustained angiogenesis, and tissue invasion and metastasis. The order in which these hallmark capabilities are acquired is variable. Events leading to acquisition of these hallmarks vary widely, although broadly, cancers arise as a result of accumulations of gain-of-function mutations in oncogenes and loss-of-function mutations in tumor-suppressor genes. Further complicating the study of lung cancer, the sequence of events that leads to disease is clearly different for the various histopathologic entities.

For cancers in general, one theory holds that a small subset of the cells within a tumor (i.e., "stem cells") are responsible for the full malignant behavior of the tumor. As part of this concept, the large bulk of the cells in a cancer are "offspring" of these cancer stem cells. While clonally related to the cancer stem cell subpopulation, most cells by themselves cannot regenerate the full malignant phenotype. The stem cell concept may explain the failure of standard medical therapies to eradicate lung cancers, even when there is a clinical complete response. Disease recurs because therapies do not eliminate the stem cell component, which may be more resistant to therapy. Precise human lung cancer stem cells have yet to be identified.

Among lung cancer histologies, adenocarcinomas have been the most extensively catalogued for recurrent genomic gains and losses as well as for somatic mutations **(Fig. 78-2, Table 78-1)**. While multiple different kinds of aberrations have been found, a major class involves "driver mutations," which are mutations that occur in genes encoding signaling proteins that, when aberrant, drive initiation and maintenance of tumor cells. Importantly, driver mutations can serve as a potential Achilles' heels for tumors, if their gene products can be targeted appropriately. These genes encode cell-surface receptors consisting of an extracellular ligand-binding domain, a transmembrane structure, and an intracellular tyrosine kinase (TK) domain. The binding of ligand to receptor activates receptor dimerization and TK autophosphorylation, initiating a cascade of intracellular events, and leading to increased cell proliferation, angiogenesis, metastasis, and a decrease in apoptosis. Lung adenocarcinomas can arise when normal alveolar type II cells develop mutations in *EGFR*, *BRAF*, *MET*, *KRAS*, and *PIK3CA*. These same tumors display high sensitivity to small-molecule TK inhibitors (TKIs). Additional subsets of lung adenocarcinoma have been identified as defined by the presence of specific chromosomal rearrangements, resulting in the aberrant activation of the TKs *ALK*, *ROS1*, *NTRK*, and *RET*. Notably, most driver mutations in lung cancer appear to be mutually exclusive, suggesting that acquisition of one of these mutations is sufficient to drive tumorigenesis. Although driver mutations have mostly been found in adenocarcinomas, three

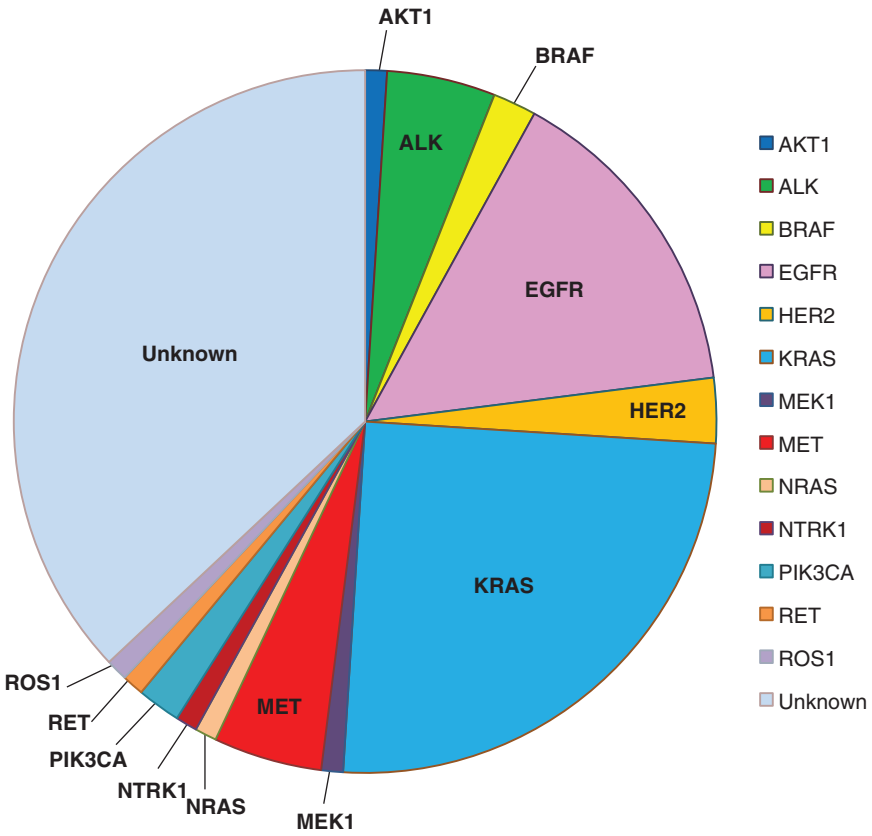

FIGURE 78-2 Driver mutations in lung adenocarcinomas.

TABLE 78-1 Driver Mutations in Non-Small-Cell Lung Cancer (NSCLC)

GENE	ALTERATION	FREQUENCY IN NSCLC	TYPICAL HISTOLOGY
AKT1	Mutation	1%	Adenocarcinoma, squamous
ALK	Rearrangement	3–7%	Adenocarcinoma
BRAF	Mutation	1–3%	Adenocarcinoma
DDR2	Mutation	~4%	Squamous
EGFR	Mutation	10–35%	Adenocarcinoma
FGFR1	Amplification	~20%	Squamous
HER2	Mutation	2–4%	Adenocarcinoma
KRAS	Mutation	15–25%	Adenocarcinoma
MEK1	Mutation	1%	Adenocarcinoma
MET	Amplification	2–4%	Adenocarcinoma
NRAS	Mutation	1%	Adenocarcinoma
NTRK	Rearrangement	1–2%	Adenocarcinoma
PIK3CA	Mutation	1–3%	Squamous
PTEN	Mutation	4–8%	Squamous
ROS1	Rearrangement	1–2%	Adenocarcinoma

potential molecular targets have been identified in squamous cell lung carcinomas: *FGFR1* amplification, *DDR2* mutations, and *PIK3CA* mutations/*PTEN* loss as well as *BRAF* and *MET* (Table 78-1).

A large number of tumor-suppressor genes have also been identified that are inactivated during the pathogenesis of lung cancer. These include *TP53*, *RB1*, *RASSF1A*, *CDKN2A/B*, *LKB1* (*STK11*), and *FHIT*. Nearly 90% of SCLCs harbor mutations in *TP53* and *RB1*. Several tumor-suppressor genes on chromosome 3p appear to be involved in nearly all lung cancers. Allelic loss of this region occurs very early in lung cancer pathogenesis, including in histologically normal smoking-damaged lung epithelium.

EARLY DETECTION AND SCREENING

In lung cancer, clinical outcome is related to the stage at diagnosis, and hence, it is generally assumed that early detection of occult tumors will lead to improved survival. Early detection is a process that involves screening tests, surveillance, diagnosis, and early treatment. Screening refers to the use of tests across a healthy population in order to identify individuals who harbor asymptomatic disease. For a screening program to be successful, the target population must have a high burden of disease; the test must be sensitive, specific, accessible, and cost effective; and effective treatment must be available that can reduce mortality. With any screening procedure, it is important to consider the possible influence of *lead-time bias* (detecting the cancer earlier without an effect on survival), *length-time bias* (indolent cancers are detected on screening and may not affect survival, whereas aggressive cancers are likely to cause symptoms earlier in patients and are less likely to be detected), and *overdiagnosis* (diagnosing cancers so slow growing that they are unlikely to cause the death of the patient).

Because a majority of lung cancer patients present with advanced disease beyond the scope of surgical resection, the value of screening for this condition is debated. Indeed, randomized controlled trials conducted in the 1960s to 1980s using screening chest x-rays (CXR), with or without sputum cytology, reported no impact on lung cancer–specific mortality in patients characterized as high risk (males age ≥45 years with a smoking history). These studies have been criticized for their design, statistical analyses, and outdated imaging modalities. In contrast to CXR, low-dose, noncontrast, thin-slice spiral chest computed tomography (LDCT) has emerged as an effective tool to screen for lung cancer. In nonrandomized studies conducted in the 1990s, LDCT scans were shown to detect more lung nodules and cancers than standard CXR in selected high-risk populations (e.g., age ≥60 years and a smoking history of ≥10 pack-years). Notably, up to 85% of the lung cancers discovered in these trials were classified as stage I disease and therefore considered potentially curable with surgical resection.

These data prompted the National Cancer Institute (NCI) to initiate the National Lung Screening Trial (NLST), a randomized study designed to determine if LDCT screening could reduce mortality from lung cancer in high-risk populations as compared with standard posterior anterior CXR. High-risk patients were defined as individuals between 55 and 74 years of age, with a ≥30 pack-year history of cigarette smoking; former smokers must have quit within the previous 15 years. Excluded from the trial were individuals with a previous lung cancer diagnosis, a history of hemoptysis, an unexplained weight loss of >15 lb in the preceding year, or a chest CT within 18 months of enrollment. A total of 53,454 persons were enrolled and randomized to annual screening yearly for 3 years (LDCT screening, n = 26,722; CXR screening, n = 26,732). Any noncalcified nodule measuring ≥4 mm in any diameter found on LDCT and CXR images with any noncalcified nodule or mass were classified as "positive." Participating radiologists had the option of not calling a final screen positive if a noncalcified nodule had been stable on the three screening examinations. Overall, 39.1% of participants in the LDCT group and 16% in the CXR group had at least one positive screening result. Of those who screened positive, the false-positive rate was 96.4% in the LDCT group and 94.5% in the CXR group. This was consistent across all three rounds. In the LDCT group, 1060 cancers were identified compared with 941 cancers in the CXR group (645 vs 572 per 100,000 person-years; relative risk [RR], 1.13; 95% confidence interval [CI], 1.03–1.23). Nearly twice as many stage IA cancers were detected in the LDCT group compared with the CXR group (40% vs 21%). The overall rates of lung cancer death were 247 and 309 deaths per 100,000 participants in the LDCT and CXR groups, respectively, representing a 20% reduction in lung cancer mortality in the LDCT-screened population (95% CI, 6.8–26.7%; $p = .004$). Compared with the CXR group, the rate of death in the LDCT group from *any* cause was reduced by 6.7% (95% CI, 1.2–13.6%; $p = .02$). The number needed to screen (NNTS) to prevent one lung cancer death was calculated to be 320.

The Nelson study was a second randomized trial comparing no screening to CT scans at baseline and in years 1, 3, and 5.5 in 13,195 men and 2594 women. Participants were 50–75 years of age and were current and former smokers with 10 years or less of cessation who smoked >15 cigarettes a day for >25 years or >10 cigarettes daily for >30 years. Participants were selected from four regions in the Netherlands or Belgium and were excluded if they were in moderate or bad self-reported health, were unable to climb two flights of stairs, had a body weight >140 kg, had a CT of the chest within the past year or a history of lung cancer <5 years ago or were still under treatment, or had current or past renal cell carcinoma, melanoma, or breast cancer. The hazard ratio for lung cancer mortality at 10 years was 0.74 (95% CI, 0.60–0.91; $p = .003$) and 0.61 (95% CI, 0.35–1.04; $p = .0543$) in men and women, respectively. These two trials have validated the use of annual CT scans for early detection of lung cancer in high-risk populations.

LDCT screening for lung cancer comes with known risks including a high rate of false-positive results, false-negative results, potential for unnecessary follow-up testing, radiation exposure, overdiagnosis, changes in anxiety level and quality of life, and substantial financial costs. By far, the biggest challenge confronting the use of CT screening is the high false-positive rate. False positives can have a substantial impact on patients through the expense and risk of unneeded further evaluation and emotional stress. The management of these patients usually consists of serial CT scans over time to see if the nodules grow, attempted fine-needle aspirates, or surgical resection. At $300 per scan (NCI estimated cost), the outlay for initial LDCT alone could run into the billions of dollars annually, an expense that only further escalates when factoring in various downstream expenditures an individual might incur in the assessment of positive findings. A formal cost-effectiveness analysis of the NLST demonstrated differences between sex, age, and current smoking status and the method of follow-up. Despite some questions, LDCT screening has been recommended for all patients meeting criteria for enrollment on NLST. When discussing the option of LDCT screening, use of absolute risks rather than relative risks is helpful because studies indicate the public can process absolute terminology more effectively than relative risk projections. A useful

TABLE 78-2 The Benefits and Harms of LDCT Screening for Lung Cancer Based on NLST Data

	LDCT	CXR
Benefits: How did CT scans help compared to CXR?		
4 in 1000 fewer died from lung cancer	13 in 1000	17 in 1000
5 in 1000 fewer died from all causes	70 in 1000	75 in 1000
Harms: What problems did CT scans cause compared to CXR?		
223 in 1000 had at least 1 false alarm	365 in 1000	142 in 1000
18 in 1000 had a false alarm leading to an invasive procedure	25 in 1000	7 in 1000
2 in 1000 had a major complication from an invasive procedure	3 in 1000	1 in 1000

Abbreviations: CXR, chest x-ray; LDCT, low-dose computed tomography; NLST, National Lung Screening Trial.

guide has been developed by the NCI to help patients and physicians assess the benefits and harms of LDCT screening for lung cancer (Table 78-2).

CLINICAL MANIFESTATIONS

Over half of all patients diagnosed with lung cancer present with locally advanced or metastatic disease at the time of diagnosis. The majority of patients present with signs, symptoms, or laboratory abnormalities that can be attributed to the primary lesion, local tumor growth, invasion or obstruction of adjacent structures, growth at distant metastatic sites, or a paraneoplastic syndrome (Tables 78-3 and 78-4). The prototypical lung cancer patient is a current or former smoker of either sex, usually in the seventh decade of life. A history of chronic cough with or without hemoptysis in a current or former smoker with chronic obstructive pulmonary disease (COPD) age 40 years or older should prompt a thorough investigation for lung cancer even in the face of a normal CXR. A persistent pneumonia without constitutional symptoms and unresponsive to repeated courses of antibiotics also should prompt an evaluation for the underlying cause. Lung cancer arising in a lifetime never smoker is more common in women and East Asians. Such patients also tend to be younger than their smoking counterparts at the time of diagnosis. The clinical presentation of lung cancer in never smokers tends to mirror that of current and former smokers.

Patients with central or endobronchial growth of the primary tumor may present with cough, hemoptysis, wheeze, stridor, dyspnea, or postobstructive pneumonia. Peripheral growth of the primary tumor may cause pain from pleural or chest wall involvement, dyspnea on a restrictive basis, and symptoms of a lung abscess resulting from tumor cavitation. Regional spread of tumor in the thorax (by contiguous growth or by metastasis to regional lymph nodes) may cause tracheal obstruction, esophageal compression with dysphagia, recurrent laryngeal nerve paralysis with hoarseness, phrenic nerve palsy with elevation of the hemidiaphragm and dyspnea, and sympathetic nerve paralysis with Horner's syndrome (enophthalmos, ptosis, miosis, and anhidrosis). Malignant pleural effusions can cause pain, dyspnea, or cough. Pancoast (or superior sulcus tumor) syndromes result from local extension of a tumor growing in the apex of the lung with involvement of the eighth cervical and first and second thoracic nerves, and present with shoulder pain that characteristically radiates in the ulnar distribution of the arm, often with radiologic destruction of the first and second ribs. Often Horner's syndrome and Pancoast syndrome coexist. Other problems of regional spread include superior vena cava syndrome from vascular obstruction; pericardial and cardiac extension with resultant tamponade, arrhythmia, or cardiac failure; lymphatic obstruction with resultant pleural effusion; and lymphangitic spread through the lungs with hypoxemia and dyspnea. In addition, lung cancer can spread transbronchially, producing tumor growth along multiple alveolar surfaces with impairment of gas exchange, respiratory insufficiency, dyspnea, hypoxemia, and sputum production. Constitutional symptoms may include anorexia, weight loss, weakness, fever, and night sweats. Apart from the brevity of symptom duration, these parameters fail to clearly distinguish SCLC from NSCLC or even from neoplasms metastatic to lungs.

TABLE 78-3 Presenting Signs and Symptoms of Lung Cancer

SYMPTOM AND SIGNS	RANGE OF FREQUENCY
Cough	8–75%
Weight loss	0–68%
Dyspnea	3–60%
Chest pain	20–49%
Hemoptysis	6–35%
Bone pain	6–25%
Clubbing	0–20%
Fever	0–20%
Weakness	0–10%
Superior vena cava obstruction	0–4%
Dysphagia	0–2%
Wheezing and stridor	0–2%

TABLE 78-4 Clinical Findings Suggestive of Metastatic Disease

Symptoms elicited in history	• Constitutional: weight loss >10 lb • Musculoskeletal: pain • Neurologic: headaches, syncope, seizures, extremity weakness, recent change in mental status
Signs found on physical examination	• Lymphadenopathy (>1 cm) • Hoarseness, superior vena cava syndrome • Bone tenderness • Hepatomegaly (>13 cm span) • Focal neurologic signs, papilledema • Soft-tissue mass
Routine laboratory tests	• Hematocrit, <40% in men; <35% in women • Elevated alkaline phosphatase, GGT, SGOT, and calcium levels

Abbreviations: GGT, gamma-glutamyltransferase; SGOT, serum glutamic-oxaloacetic transaminase.

Source: Reproduced with permission from GA Silvestri et al: The noninvasive staging of non-small cell lung cancer. Chest 123:147S, 2003.

Extrathoracic metastatic disease is found at autopsy in >50% of patients with squamous carcinoma, 80% of patients with adenocarcinoma and large-cell carcinoma, and >95% of patients with SCLC. Approximately one-third of patients present with symptoms as a result of distant metastases. Lung cancer metastases may occur in virtually every organ system, and the site of metastatic involvement largely determines other symptoms. Patients with brain metastases may present with headache, nausea and vomiting, seizures, or neurologic deficits. Patients with bone metastases may present with pain, pathologic fractures, or spinal cord compression. The latter may also occur with epidural metastases. Individuals with bone marrow invasion may present with cytopenias or leukoerythroblastosis. Those with liver metastases may present with hepatomegaly, right upper quadrant pain, fever, anorexia, and weight loss. Liver dysfunction and biliary obstruction are rare. Adrenal metastases are common but rarely cause pain or adrenal insufficiency unless they are large.

Paraneoplastic syndromes are common in patients with lung cancer, especially those with SCLC, and may be the presenting finding or the first sign of recurrence. In addition, paraneoplastic syndromes may mimic metastatic disease and, unless detected, lead to inappropriate

palliative rather than curative treatment. Often the paraneoplastic syndrome may be relieved with successful treatment of the tumor. In some cases, the pathophysiology of the paraneoplastic syndrome is known, particularly when a hormone with biologic activity is secreted by a tumor. However, in many cases, the pathophysiology is unknown. Systemic symptoms of anorexia, cachexia, weight loss (seen in 30% of patients), fever, and suppressed immunity are paraneoplastic syndromes of unknown etiology or at least not well defined. Weight loss >10% of total body weight is considered a bad prognostic sign. Endocrine syndromes are seen in 12% of patients; hypercalcemia resulting from ectopic production of parathyroid hormone (PTH) or, more commonly, PTH-related peptide is the most common life-threatening metabolic complication of malignancy, primarily occurring with squamous cell carcinomas of the lung. Clinical symptoms include nausea, vomiting, abdominal pain, constipation, polyuria, thirst, and altered mental status.

Hyponatremia may be caused by the syndrome of inappropriate secretion of antidiuretic hormone (SIADH) or possibly atrial natriuretic peptide (ANP) **(Chap. 93)**. SIADH resolves within 1–4 weeks of initiating chemotherapy in the vast majority of cases. During this period, serum sodium can usually be managed and maintained above 128 mEq/L via fluid restriction. Demeclocycline can be a useful adjunctive measure when fluid restriction alone is insufficient. Vasopressin receptor antagonists like tolvaptan also have been used in the management of SIADH. However, the use of tolvaptan has significant limitations including liver injury and overly rapid correction of the hyponatremia, which can lead to irreversible neurologic injury. Likewise, the cost of tolvaptan may be prohibitive (as high as $300 per tablet in some areas). Of note, patients with ectopic ANP may have worsening hyponatremia if sodium intake is not concomitantly increased. Accordingly, if hyponatremia fails to improve or worsens after 3–4 days of adequate fluid restriction, plasma levels of ANP should be measured to determine the causative syndrome.

Ectopic secretion of ACTH by SCLC and pulmonary carcinoids usually results in additional electrolyte disturbances, especially hypokalemia, rather than the changes in body habitus that occur in Cushing's syndrome from a pituitary adenoma **(Chap. 93)**. Treatment with standard medications, such as metyrapone and ketoconazole, is largely ineffective due to extremely high cortisol levels. The most effective strategy for management of the Cushing's syndrome is effective treatment of the underlying SCLC. Bilateral adrenalectomy may be considered in extreme cases.

Skeletal–connective tissue syndromes include clubbing in 30% of cases (usually NSCLCs) and hypertrophic primary osteoarthropathy in 1–10% of cases (usually adenocarcinomas). Patients may develop periostitis, causing pain, tenderness, and swelling over the affected bones and a positive bone scan. Neurologic–myopathic syndromes are seen in only 1% of patients but are dramatic and include the myasthenic Eaton-Lambert syndrome and retinal blindness with SCLC, whereas peripheral neuropathies, subacute cerebellar degeneration, cortical degeneration, and polymyositis are seen with all lung cancer types. Many of these are caused by autoimmune responses such as the development of anti-voltage-gated calcium channel antibodies in Eaton-Lambert syndrome. Patients with this disorder present with proximal muscle weakness, usually in the lower extremities, occasional autonomic dysfunction, and rarely, cranial nerve symptoms or involvement of the bulbar or respiratory muscles. Depressed deep tendon reflexes are frequently present. In contrast to patients with myasthenia gravis, strength improves with serial effort. Some patients who respond to chemotherapy will have resolution of the neurologic abnormalities. Thus, chemotherapy is the initial treatment of choice. Paraneoplastic encephalomyelitis and sensory neuropathies, cerebellar degeneration, limbic encephalitis, and brainstem encephalitis occur in SCLC in association with a variety of antineuronal antibodies such as anti-Hu, anti-CRMP5, and ANNA-3. Paraneoplastic cerebellar degeneration may be associated with anti-Hu, anti-Yo, or P/Q calcium channel autoantibodies. Coagulation or thrombotic or other hematologic manifestations occur in 1–8% of patients and include migratory venous thrombophlebitis (Trousseau's syndrome), nonbacterial thrombotic (marantic) endocarditis with arterial emboli, and disseminated intravascular coagulation with hemorrhage, anemia, granulocytosis, and leukoerythroblastosis. Thrombotic disease complicating cancer is usually a poor prognostic sign. Cutaneous manifestations such as dermatomyositis and acanthosis nigricans are uncommon (1%), as are the renal manifestations of nephrotic syndrome and glomerulonephritis (≤1%).

DIAGNOSING LUNG CANCER

Tissue sampling is required to confirm a diagnosis in all patients with suspected lung cancer. In patients with suspected metastatic disease, a biopsy of a distant site of disease is preferred for tissue confirmation. Given the greater emphasis placed on molecular and PD-L1 testing for NSCLC patients, a core biopsy is preferred to ensure adequate tissue for analysis. Tumor tissue may be obtained via minimally invasive techniques such as bronchial or transbronchial biopsy during fiberoptic bronchoscopy, by fine-needle aspiration (FNA) or percutaneous biopsy using image guidance, or via endobronchial ultrasound (EBUS)-guided biopsy. Depending on the location, lymph node sampling may occur via transesophageal endoscopic ultrasound (EUS)-guided biopsy, EBUS-guided biopsy, or blind biopsy. In patients with suspected metastatic disease, a diagnosis may be confirmed by bronchoscopy, percutaneous biopsy of a soft tissue mass, lytic bone lesion, bone marrow, pleural or liver lesion, or an adequate cell block obtained from a malignant pleural effusion. In patients with a suspected malignant pleural effusion, if the initial thoracentesis is negative, a repeat thoracentesis is warranted. Although the majority of pleural effusions are due to malignant disease, particularly if they are exudative or bloody, some may be parapneumonic. In the absence of distant disease, such patients should be considered for possible curative treatment.

The diagnostic yield of any biopsy depends on several factors including location (accessibility) of the tumor, tumor size, tumor type, and technical aspects of the diagnostic procedure including the experience level of the bronchoscopist and pathologist. In general, central lesions such as squamous cell carcinomas, small-cell carcinomas, or endobronchial lesions such as carcinoid tumors are more readily diagnosed by bronchoscopic examination, whereas peripheral lesions such as adenocarcinomas and large-cell carcinomas are more amenable to transthoracic biopsy.

Sputum cytology is inexpensive and noninvasive but has a lower yield than other specimen types due to poor preservation of the cells and more variability in acquiring a good-quality specimen. The yield for sputum cytology is highest for larger and centrally located tumors such as squamous cell carcinoma and small-cell carcinoma histology. The specificity for sputum cytology averages close to 100%, although sensitivity is generally <70%. The accuracy of sputum cytology improves with increased numbers of specimens analyzed. Consequently, analysis of at least three sputum specimens is recommended. However, the quality of the specimen may not be adequate for histologic subclassification and PD-L1 and molecular testing.

STAGING LUNG CANCER

Lung cancer staging consists of two parts: first, a determination of the location of the tumor and possible metastatic sites (anatomic staging), and second, an assessment of a patient's ability to withstand various antitumor treatments (physiologic staging). All patients with lung cancer should have a complete history and physical examination, with evaluation of all other medical problems, determination of performance status, and history of weight loss. Staging with regard to a patient's potential for surgical resection is principally applicable to NSCLC.

ANATOMIC STAGING OF PATIENTS WITH LUNG CANCER

The accurate staging of patients with NSCLC is essential for determining the appropriate treatment in patients with resectable disease and for avoiding unnecessary surgical procedures in patients with advanced disease. All patients with NSCLC should undergo initial radiographic imaging with CT scan, positron emission tomography (PET), or preferably CT-PET. PET scanning attempts to identify sites of malignancy based on glucose metabolism by measuring the uptake

of ^{18}F-fluorodeoxyglucose (FDG). Rapidly dividing cells, presumably in the lung tumors, will preferentially take up ^{18}F-FDG and appear as a "hot spot." To date, PET has been mostly used for staging and detection of metastases in lung cancer and in the detection of nodules >15 mm in diameter. Combined ^{18}F-FDG PET-CT imaging has been shown to improve the accuracy of staging in NSCLC compared to visual correlation of PET and CT or either study alone. CT-PET has been found to be superior in identifying pathologically enlarged mediastinal lymph nodes and extrathoracic metastases. A standardized uptake value (SUV) of >2.5 on PET is highly suspicious for malignancy. False negatives can be seen in diabetes, in lesions <8 mm, and in slow-growing tumors (e.g., carcinoid tumors or well-differentiated adenocarcinoma). False positives can be seen in certain infections and granulomatous disease (e.g., tuberculosis). Thus, PET should never be used alone to diagnose lung cancer, mediastinal involvement, or metastases. Confirmation with tissue biopsy is required. For brain metastases, magnetic resonance imaging (MRI) is the most effective method. MRI can also be useful in selected circumstances, such as superior sulcus tumors to rule out brachial plexus involvement, but in general, MRI does not play a major role in NSCLC staging.

In patients with NSCLC, the following are contraindications to potential curative resection: extrathoracic metastases, superior vena cava syndrome, vocal cord and, in most cases, phrenic nerve paralysis, malignant pleural effusion, cardiac tamponade, tumor within 2 cm of the carina (potentially curable with combined chemoradiotherapy), metastasis to the contralateral lung, metastases to supraclavicular lymph nodes, contralateral mediastinal node metastases (potentially curable with combined chemoradiotherapy), and involvement of the main pulmonary artery. In situations where it will make a difference in treatment, abnormal scan findings require tissue confirmation of malignancy so that patients are not precluded from having potentially curative therapy.

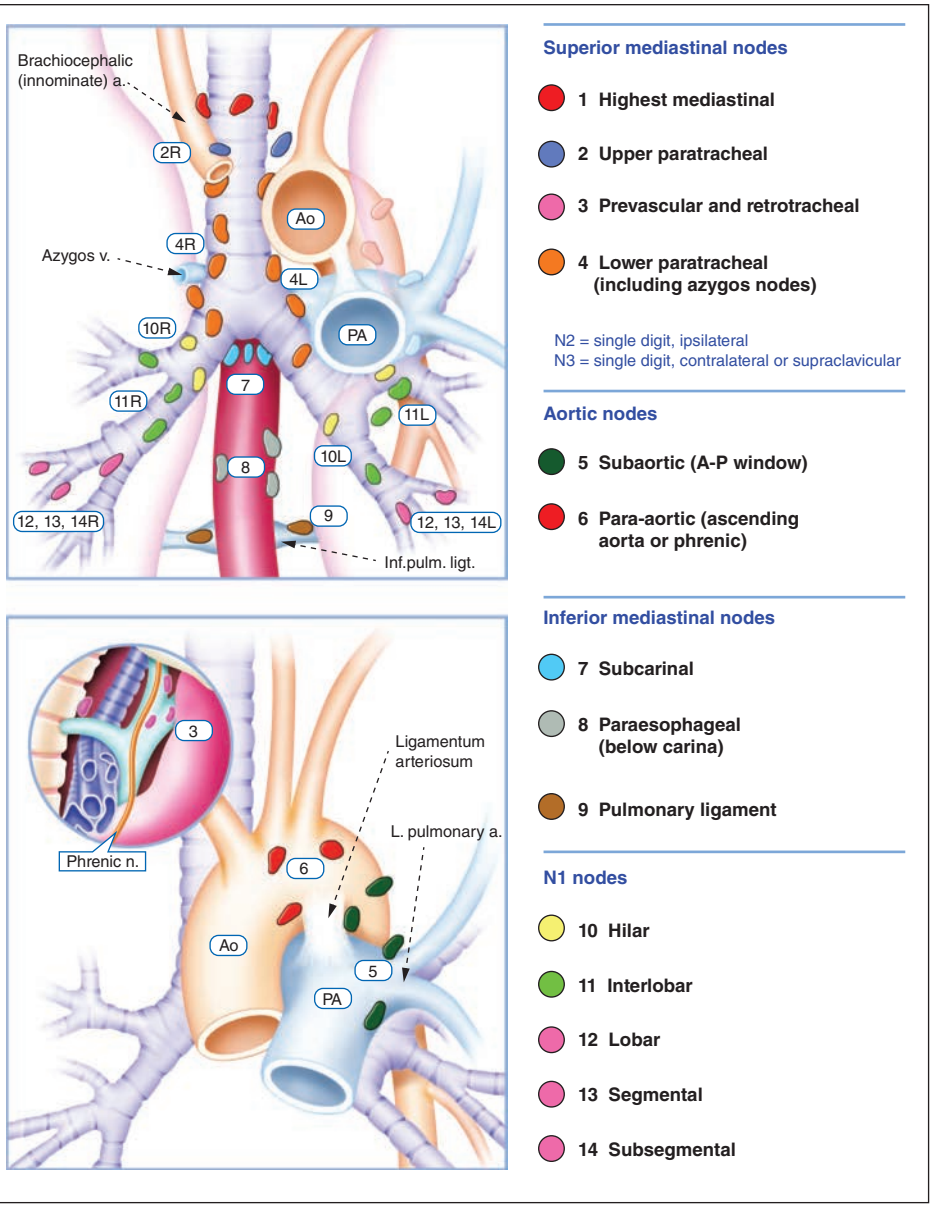

FIGURE 78-3 Lymph node stations in staging non-small-cell lung cancer. The International Association for the Study of Lung Cancer (IASLC) lymph node map, including the proposed grouping of lymph node stations into "zones" for the purposes of prognostic analyses. a., artery; Ao, aorta; Inf. pulm. ligt., inferior pulmonary ligament; n., nerve; PA, pulmonary artery; v., vein.

The best predictor of metastatic disease remains a careful history and physical examination. If signs, symptoms, or findings from the physical examination suggest the presence of malignancy, then sequential imaging starting with the most appropriate study should be performed. If the findings from the clinical evaluation are negative, then imaging studies beyond CT-PET are unnecessary and the search for metastatic disease is complete. In patients in whom distant metastatic disease has been ruled out, lymph node status needs to be assessed via minimally invasive techniques such as those mentioned above and/or invasive techniques such as mediastinoscopy, mediastinotomy, thoracoscopy, or thoracotomy. Approximately one-quarter to one-half of patients diagnosed with NSCLC will have mediastinal lymph node metastases at the time of diagnosis. Lymph node sampling is recommended in all patients with enlarged nodes detected by CT or PET scan and in patients with large tumors or tumors occupying the inner third of the lung. The extent of mediastinal lymph node involvement is important in determining the appropriate treatment strategy: surgical resection followed by adjuvant chemotherapy versus combined chemoradiation followed by immunotherapy (durvalumab) (see below). A standard nomenclature for referring to the location of lymph nodes involved with lung cancer has evolved **(Fig. 78-3)**.

In SCLC patients, current staging recommendations include a PET-CT scan and MRI of the brain (positive in 10% of asymptomatic patients). Bone marrow biopsies and aspirations are rarely performed now given the low incidence of isolated bone marrow metastases. Confirmation of metastatic disease, ipsilateral or contralateral lung nodules, or metastases beyond the mediastinum may be achieved by the same modalities recommended earlier for patients with NSCLC.

If a patient has signs or symptoms of spinal cord compression (pain, weakness, paralysis, urinary retention), a spinal CT or MRI scan should be performed. If metastases are evident on imaging, a neurosurgeon should be consulted for possible palliative surgical resection and/or a radiation oncologist should be consulted for palliative radiotherapy to the site of compression. If signs or symptoms of leptomeningeal disease develop at any time in a patient with lung cancer, an MRI of the brain and spinal cord should be performed, as well as a spinal tap, for

detection of malignant cells. If the spinal tap is negative, a repeat spinal tap should be considered. There is currently no approved therapy for the treatment of leptomeningeal disease.

STAGING SYSTEM FOR NON-SMALL-CELL LUNG CANCER

The tumor-node-metastasis (TNM) international staging system provides useful prognostic information and is used to stage all patients with NSCLC. The various T (tumor size), N (regional node involvement), and M (presence or absence of distant metastasis) stages are combined to form different stage groups (Tables 74-5 and 74-6). The eighth edition of the TNM staging system went into effect in 2018. T1 tumors are divided into tumors ≤1 cm (T1a), >1 cm and ≤2 cm (T1b), and >2 cm and ≤3 cm (T1c). T2 tumors are those that are >3 cm but ≤5 cm, involve the visceral pleura or main bronchus, or are associated with atelectasis; T2a tumors are >3 cm and ≤4 cm, and T2b are >4 cm and ≤5 cm. T3 tumors are >5 cm and ≤7 cm. T3 tumors also include tumors with invasion into local structures such as the chest wall and diaphragm and with additional nodules in the same lobe. T4 tumors include tumors >7 cm or tumors of any size with invasion into mediastinum, heart, great vessels, trachea, esophagus, or spine or with multiple nodules in the ipsilateral lung. Lymph node staging depends on metastasis to ipsilateral pulmonary or hilar nodes (N1), mediastinal or subcarinal nodes (N2), or contralateral mediastinal, hilar, or supraclavicular nodes (N3). Patients with metastasis may be classified as M1a (malignant pleural or pericardial effusion, pleural nodules, or nodules in the contralateral lung), M1b (single distant metastasis to a single organ; e.g., bone, liver, adrenal, or brain metastasis), or M1c (multiple metastases to a single organ or metastases to multiple organs). The effect of stage on survival is illustrated in Fig. 78-4. Approximately 15% of patients have localized disease that can be treated with curative attempt (surgery or radiotherapy), about a quarter have local or regional disease that may or may not be amenable to a curative attempt, and half have metastatic disease at the time of diagnosis. In 10%, the extent of disease is undefined.

TABLE 78-5 TNM Staging System for Lung Cancer (Eighth Edition)

Primary Tumor (T)	
T1	Tumor ≤3 cm diameter, surrounded by lung or visceral pleura, without invasion more proximal than lobar bronchus
T1mi	Minimally invasive adenocarcinoma (pure lepidic pattern, <3 cm in greatest dimension and <5 mm invasion)—T1a (size <1 cm)—T1b (1 cm < size <2 cm)—T1c (2 cm < size <3 cm)
T2	Tumor >3 cm but ≤7 cm, or tumor with any of the following features: Involves main bronchus ≥2 cm distal to carina Invades visceral pleura Associated with atelectasis or obstructive pneumonitis that extends to the hilar region but does not involve the entire lung
T2a	Tumor >3 cm but ≤5 cm
T2b	Tumor >5 cm but ≤7 cm
T3	Tumor >7 cm or any of the following: Directly invades any of the following: chest wall, diaphragm, phrenic nerve, mediastinal pleura, parietal pericardium, main bronchus <2 cm from carina (without involvement of carina) Atelectasis or obstructive pneumonitis of the entire lung Separate tumor nodules in the same lobe
T4	Tumor of any size that invades the mediastinum, heart, great vessels, trachea, recurrent laryngeal nerve, esophagus, vertebral body, or carina, or with separate tumor nodules in a different ipsilateral lobe
Nodal Stage (N)	
N0	No regional lymph node metastases
N1	Metastasis in ipsilateral peribronchial and/or ipsilateral hilar lymph nodes and intrapulmonary nodes, including involvement by direct extension
N2	Metastasis in ipsilateral mediastinal and/or subcarinal lymph node(s)
N3	Metastasis in contralateral mediastinal, contralateral hilar, ipsilateral or contralateral scalene, or supraclavicular lymph node(s)
Metastases (M)	
M0	No distant metastasis
M1	Distant metastasis
M1a	Separate tumor nodule(s) in a contralateral lobe; tumor with pleural nodules or malignant pleural or pericardial effusion
M1b	Distant metastasis (in extrathoracic organs)
M1c	

Abbreviation: M1b, distant metastasis in single organ outside chest; M1c, multiple extrathoracic metastases to one or more organs; TNM, tumor-node-metastasis.

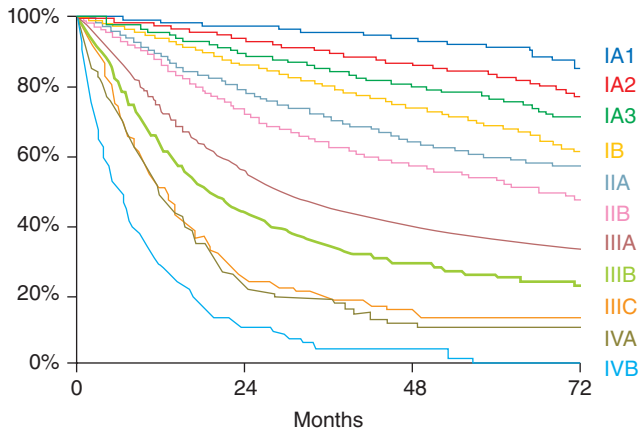
STAGING SYSTEM FOR SMALL-CELL LUNG CANCER

In patients with SCLC, it is now recommended that both the Veterans Administration system and the American Joint Committee on Cancer/International Union Against Cancer eighth edition system (TNM) be used to classify the tumor stage. The Veterans Administration system is a distinct two-stage system dividing patients into those with limited- or extensive-stage disease. Patients with limited-stage disease (LD) have cancer that is confined to the ipsilateral hemithorax and can be encompassed within a tolerable radiation port. Thus, contralateral supraclavicular nodes, recurrent laryngeal nerve involvement, and superior vena caval obstruction can all be part of LD. Patients with extensive-stage disease (ED) have overt metastatic disease by imaging or physical examination. Cardiac tamponade, malignant pleural effusion, and bilateral pulmonary parenchymal involvement generally qualify disease as ED, because the involved organs cannot be encompassed safely or effectively within a single radiation therapy port. Sixty to 70% of patients are diagnosed with ED at presentation. The TNM staging system is preferred in the rare SCLC patient presenting with what appears to be clinical stage I disease (see above).

PHYSIOLOGIC STAGING

Patients with lung cancer often have other comorbid conditions related to smoking including cardiovascular disease and COPD. To improve their preoperative condition, correctable problems (e.g., anemia, electrolyte and fluid disorders, infections, cardiac disease, and arrhythmias) should be addressed, appropriate chest physical therapy should be instituted, and patients should be encouraged to stop smoking. Patients with a forced expiratory volume in 1 s (FEV_1) of >2 L or >80% of predicted can tolerate a pneumonectomy, and those with an FEV_1 >1.5 L have adequate reserve for a lobectomy. In patients with borderline lung function but a resectable tumor, cardiopulmonary exercise testing could be performed as part of the physiologic evaluation. This test allows an estimate of the maximal oxygen consumption (Vo_{2max}). A Vo_{2max}



Stage	24 months	60 months
IA1	97%	92%
IA2	94%	83%
IA3	90%	77%
IB	87%	68%
IIA	79%	60%
IIB	72%	53%
IIIA	55%	36%
IIIB	44%	26%
IIIC	24%	13%
IVA	23%	10%
IVB	10%	0%

FIGURE 78-4 Influence of non-small-cell lung cancer stage on survival.

<15 mL/(kg.min) predicts for a higher risk of postoperative complications. Patients deemed unable to tolerate lobectomy or pneumonectomy from a pulmonary functional standpoint may be candidates for more limited resections, such as wedge or anatomic segmental resection, although such procedures are associated with significantly higher rates of local recurrence and a trend toward decreased overall survival. All patients should be assessed for cardiovascular risk using American College of Cardiology and American Heart Association guidelines. A myocardial infarction within the past 3 months is a contraindication to thoracic surgery because 20% of patients will die of reinfarction. An infarction in the past 6 months is a relative contraindication. Other major contraindications include uncontrolled arrhythmias, an FEV_1 of <1 L, CO_2 retention (resting P_{CO_2} >45 mmHg), DLCO <40%, and severe pulmonary hypertension.

TREATMENT

Non-Small-Cell Lung Cancer

The overall treatment approach to patients with NSCLC is shown in **Fig. 78-5**.

OCCULT AND STAGE 0 CARCINOMAS

Patients with severe atypia on sputum cytology have an increased risk of developing lung cancer compared to those without atypia. In the uncommon circumstance where malignant cells are identified in a sputum or bronchial washing specimen but the chest imaging appears normal (TX tumor stage), the lesion must be localized. More than 90% of tumors can be localized by meticulous examination of the bronchial tree with a fiberoptic bronchoscope under general anesthesia and collection of a series of differential brushings and biopsies. Surgical resection following bronchoscopic localization has been shown to improve survival compared to no treatment. Close follow-up of these patients is indicated because of the high incidence of second primary lung cancers (5% per patient per year).

SOLITARY PULMONARY NODULE AND "GROUND-GLASS" OPACITIES

A solitary pulmonary nodule is defined as an x-ray density completely surrounded by normal aerated lung with circumscribed margins, of any shape, usually 1–6 cm in greatest diameter. The approach to a patient with a solitary pulmonary nodule is based on an estimate of the probability of cancer, determined according to the patient's smoking history, age, and characteristics on imaging **(Table 78-7)**. Prior CXRs and CT scans should be obtained if available for comparison. A PET scan may be useful if the lesion is greater than 7–8 mm in diameter. If no diagnosis is apparent, Mayo investigators reported that clinical characteristics (age, cigarette smoking status, and prior cancer diagnosis) and three radiologic characteristics (nodule diameter, spiculation, and upper lobe location) were independent predictors of malignancy. At present, only two radiographic criteria are thought to predict the benign nature of a solitary pulmonary nodule: lack of growth over a period >2 years and certain characteristic patterns of calcification. Calcification alone, however, does not exclude malignancy; a dense central nidus, multiple punctuate foci, and "bull's eye" (granuloma) and "popcorn ball" (hamartoma) calcifications are highly suggestive of a benign lesion. In contrast, a relatively large lesion, lack of or asymmetric calcification, chest symptoms, associated atelectasis, pneumonitis, or growth of the lesion revealed by comparison with an old x-ray or CT scan or a positive PET scan may be suggestive of a malignant process and warrant further attempts to establish a histologic diagnosis. An algorithm for assessing these lesions is shown in **Fig. 78-6**.

Since the advent of screening CTs, small "ground-glass" opacities (GGOs) have often been observed, particularly as the increased sensitivity of CTs enables detection of smaller lesions. Many of these GGOs, when biopsied, are found to be atypical adenomatous hyperplasia (AAH), adenocarcinoma in situ (AIS), or minimally invasive adenocarcinoma (MIA). AAH is usually a nodule of <5 mm and is minimally hazy, also called nonsolid or ground glass (i.e., hazy slightly increased attenuation, no solid component, and preservation of bronchial and vascular margins). On thin-section CT, AIS is usually a nonsolid nodule and tends to be slightly more opaque than AAH. MIA is mainly solid, usually with a small (<5 mm) central solid component. However, overlap exists among the imaging features of the preinvasive and minimally invasive lesions in the lung adenocarcinoma spectrum. Lepidic adenocarcinomas are usually solid but may be nonsolid. Likewise, the small invasive adenocarcinomas also are usually solid but may exhibit a small nonsolid component.

MANAGEMENT OF STAGES I AND II NSCLC

Surgical Resection of Stage I and II NSCLC Surgical resection, ideally by an experienced thoracic surgeon, is the treatment of choice for patients with clinical stage I and II NSCLC who are able to tolerate the procedure. Operative mortality rates for patients resected by thoracic or cardiothoracic surgeons are lower compared to general surgeons. Moreover, survival rates are higher in patients who undergo resection in facilities with a high surgical volume compared to those performing fewer than 70 procedures per year, even though the higher-volume facilities often serve older and less socioeconomically advantaged populations. The improvement in survival is most evident in the immediate postoperative period. In patients with stage I NSCLC, lobectomy is superior to wedge

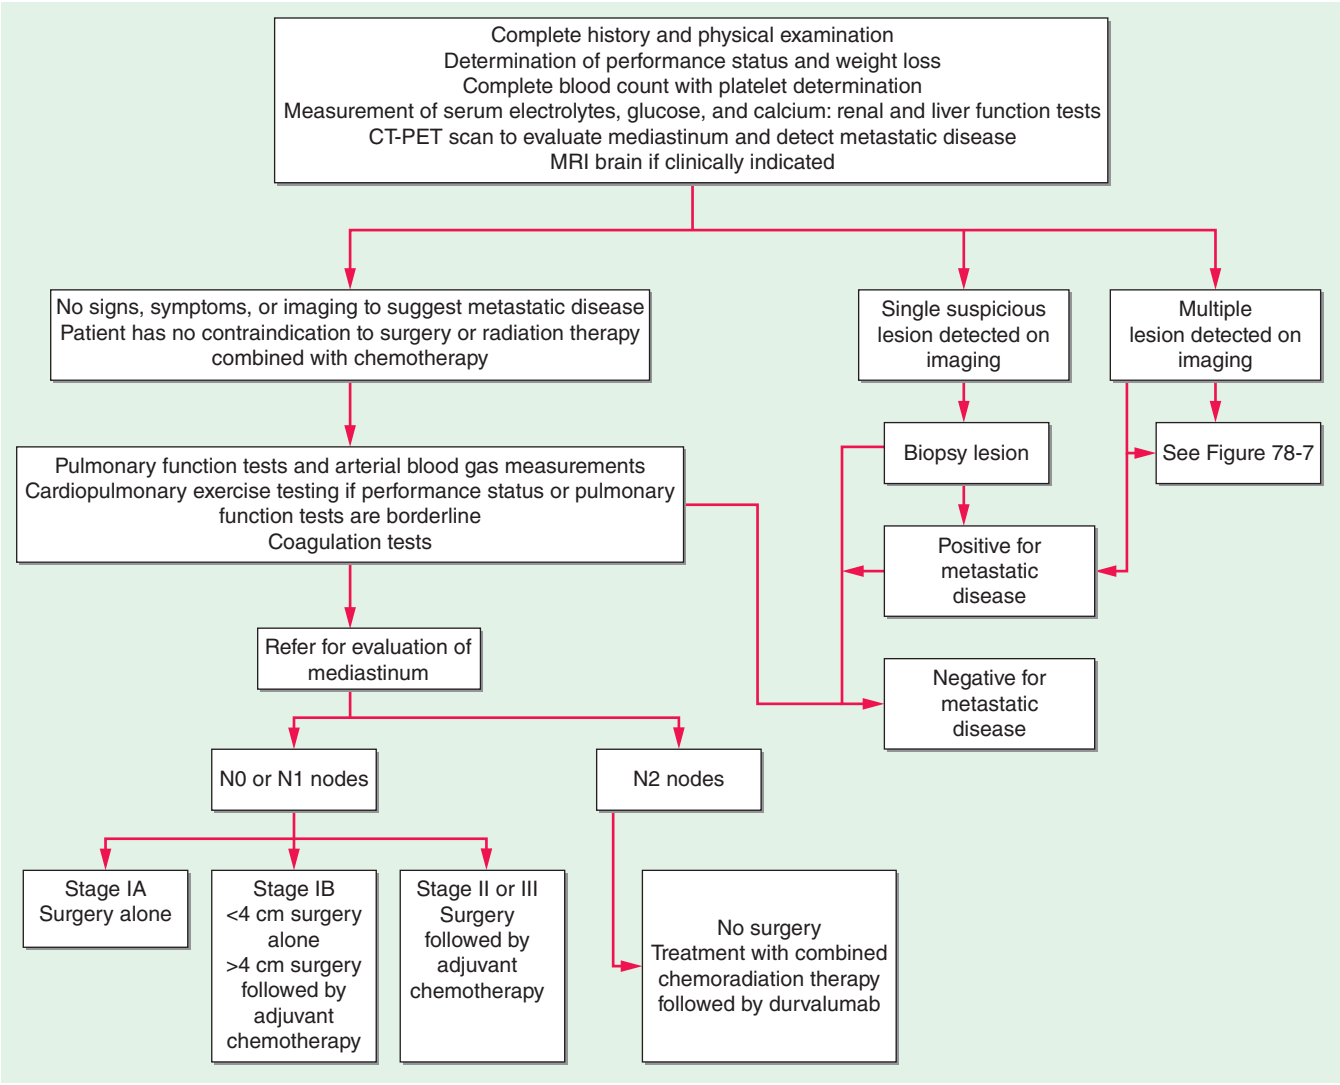


FIGURE 78-5 Algorithm for management of non-small-cell lung cancer. MRI, magnetic resonance imaging; PET, positron emission tomography.

resection with respect to rates of local recurrence. There is also a trend toward improvement in overall survival. In patients with comorbidities, compromised pulmonary reserve, and small peripheral lesions, a limited resection, wedge resection, or segmentectomy (potentially by video-assisted thoracoscopic surgery) may be reasonable surgical options. Pneumonectomy is reserved for patients with central tumors and should be performed only in patients with excellent pulmonary reserve. The 5-year survival rates are 68–92% for patients with stage I NSCLC and 53–60% for patients with stage II NSCLC.

TABLE 78-7 Assessment of Risk of Cancer in Patients with Solitary Pulmonary Nodules

	RISK		
VARIABLE	LOW	INTERMEDIATE	HIGH
Diameter (cm)	<1.5	1.5–2.2	≥2.3
Age (years)	<45	45–60	>60
Smoking status	Never smoker	Current smoker (<20 cigarettes/d)	Current smoker (>20 cigarettes/d)
Smoking cessation status	Quit ≥7 years ago or quit	Quit <7 years ago	Never quit
Characteristics of nodule margins	Smooth	Scalloped	Corona radiata or spiculated

Accurate pathologic staging requires adequate segmental, hilar, and mediastinal lymph node sampling. Ideally, this includes a mediastinal lymph node dissection. On the right side, mediastinal stations 2R, 4R, 7, 8R, and 9R should be dissected; on the left side, stations 5, 6, 7, 8L, and 9L should be dissected. Hilar lymph nodes are typically resected and sent for pathologic review, although it is helpful to specifically dissect and label level 10 lymph nodes when possible. On the left side, level 2 and sometimes level 4 lymph nodes are generally obscured by the aorta. Although the therapeutic benefit of nodal dissection versus nodal sampling is controversial, a pooled analysis of three trials involving patients with stages I to IIIA NSCLC demonstrated a superior 4-year survival in patients undergoing resection and a complete mediastinal lymph node dissection compared with lymph node sampling. Moreover, complete mediastinal lymphadenectomy added little morbidity to a pulmonary resection for lung cancer when carried out by an experienced thoracic surgeon.

Radiation Therapy in Stages I and II NSCLC There is currently no role for postoperative radiation therapy in patients following resection of stage I or II NSCLC with negative margins. However, patients with stage I and II disease who either refuse or are not suitable candidates for surgery should be considered for radiation therapy with *curative* intent. Stereotactic body radiation therapy (SBRT) is a technique used to treat patients with isolated pulmonary nodules (≤5 cm) who are not candidates for or refuse surgical resection. Treatment is typically administered in three to five

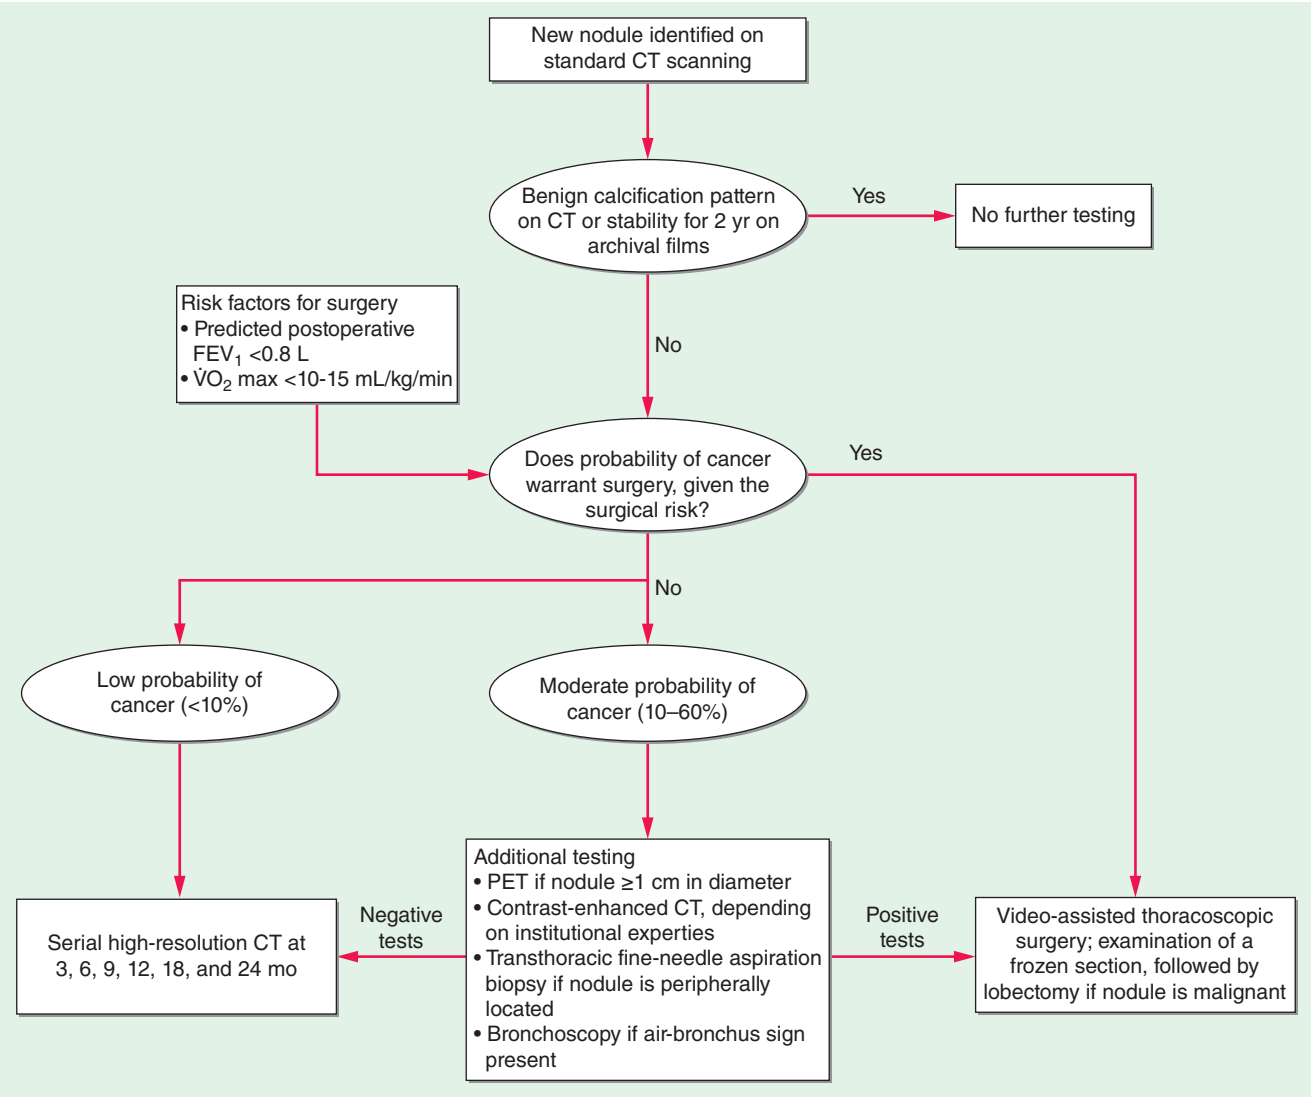

FIGURE 78-6 Approach to the solitary pulmonary nodule. FEV_1, forced expiratory volume in 1 s; PET, positron emission tomography.

fractions delivered over 1–2 weeks. In uncontrolled studies, disease control rates are >90%, and 5-year survival rates of up to 60% have been reported with SBRT. By comparison, survival rates typically range from 13 to 39% in patients with stage I or II NSCLC treated with standard external-beam radiotherapy. Cryoablation is another technique occasionally used to treat small, isolated tumors (i.e., ≤3 cm). However, very little data exist on long-term outcomes with this technique.

Chemotherapy in Stages I and II NSCLC Although a landmark meta-analysis of cisplatin-based adjuvant chemotherapy trials in patients with resected stages I to IIIA NSCLC (the Lung Adjuvant Cisplatin Evaluation [LACE] Study) demonstrated a 5.4% improvement in 5-year survival for adjuvant chemotherapy compared to surgery alone, the survival benefit was seemingly confined to patients with stage II or III disease **(Table 78-8)**. By contrast, survival was actually worsened in stage IA patients with the application of adjuvant therapy. In stage IB, there was a modest improvement in survival of questionable clinical significance. Adjuvant chemotherapy was also detrimental in patients with poor performance status (Eastern Cooperative Oncology Group [ECOG] performance status = 2). These data suggest that adjuvant chemotherapy is best applied in patients with resected stage II or III NSCLC. There is no apparent role for adjuvant chemotherapy in patients with resected stage IA or IB NSCLC. A possible exception to the prohibition of adjuvant therapy in this setting is the stage IB patient with a resected lesion ≥4 cm. Osimertinib, an EGFR TKI, demonstrated improved disease-free survival for patients with *EGFR* mutation (exon 19 deletion or L858R)–positive NSCLC treated for 3 years following chemotherapy. However, the effect on overall survival is unknown.

As with any treatment recommendation, the risks and benefits of adjuvant chemotherapy should be considered on an individual patient basis. If a decision is made to proceed with adjuvant chemotherapy, in general, treatment should be initiated 6–12 weeks after surgery, assuming the patient has fully recovered, and should be administered for no more than four cycles. Although cisplatin-based chemotherapy is the preferred treatment regimen, carboplatin can be substituted for cisplatin in patients who are unlikely to tolerate cisplatin for reasons such as reduced renal function, presence of neuropathy, or hearing impairment. A large cooperative group trial compared cisplatin-based chemotherapy with vinorelbine, pemetrexed, gemcitabine, or docetaxel with or without antiangiogenic therapy. While adding antiangiogenic therapy to platinum-based chemotherapy offered no benefit, the trial also demonstrated no difference in survival among the four chemotherapy regimens. Therefore, no specific chemotherapy regimen is considered superior in this setting, and treatment selection may be based on cost and patient comorbidities.

Neoadjuvant chemotherapy, which is the application of chemotherapy administered *before* an attempted surgical resection, has been advocated by some experts on the assumption that such an approach will more effectively extinguish occult micrometastases compared to

TABLE 78-8 Adjuvant Chemotherapy Trials in Non-Small-Cell Lung Cancer

postoperative chemotherapy. In addition, it is thought that preoperative chemotherapy might render an inoperable lesion resectable. A meta-analysis of 15 randomized controlled trials involving more than 2300 patients with stage I to III NSCLC suggested there may be a modest 5-year survival benefit (i.e., ~5%) that is virtually identical to the survival benefit achieved with postoperative chemotherapy. Accordingly, neoadjuvant therapy may prove useful in selected cases (see below). A decision to use neoadjuvant chemotherapy should always be made in consultation with an experienced surgeon.

All patients with resected NSCLC are at high risk of developing a second primary lung cancer or recurrence, most of which occur within 18–24 months of surgery. Thus, it is reasonable to follow these patients with periodic imaging studies. Given the results of the NLST, periodic CT scans appear to be the most appropriate screening modality. Based on the timing of most recurrences, some guidelines recommend a contrasted chest CT scan every 6 months for the first 3 years after surgery, followed by yearly CT scans of the chest without contrast thereafter.

MANAGEMENT OF STAGE III NSCLC

Management of patients with stage III NSCLC usually requires a combined-modality approach. Patients with stage IIIA disease commonly are stratified into those with "nonbulky" or "bulky" mediastinal lymph node (N2) disease. Although the definition of "bulky" N2 disease varies somewhat in the literature, the usual criteria include the size of a dominant lymph node (i.e., >2–3 cm in short-axis diameter as measured by CT), groupings of multiple smaller lymph nodes, evidence of extracapsular nodal involvement, or involvement of more than two lymph node stations. The distinction between nonbulky and bulky stage IIIA disease is mainly used to select potential candidates for *upfront* surgical resection or for resection after neoadjuvant therapy. Many aspects of therapy of patients with stage III NSCLC remain controversial, and the optimal treatment strategy has not been clearly defined. Furthermore, because stage III disease is highly heterogeneous, no single treatment approach can be recommended for all patients. Key factors guiding treatment choices include the particular combination of tumor (T) and nodal (N) disease, the ability to achieve a complete surgical resection if indicated, and the patient's overall physical condition and preferences. For example, in carefully selected patients with limited stage IIIA disease where involved mediastinal lymph nodes can be completed resected, initial surgery followed by postoperative chemotherapy (with or without radiation therapy) may be indicated. By contrast, for patients with clinically evident bulky mediastinal lymph node involvement, the standard approach to treatment is concurrent chemoradiotherapy followed by a year of immunotherapy with durvalumab or other PD-L1-directed antibody.

Absent and Nonbulky Mediastinal (N2, N3) Lymph Node Disease

For the subset of stage IIIA patients initially thought to have clinical stage I or II disease (i.e., pathologic involvement of mediastinal [N2] lymph nodes is *not* detected preoperatively), surgical resection is often the treatment of choice. This is followed by adjuvant chemotherapy in patients with microscopic lymph node involvement in a resection specimen. Postoperative radiation therapy (PORT) may also have a role for those with close or positive surgical margins. Patients with tumors exceeding 7 cm in size or involving the chest wall or proximal airways within 2 cm of the carina with hilar lymph node involvement (but not N2 disease) are classified as having T3N1 stage IIIA disease. They too are best managed with surgical resection, if technically feasible, followed by adjuvant chemotherapy if completely resected. Patients with T3N0 or T3N1 disease due to the presence of satellite nodules within the same lobe as the primary tumor are also candidates for surgery, as are patients with ipsilateral nodules in another lobe and negative mediastinal nodes (IIIA, T4N0 or T4N1). Although data regarding adjuvant chemotherapy in the latter subsets of patients are limited, it is often recommended.

Patients with T4N0-1 may have involvement of the carina, superior vena cava, or a vertebral body and yet still be candidates for surgical resection in selected circumstances. The decision to proceed with an attempted resection must be made in consultation with an experienced thoracic surgeon often in association with a vascular or cardiac surgeon and an orthopedic surgeon depending on tumor location. However, if an incomplete resection is inevitable or if there is evidence of N2 involvement (stage IIIB), surgery for T4 disease is contraindicated. Most T4 lesions are best treated with concurrent chemoradiotherapy followed by durvalumab.

The role of PORT in patients with completely resected stage III NSCLC is controversial. To a large extent, the use of PORT is dictated by the presence or absence of N2 involvement and, to a lesser degree, by the biases of the treating physician. Using the Surveillance, Epidemiology, and End Results (SEER) database, a recent meta-analysis of PORT identified a significant increase in survival in patients with N2 disease but not in patients with N0 or N1 disease. An earlier analysis by the PORT Meta-analysis Trialist Group using an older database produced similar results.

Known Mediastinal (N2, N3) Lymph Node Disease When pathologic involvement of mediastinal lymph nodes is documented preoperatively, a combined-modality approach is recommended assuming the patient is a candidate for treatment with curative intent. These patients are at high risk for both local and distant recurrence if managed with resection alone. For patients with stage III disease who are not candidates for surgical resection, *concurrent* chemoradiotherapy is most commonly used as the initial treatment followed by durvalumab. Concurrent chemoradiotherapy has been shown to produce superior survival compared to *sequential* chemoradiotherapy; however, it also is associated with greater host toxicities (including fatigue, esophagitis, and neutropenia). Therefore, for patients with a good performance status, concurrent chemoradiotherapy is the preferred treatment approach, whereas sequential chemoradiotherapy may be more appropriate for patients with a performance status that is not as good. For patients who are *not* candidates for a combined-modality treatment approach, typically due to a poor performance status or a comorbidity that makes chemotherapy untenable, radiotherapy alone may provide a modest survival benefit in addition to symptom palliation.

For patients with potentially resectable N2 disease, it remains uncertain whether surgery after neoadjuvant chemoradiotherapy improves survival. In an NCI-sponsored Intergroup randomized trial comparing concurrent chemoradiotherapy alone to concurrent chemoradiotherapy followed by attempted surgical resection, no survival benefit was observed in the trimodality arm compared to the bimodality therapy. In fact, patients subjected to a pneumonectomy had a worse survival outcome. By contrast, those treated with a lobectomy appeared to have a survival advantage based on a retrospective subset analysis. Thus, in carefully selected, otherwise healthy patients with nonbulky mediastinal lymph node involvement, surgery may be a reasonable option if the primary tumor can be fully resected with a lobectomy. This is not the case if a pneumonectomy is required to achieve complete resection.

Superior Sulcus Tumors (Pancoast Tumors) Superior sulcus tumors represent a distinctive subset of stage III disease. These tumors arise in the apex of the lung and may invade the second and third ribs, the brachial plexus, the subclavian vessels, the stellate ganglion, and adjacent vertebral bodies. They also may be associated with Pancoast syndrome, characterized by pain that may arise in the shoulder or chest wall or radiate to the neck. Pain characteristically radiates to the ulnar surface of the hand. Horner's syndrome (enophthalmos, ptosis, miosis, and anhidrosis) due to invasion of the paravertebral sympathetic chain may be present as well. Patients with these tumors should undergo the same staging procedures as all patients with stage II and III NSCLC. Neoadjuvant chemotherapy or combined chemoradiotherapy followed by surgery is reserved for those without N2 involvement. This approach yields excellent survival outcomes (>50% 5-year survival in patients with an R0 resection). Patients with N2 disease are less likely to benefit from surgery and can be managed with chemoradiotherapy followed by durvalumab. Patients presenting with metastatic disease can be treated with radiation therapy (with or without chemotherapy) for symptom palliation.

MANAGEMENT OF METASTATIC NSCLC

Approximately 40% of NSCLC patients present with advanced, stage IV disease at the time of diagnosis. In addition, a significant number of patients who first presented with early-stage NSCLC will eventually relapse with distant disease. Patients who have recurrent disease have a better prognosis than those presenting with metastatic disease at the time of diagnosis. Standard medical management, the judicious use of pain medications, and the appropriate use of radiotherapy and systemic therapy—which may consist of targeted therapy, immunotherapy, and/or traditional cytotoxic chemotherapy depending on the specific diagnosis as well as PD-L1 tumor proportion score (TPS) and molecular subtype—form the cornerstone of management. Systemic therapy palliates symptoms, improves quality of life, and improves survival in patients with metastatic NSCLC, particularly in patients with good performance status. Of note, the early application of palliative care in conjunction with chemotherapy in patients with advanced NSCLC is associated with both improved survival and quality of life.

Targeted Therapies for Select Molecular Cohorts of NSCLC For a cohort of NSCLC patients, the presence of an oncogenic driver mutation allows the use of oral therapies with significant antitumor activity and improved survival compared to cytotoxic chemotherapy. These driver mutations occur in genes encoding signaling proteins that, when aberrant, promote the uncontrolled growth and metastasis of tumor cells. Importantly, driver mutations can serve as Achilles' heels for tumors, if their gene products can be targeted therapeutically with small-molecule inhibitors. All patients with advanced NSCLC should undergo molecular testing with broad panel-based testing techniques such as next-generation sequencing (NGS) to look for oncogenic drivers. Mutations, fusions, and deletions have been reported in a number of genes including *EGFR*, *ALK*, *ROS1*, *BRAF*, *RET*, *MET*, *NTRK*, *KRAS*, *PIK3CA*, *NRAS*, *AKT1*, and *MEK1* (*MAP2K1*); however, not all are considered actionable at this time. As our treatment armamentarium expands, knowledge of these mutations is critical for selection of appropriate therapy.

EGFR mutations have been detected in 10–15% of North American patients diagnosed with NSCLC. *EGFR* mutations are associated with younger age, light (<10 pack-year) and nonsmokers, and adenocarcinoma histology. Approximately 90% of these mutations are exon 19 deletions or exon 21 L858R point mutations within the EGFR TK domain, resulting in hyperactivation of both EGFR kinase activity and downstream signaling. Lung tumors that harbor activating mutations within the EGFR kinase domain display high sensitivity to small-molecule EGFR TKIs. Osimertinib, erlotinib, gefitinib, afatinib and dacomitinib are FDA-approved oral small-molecule TKIs that inhibit EGFR. Several large, international, phase 3 studies have demonstrated improved response rates and progression-free survival in patients with *EGFR* mutation–positive NSCLC treated with an EGFR TKI as compared with standard first-line chemotherapy regimens **(Table 78-9)**. Osimertinib was shown in a randomized phase 3 trial to have superior progression-free and overall survival in patients with *EGFR*-mutant NSCLC compared to earlier-generation EGFR TKIs (erlotinib or gefitinib) and to chemotherapy.

Chromosomal rearrangements involving the anaplastic lymphoma kinase (*ALK*) gene on chromosome 2 have been found in ~3–7% of patients with NSCLC. *ALK* rearrangements lead to hyperactivation of the ALK TK domain. Similar to EGFR, *ALK* rearrangements are typically (but not exclusively) associated with younger age, light (<10 pack-year) and nonsmokers, and adenocarcinoma histology. Crizotinib is a first-generation ALK TKI, whereas alectinib, brigatinib and ceritinib are second-generation ALK TKIs approved as first-line treatment options for patients with lung tumors harboring *ALK* rearrangements. Both alectinib and brigatinib have been found to have superior progression-free survival to crizotinib, whereas lorlatinib, a third-generation ALK TKI, is approved in patients who progress on a second-generation ALK TKI **(Table 78-10)**. *ALK* testing may be performed via fluorescence

in situ hybridization (FISH), immunohistochemistry (IHC), or NGS.

ROS1 fusions, detected by FISH or NGS, have been identified in ~1% of patients with NSCLC, and similar to *EGFR* mutations and *ALK* fusions, *ROS1* rearrangements are typically associated with younger age and light or never smoking status. Crizotinib and lorlatinib, which inhibit both ALK and ROS1 kinases, and entrectinib have been FDA approved for patients whose tumors harbor a *ROS1* fusion.

NTRK fusions occur in members of the *NTRK* gene family (*NTRK1*, *NTRK2*, *NTRK3*) and result in constitutive protein kinase activation. *NTRK* fusions are rare, occurring in <1% of patients with NSCLC. Similar to the above mutations, they more commonly occur in never smokers; however, patients with *NTRK* fusions are often older patient compared to those with *ROS1* and *ALK* alterations. Entrectinib and larotrectinib have demonstrated durable antitumor efficacy and are currently approved for *NTRK*-positive NSCLC.

MET exon 14 skipping mutations have also been identified in approximately 3–5% of patients with NSCLC. Unlike the above-mentioned mutations, *MET* exon 14 skipping mutations occur in both squamous and nonsquamous NSCLC patients and those with a history of smoking. Pharmacologic inhibition of the overactive MET pathway with capmatinib or tepotinib resulted response rates >70%, particularly in treatment-naïve NSCLC patients.

Oncogenic mutations in *BRAF* have been observed in ~2% of patients with NSCLC and, similar to *MET*, occur in both squamous and nonsquamous NSCLC and with an equal prevalence in patients with a history of smoking. This mutation is typically most targetable when it occurs at the 600th amino acid valine (V600). Combined inhibition with a BRAF and MEK inhibitor, dabrafenib plus trametinib, is a first-line or later therapeutic option in patients with *BRAF* V600–mutant NSCLC and appears to be superior to BRAF or MEK inhibition alone.

RET alterations typically occur as chromosomal rearrangements resulting in constitutive TKI activation. *RET* rearrangements may be detected by either FISH or NGS in ~1% of NSCLC patients. Analogous to capmatinib, selpercatinib has demonstrated an excellent response rate; as many as 85% of treatment-naïve NSCLC patients with *RET* alterations responded. All National Comprehensive Cancer Network–supported targetable oncogenic driver mutations and potential therapeutic options are summarized in **Fig. 78-7**.

Mutations within the *KRAS* GTPase are found in ~20% of lung adenocarcinomas. Agents targeting *KRAS* G12C are in development. Each of the other driver mutations occurs in <1–3% of lung adenocarcinomas. The great majority of the driver mutations are mutually exclusive. Most cancers have just one main driver. Defining mechanisms of acquired resistance to small-molecule inhibitors is a high research priority.

Immunotherapy Immune checkpoint inhibitors have significantly improved the quality of life and survival for a group of patients with locally advanced and metastatic NSCLC. These agents are used primarily in patients whose tumors do not express a targetable genetic lesion **(Fig. 78-8)**. Immune checkpoint inhibitors work by blocking interactions between T cells and antigen presenting cells (APCs) or tumor cells that lead to T-cell inactivation. By inhibiting this interaction, the immune system is effectively upregulated and T cells become activated against tumor cells. Several randomized studies have demonstrated superior overall survival in patients treated with pembrolizumab or atezolizumab monotherapy or nivolumab plus ipilimumab combination immunotherapy compared to chemotherapy in patients with metastatic NSCLC with PD-L1 expression in ≥50% of tumor cells (Keynote 024, IMPOWER 110) and ≥1% of tumor cells (Keynote 042, CheckMate 227) **(Table 78-11)**. The evidence supporting the use of single-agent immunotherapy in patients with tumor PD-L1 <50% remains unclear; current recommendations suggest the use of chemotherapy plus immunotherapy or immunotherapy combinations as the first-line treatment strategy in patients with metastatic NSCLC with tumor PD-L1 <50%. As discussed below, specific regimens vary by tumor histology (adenocarcinoma vs squamous cell carcinoma). Although PD-L1 has been identified as a biomarker that can predict response to immune checkpoint inhibitors, responses are observed in patients who do

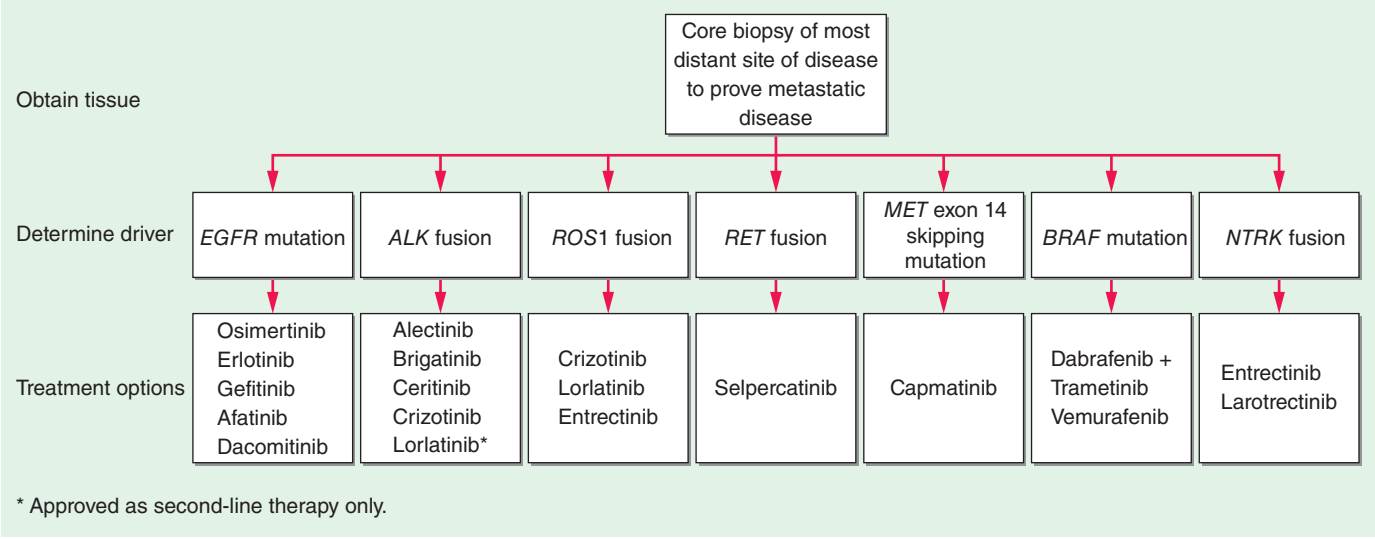

FIGURE 78-7 Approach to targeted therapy in non-small-cell lung cancer (NSCLC).

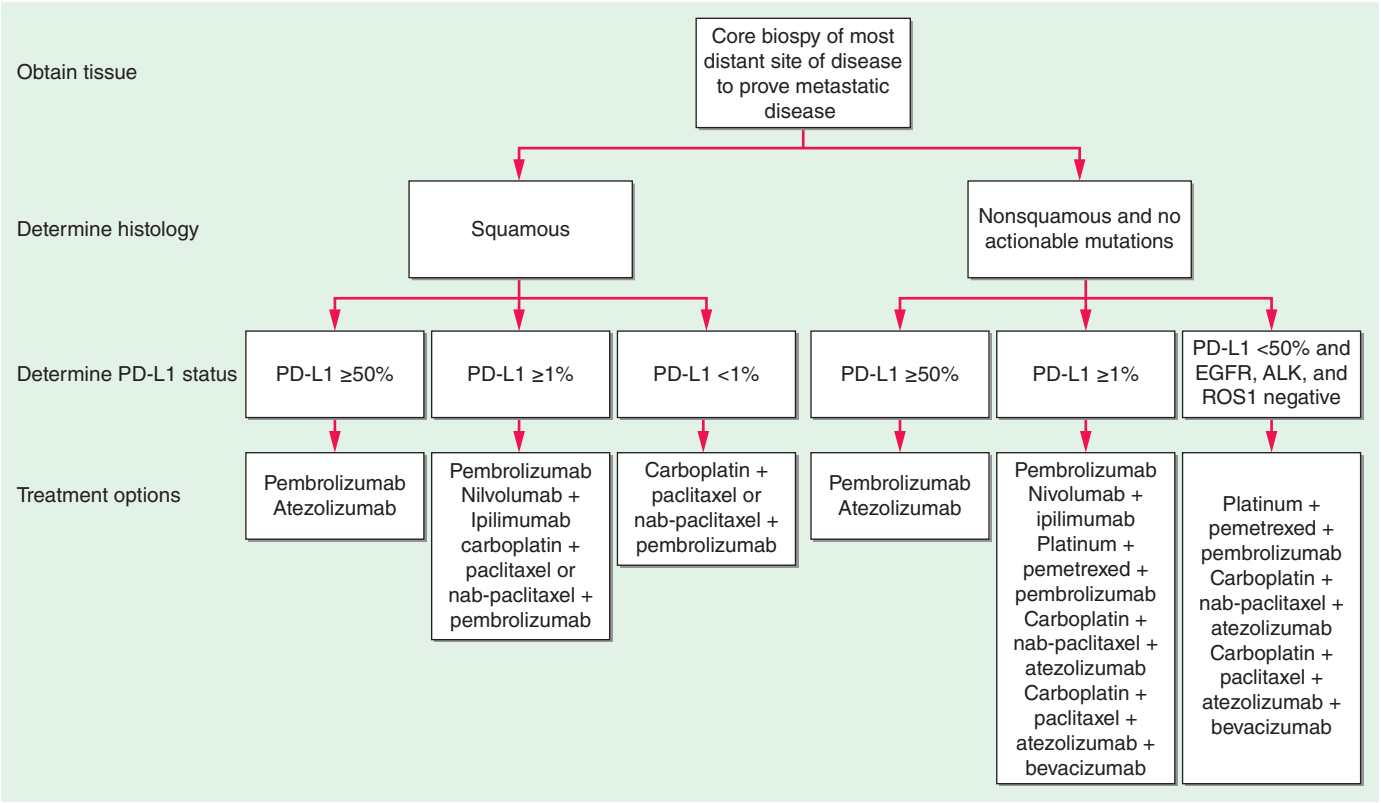

FIGURE 78-8 Approach to first-line therapy in a patient with stage IV, driver mutation–negative non-small-cell lung cancer (NSCLC).

not appear to express the biomarker, and not all PD-L1-positive patients respond to checkpoint inhibition. Importantly patients with driver mutations such as *EGFR* and *ALK* appear to derive greater benefit from targeted therapy than immunotherapy and should be treated with a TKI, even in the presence of high PD-L1 expression. Further evaluation of these agents in the neoadjuvant setting and combined with chemoradiotherapy is ongoing.

Cytotoxic Chemotherapy for Metastatic or Recurrent NSCLC

Cytotoxic chemotherapy is typically used in combination with immunotherapy as the initial treatment in patients with metastatic or recurrent NSCLC only when there is no contraindication to immunotherapy. Selected chemotherapy agents perform quite differently in squamous carcinomas versus adenocarcinomas. Patients with nonsquamous NSCLC have an improved survival when

Note: Platinum-chemotherapy refers to first-line platinum doublet or triplet chemotherapy.

treated with cisplatin and pemetrexed compared to cisplatin and gemcitabine. By contrast, patients with squamous carcinoma have an improved survival when treated with cisplatin and gemcitabine. This survival difference is thought to be related to the differential expression between tumor types of thymidylate synthase (TS). Squamous cancers have a much higher expression of TS compared to adenocarcinomas, accounting for their lower responsiveness to pemetrexed. By contrast, the activity of gemcitabine is not impacted by the levels of TS.

Second-Line Therapy and Beyond Second-line therapy for advanced NSCLC relies on docetaxel; it improves survival compared to supportive care alone. Ramucirumab is a recombinant human IgG1 monoclonal antibody that targets VEGFR-2 and blocks the interaction of VEGF ligands and VEGFR-2. A phase 3 trial demonstrated a significant improvement in progression-free survival and overall survival when ramucirumab was combined with docetaxel as second-line therapy in patients who had progressed on platinum-based chemotherapy. Contrary to bevacizumab, ramucirumab was safe in patients with both squamous and nonsquamous NSCLC and is approved regardless of histology.

Supportive Care No discussion of the treatment strategies for patients with advanced lung cancer would be complete without a mention of supportive care. Coincident with advances in chemotherapy and targeted therapy was a pivotal study that demonstrated that the early integration of palliative care with standard treatment strategies improves both quality of life and overall survival for patients with stage IV NSCLC **(Chaps. 12** and **69)**. Aggressive pain and symptom control are important components of optimal treatment of these patients.

TREATMENT

Small-Cell Lung Cancer

The overall treatment approach to patients with SCLC is shown in **Fig. 78-9**.

SURGERY FOR LIMITED-DISEASE SMALL-CELL LUNG CANCER

SCLC is a highly aggressive disease characterized by its rapid doubling time, high growth fraction, early development of disseminated disease, and dramatic response to first-line chemotherapy and radiation. In general, surgical resection is *not* routinely recommended for patients because even patients with LD-SCLC still have occult micrometastases. However, the American College of Chest Physicians Evidence-Based Clinical Practice Guidelines recommend surgical resection over nonsurgical treatment in SCLC patients with clinical stage I disease after a thorough evaluation for distant metastases and invasive mediastinal stage evaluation (grade 2C). After resection, these patients should receive platinum-based adjuvant chemotherapy (grade 1C). If the histologic diagnosis of SCLC is made in patients on review of a resected surgical specimen, such patients should receive standard SCLC chemotherapy as well.

CHEMOTHERAPY

In patients with limited-stage SCLC, concurrent chemoradiotherapy with cisplatin-etoposide for four cycles has remained standard of care for over 4 decades. Two randomized phase 3 trials have demonstrated that chemotherapy with either cisplatin or carboplatin plus either etoposide and a PD-L1 inhibitor, atezolizumab (IMPOWER 133) or durvalumab (CASPIAN), provides superior progression-free and overall survival compared to chemotherapy alone, making combination therapy the preferred choice in appropriate patients. Despite response rates to first-line therapy as high as 80%, the median survival ranges from 12 to 20 months for patients with LD and approximately 12 months for patients with ED. Regardless of disease extent, the majority of patients relapse and develop chemotherapy-resistant disease. The prognosis is especially poor for patients who relapse within the first 3 months of therapy; these patients are said to have *chemotherapy-resistant disease*. Patients are said to have *sensitive disease* if they relapse >3 months after their initial therapy and are thought to have a somewhat better overall survival. These patients also are thought to have the greatest potential benefit from second-line chemotherapy. Topotecan and

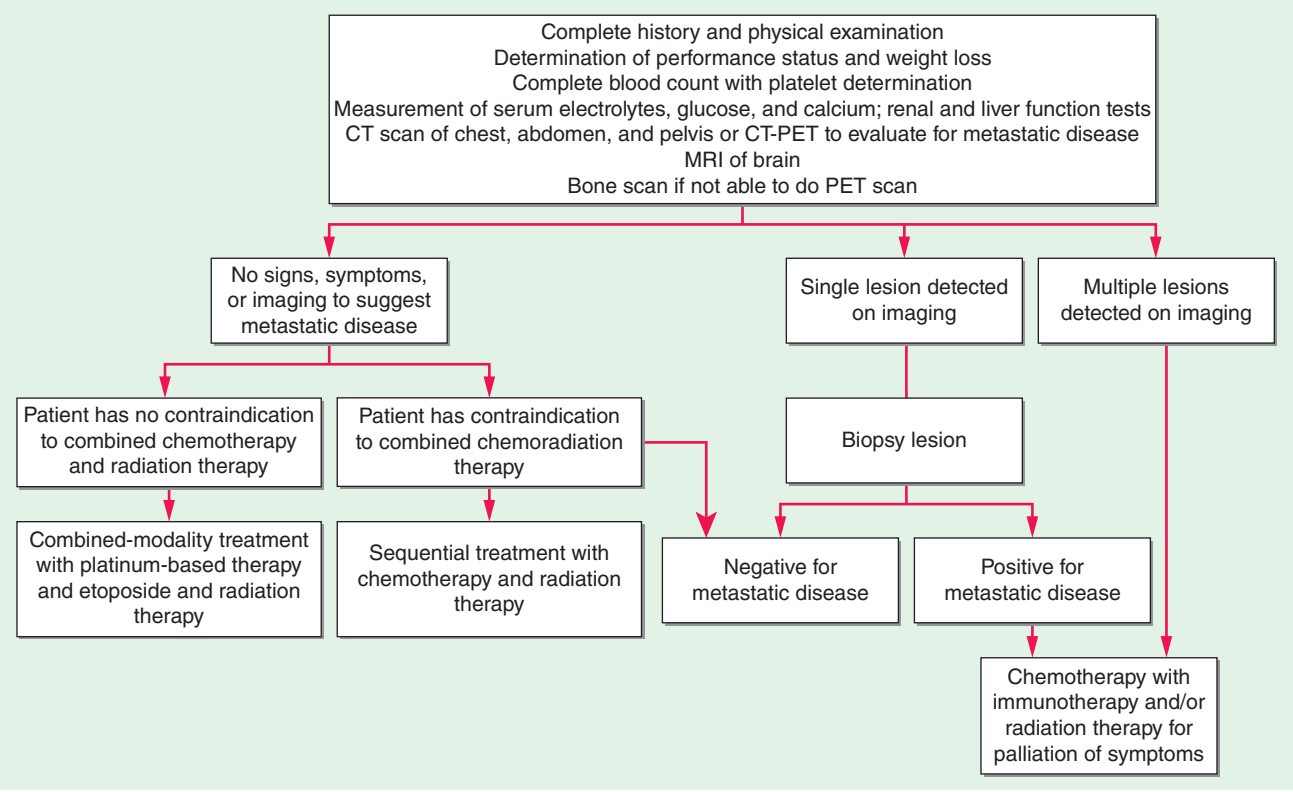

FIGURE 78-9 Algorithm for management of small-cell lung cancer. MRI, magnetic resonance imaging; PET, positron emission tomography.

lurbinectedin are FDA-approved agents for second-line therapy in patients with SCLC. Topotecan has only modest activity and can be given either intravenously or orally; it appears to have more efficacy in patients with chemotherapy-sensitive disease. Lurbinectedin has a 35% response rate and progression-free survival of 3.5 months, with a greater benefit in patients with chemotherapy-sensitive disease. Other agents with similar low levels of activity in the second-line setting include irinotecan, paclitaxel, docetaxel, vinorelbine, oral etoposide, and gemcitabine.

THORACIC RADIATION THERAPY

Thoracic radiation therapy (TRT) is a standard component of induction therapy for patients with good performance status and limited-stage SCLC. Meta-analyses indicate that chemotherapy combined with chest irradiation improves 3-year survival by ~5% as compared with chemotherapy alone. The 5-year survival rate, however, remains disappointingly low at ~10–15%. Most commonly, TRT is combined with cisplatin and etoposide chemotherapy due to a superior toxicity profile as compared to anthracycline-containing chemotherapy regimens. As observed in locally advanced NSCLC, *concurrent* chemoradiotherapy is more effective than *sequential* chemoradiation but is associated with significantly more esophagitis and hematologic toxicity. Ideally TRT should be administered with the first two cycles of chemotherapy because later application appears slightly less effective. If for reasons of fitness or availability, this regimen cannot be offered, TRT should follow induction chemotherapy. With respect to fractionation of TRT, twice-daily 1.5-Gy fractioned radiation therapy has been shown to improve survival in LD-SCLC patients but is associated with higher rates of grade 3 esophagitis and pulmonary toxicity. Although it is feasible to deliver once-daily radiation therapy doses up to 70 Gy concurrently with cisplatin-based chemotherapy, there are no data to support equivalency of this approach compared with the 45-Gy twice-daily radiotherapy dose. Therefore, the current standard regimen of a 45-Gy dose administered in 1.5-Gy fractions twice daily for 30 days is being compared with higher-dose regimens in two phase 3 trials, one in the United States and one in Europe. Patients should be carefully selected for concurrent chemoradiation therapy based on good performance status and adequate pulmonary reserve. The role of radiotherapy in ED-SCLC is largely restricted to palliation of tumor-related symptoms such as bone pain and bronchial obstruction.

PROPHYLACTIC CRANIAL IRRADIATION

Prophylactic cranial irradiation (PCI) should be considered in all patients either with LD-SCLC or who have responded well to initial therapy; its role in patients with ED-SCLC is more controversial. A meta-analysis including seven trials and 987 patients with LD-SCLC who had achieved a complete remission after upfront chemotherapy yielded a 5.4% improvement in overall survival for patients treated with PCI. In patients with ED-SCLC who have responded to first-line chemotherapy and had no CNS disease, patients randomized to observation had a higher incidence of brain metastases; however, use of PCI did not improve overall survival. Long-term toxicities, including deficits in cognition, have been reported after PCI but are difficult to sort out from the effects of chemotherapy or normal aging.

THYMIC TUMORS

Thymic tumors are rare malignancies accounting for 0.5–1.5% of all malignancies in the United States with a higher incidence among Asian populations. They are particularly rare among children and young adults with incidence peaking in the fifth decade of life. There is no difference between sexes, and no clear risk factors have been identified.

CLINICAL MANIFESTATIONS

The majority of thymic tumors occur in the anterior mediastinum. Approximately 40% of patients with mediastinal masses will be asymptomatic with an incidental finding on chest imaging. In patients presenting with an anterior mediastinal mass, if appropriate, serum β-human chorionic gonadotropin (HCG) and α fetoprotein (AFP) should be sent to rule out a germ cell tumor. A patient with a sign or symptom of thymoma or thymic carcinoma may present with chest pain, dyspnea, cough, or superior vena cava syndrome secondary to effects on adjacent organs or a paraneoplastic syndrome, most commonly myasthenia gravis, pure red cell aplasia, or hypogammaglobulinemia. More rare paraneoplastic syndromes include limbic encephalitis, aplastic anemia, hemolytic anemia, and autoimmune disease such as Sjögren's syndrome, polymyositis, rheumatoid arthritis, and ulcerative colitis, among others.

STAGING

Given the rarity of the tumor, patients with suspected thymoma should be evaluated by a multidisciplinary team including a surgeon, medical and radiation oncologist, and pathologist with experience in treating the disease. A CT scan of the chest with contrast is recommended to determine if the mass is resectable based on relationship to surrounding structures. An MRI with contrast may be performed if clinically indicated. A PET scan may be useful in the evaluation of a patient with thymic tumors, although it may be less useful in the staging of thymoma compared to thymic carcinoma. A core needle biopsy is considered standard of care for obtaining a histologic diagnosis of an anterior mediastinal tumor. This may be obtained via CT or ultrasound imaging. However, in some circumstances, a mediastinoscopy or open biopsy may be required.

Thymomas are commonly staged using the Masaoka system or the World Health Organization (WHO) staging system, as described in Table 78-12. WHO types A, AB, and B1 tend to be more well-differentiated, types B2 and B3 are moderately differentiated, and type C is poorly differentiated.

TREATMENT

Surgical resection is the mainstay of treatment for patients with Masaoka type I and II thymic tumors. In patients with type III and IV who have potentially resectable thymic tumors, neoadjuvant chemotherapy may be given to decrease the tumor size and allow for a resection with negative margins. Surgery remains controversial and provides a limited role in the treatment of stage III and IV disease. No

TABLE 78-12 Staging Thymic Tumors

MASAOKA STAGE	DEFINITION
I	Grossly and microscopically encapsulated
IIA	Microscopic transcapsular invasion
IIB	Macroscopic invasion into surrounding tissue excluding pericardium, lung, and great vessels
III	Macroscopic invasion into neighboring organs of the lower neck or upper chest
IVA	Pleural or pericardial dissemination
IVB	Hematogenous or lymphatic dissemination to distal organs
WHO	
A	Tumor with few lymphocytes
AB	Tumor with features of type A and foci rich in lymphocytes
B1	Tumor with features of normal epithelial cells with vesicular nuclei and distinct nucleoli and an abundant population of lymphocytes. Also known as cortical thymoma, lymphocyte-rich thymoma
B2	Thymoma with no or mild atypia with round or polygonal-shaped cells with small component of lymphocytes
B3	Well-differentiated thymic carcinoma with mild atypia
C	Thymic carcinoma with high atypia

additional therapy may be required in patients with type I who have a resection with negative margins. Postoperative radiation therapy may be recommended based on extracapsular extension and the presence of positive margins in patients with type II or III thymic tumors or histologic evaluation WHO B3 and C. Radiation therapy may be beneficial in patients with locally advanced disease (type III or IV) or in patients with symptoms secondary to compression of surrounding structures. Chemotherapy with cisplatin, doxorubicin, and cyclophosphamide (CAP) remains the mainstay of therapy in the neoadjuvant and adjuvant setting as well as first-line therapy in patients with metastatic thymoma, whereas carboplatin and paclitaxel are often employed in patients with thymic carcinoma. Limited additional agents are recommended based on small phase 2 trials as second-line therapy and beyond.

COVID-19 AND LUNG CANCER

COVID-19, a respiratory tract infection caused by SARS-CoV-2, emerged in Wuhan, China, in late 2019. The rapid global spread led the WHO to declare a pandemic in early March 2020. Large retrospective data sets have shown that cancer patients, and particularly patients with lung cancer, are at increased risk of morbidity and mortality from COVID-19. The dilemma of distinguishing COVID-19 symptoms from lung cancer and radiographic diagnosis of pneumonia or pneumonitis from radiation therapy or immunotherapy versus COVID-19 pneumonia has presented a particular challenge to health care providers. Mortality as high as 35% has been reported for patients with lung cancer infected with SARS-CoV-2. Older patients (≥65 years old), patients with a worse performance status (Eastern Cooperative Oncology Group performance status ≥1), patients on glucocorticoids (≥10 mg prednisone equivalent) and anticoagulation, and patients on chemotherapy within 3 months of diagnosis appear to be particularly at risk for morality if infected. The long-term impact on lung cancer mortality due to delays in screening, diagnosis, and treatment are likely to be felt for years to come.

SUMMARY

The management of SCLC and NSCLC has undergone major change in the past decade, resulting in a reduction in lung cancer mortality. For patients with early-stage disease, advances in radiotherapy and surgical procedures as well as new systemic therapies have greatly improved prognosis in all diseases. For patients with advanced lung cancer, major progress in understanding tumor genetics and tumor immunology has led to the development of rational targets and specific inhibitors, which have documented efficacy in specific subsets of NSCLC. Furthermore, increased understanding of how to activate the immune system to drive antitumor immunity has proven to be a successful therapeutic strategy for a subset of patients with advanced lung cancer. However, only a small subset of patients responds to immune checkpoint inhibitors, and the majority of patients treated with targeted therapies or chemotherapy eventually develop resistance, which provides strong motivation for further research and enrollment of patients onto clinical trials in this rapidly evolving area.

79 Breast Cancer

Daniel F. Hayes, Marc E. Lippman

INTRODUCTION AND BACKGROUND

CONCEPTUAL AND BIOLOGICAL ISSUES OF BREAST CANCER

Breast cancer is a malignant proliferation of epithelial cells lining the ducts or lobules of the breast. In the year 2020, approximately a quarter million cases of invasive and 61,000 cases of in situ breast cancer were diagnosed in the United States, with nearly 41,000 deaths. Epithelial malignancies of the breast are the most common cause of cancer in women (excluding skin cancer), accounting for about one-third of all cancer in women. As a result of earlier detection and improved treatments, the mortality rate from breast cancer decreased by more than one-third over the past three decades in high- and middle-income countries. This chapter does not consider rare malignancies presenting in the breast, such as sarcomas and lymphomas, but focuses on the epithelial cancers.

Breast cancer has served as a paradigm for several oncologic principles related to solid tumors. It spans a spectrum of conditions for which different clinical considerations must be made, including risk assessment, prevention, screening, evaluation of breast abnormalities, local and adjuvant systemic treatments, metastatic therapies, and survivorship issues **(Fig. 79-1)**.

The unique biology of breast cancer has rendered it amenable to a variety of therapeutic "targeted" strategies based on the appreciation of differences in subtypes that reflect the need for differences in assessment and therapy. These subtypes include expression of the estrogen receptor (ER) and the human epidermal growth factor receptor type 2 (HER2), as well as germline or somatic mutations in inherited tumor suppressor genes, such as *BRCA1* and *BRCA2*. Identifiable somatic mutations in genes that appear to drive the cancer, including mammalian target of rapamycin (*mTOR*), cyclin-dependent kinase 4 and 6 (*CDK4/6*), and S-phosphatidylinositol-4,5-bisphosphate 3-kinase

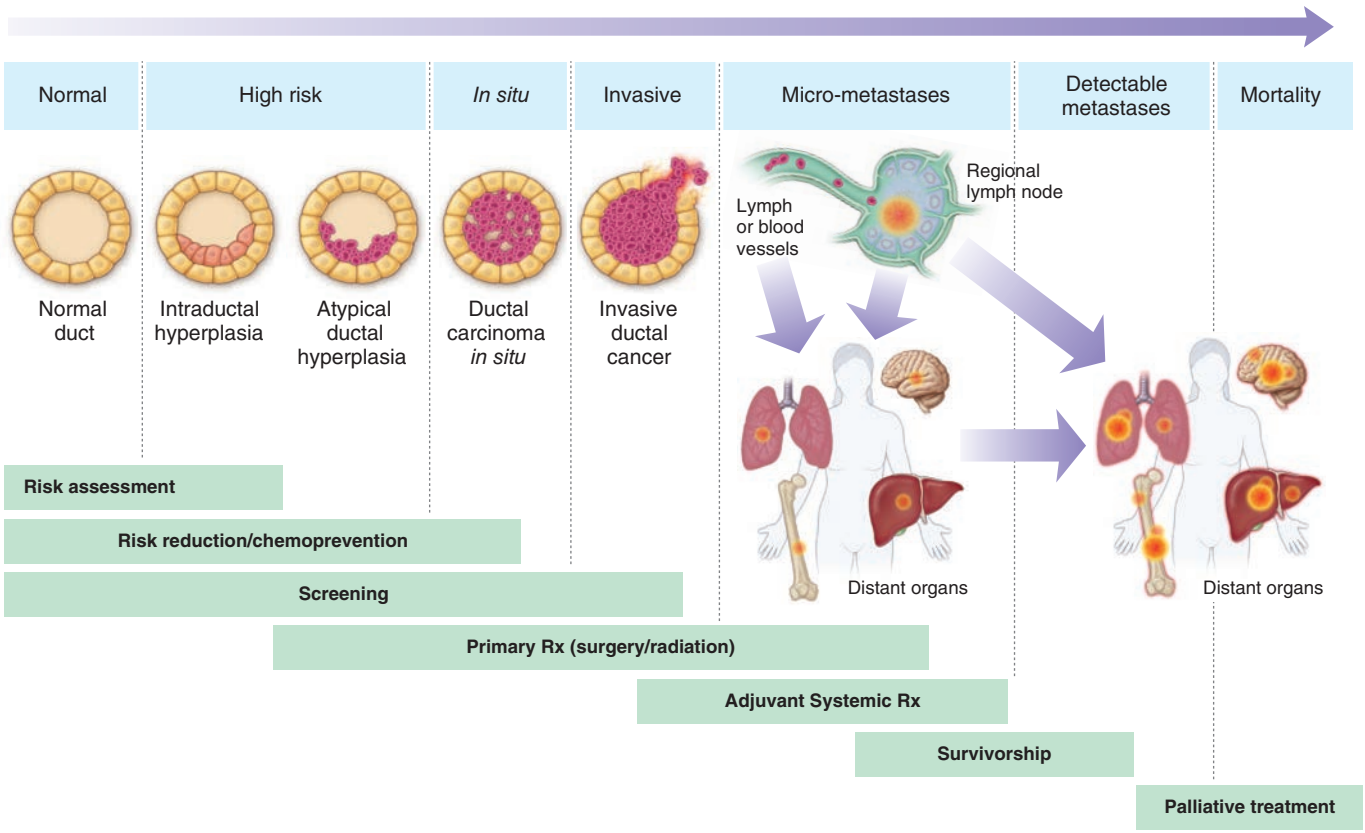

FIGURE 79-1 Breast cancer continuum conceptual model. Most breast cancers begin in epithelial cells within the lobules or ducts. They proceed through a continuum of atypia and hyperplasia to in situ malignancy to invasion into surrounding normal tissues followed by intravasation into lymph and blood channels to local lymph nodes and distant organs, culminating in distant metastases. This is a conceptual model. Not all metastatic breast cancers have progressed through these stages, and many lesions do not progress to the next.

catalytic subunit alpha (*PIK3CA*) make it susceptible to specific therapeutic interventions directed against each of these targets (Table 79-1). Furthermore, immune checkpoint inhibition has been applied to specific types of breast cancers.

EPIDEMIOLOGY AND RISK FACTORS

CLINICAL, HORMONAL, AND OTHER NONGENETIC RISK FACTORS

Seventy-five percent of all breast cancers occur in women aged >50 years, but breast cancer is not uncommon in women in their forties and can occur in women in their thirties and even twenties, and very rarely in adolescence.

Breast cancer is principally a sex hormone–dependent disease through increased activity of the ER and its ligands, estradiol and estrone (Fig. 79-1, Table 79-1). Indeed, the female-to-male ratio is ~150:1. Relative exposure to both endogenous and exogenous estrogens increases risk of breast cancer. Risk of developing breast cancer is higher in women with early menarche (<12 years) and late first full-term pregnancy (>35 years), and it is increased by exogenous hormone replacement therapy. Women without functioning ovaries, who experience an early menopause, or who never receive combination estrogen/progesterone replacement therapy are much less likely to develop breast cancer than those who have a normal menstrual history. Also, duration of maternal nursing correlates with substantial risk reduction independent of either parity or age at first full-term pregnancy.

Menstrual and reproductive history accounts for 70–80% of the variation in breast cancer frequency in different countries, providing insight into hormonal carcinogenesis. A woman living to age 80 years in North America has a one in nine chance of developing invasive breast cancer. Women who live in agrarian societies, especially in Asia, have traditionally had only 1/5th to 1/10th the risk of breast cancer of women in North America or Western Europe. However, Asian women who immigrate to North America or European countries during preadolescence or in adolescence have the same risk as women born in these countries. Further, with shifts from agrarian to industrialized economic systems, the incidence of breast cancer has risen dramatically in Asia, approaching that observed in Western nations.

Exogenous use of female hormones also plays a role in breast cancer incidence. The elevated risk related to oral contraceptives is quite modest if present at all. Regardless, this risk is more than balanced by avoidance of an undesired pregnancy and a substantial protective effect against ovarian epithelial and endometrial cancers.

Hormone replacement therapy (HRT) with conjugated equine estrogens plus progestins increases the risk of breast cancer; 6–7 years of HRT nearly doubles the risk of breast cancer and also increases the incidence of adverse cardiovascular events. However, it decreases the risk of bone fractures and colorectal cancer. On balance, more negative than positive events are associated with HRT. Administration of conjugated estrogens is usually combined with companion progesterone to abrogate the increased risk of endometrial cancer with estrogen alone. However, single-agent estrogen replacement therapy in women who have had hysterectomies produces no significant increase in breast cancer incidence and, if anything, reduces the risk. Thus, there are serious concerns about long-term HRT, especially in combination with progestins, in terms of cardiovascular disease and breast cancer. No comparable safety data are available for other less potent forms of estrogen replacement, such as bioequivalent estrogen found in soy, and they should not be routinely used as substitutes. Epidemiologic studies demonstrate a rapid decrease in elevated breast cancer incidence coincident with discontinuation of HRT.

HRT in women previously diagnosed with breast cancer, especially of the subtype that expresses ERs, counteracts much of the effectiveness of antineoplastic endocrine therapies and is contraindicated. Although

TABLE 79-1 Breast Cancer Molecular Features and Associated Targeted Therapies

MOLECULE	GENE THAT ENCODES MOLECULE	ABNORMALITY	CLASS OF TARGETED THERAPIES	SPECIFIC THERAPIES
Estrogen receptor (ER)	*ESR1*	Overexpression of cellular protein	Endocrine therapies	
			Estrogen ablation (surgical, chemical)	***Premenopausal*** Oophorectomy Luteinizing hormone releasing hormone (LHRH) agonists (goserelin, leuprolide) or antagonist (triptorelin) ***Postmenopausal*** Aromatase inhibitors (AIs) (anastrozole, letrozole, exemestane)
			ER antagonists	Selective estrogen receptor modulators (SERMs) (tamoxifen, toremifene, raloxifene) Selective estrogen receptor downregulators (SERDs) (fulvestrant)
Human epidermal growth factor receptor type 2 (HER2)	*c-neu/erbB2*	Overexpression of cell surface protein	Antibodies against HER2	Trastuzumab, pertuzumab, margetuximab
			Antibody-drug conjugates against HER2	Ado-trastuzumab emtansine, fam-trastuzumab deruxtecan-nxki
			Tyrosine kinase inhibitors	Lapatinib, neratinib, tucatinib
		Mutations	Tyrosine kinase inhibitors	Neratinib *(indication not FDA approved)*
Mammalian target of rapamycin (mTOR)	*MTOR*	Loss of protein suppressor of mTOR pathway, phosphatase and tensin homolog (*PTEN*)	Tyrosine kinase inhibitor	Everolimus
Cyclin-dependent kinase 4 and 6 (CDK4/6)	*CDK4, CDK6*	Loss of the protein suppressor of CDK4/6 pathway, retinoblastoma (*RB1*)	Inhibition of CDK4/6 enzyme activity	Palbociclib, ribociclib, abemociclib
Phosphatidylinositol-4,5-bisphosphate 3-kinase catalytic subunit alpha (PIK3CA)	*PIK3CA*	Mutations	Enzyme inhibition of mutated/activated PIK3CA protein	Alpelisib
BRCA1/2	*BRCA1, BRCA2*	Loss of tumor suppressor activity of BRCA1/2	Inhibition of poly (ADP-ribose) polymerase (PARP) activity and synthetic lethality	PARP inhibitors (olaparib, talazoparib)
TROP-2	*TACSTD2*	Over expression of TROP-2 cell surface protein	Antibody-drug conjugate against TROP-2	Sacituzumab govitecan
Immune checkpoints	NA	Programmed death-ligand 1 (PD-L1) suppression of immune effector cells	Inhibition of PD-L1/PD-1 suppression of immune effector cells	Atezolizumab

Abbreviations: FDA, U.S. Food and Drug Administration; NA, not applicable.

intravaginal estrogen therapy has been used for atrophic vaginitis associated with antiestrogenic endocrine therapies, it does result in some absorption and systemic estrogenic effects and should generally be avoided.

In addition to sex, age, and hormonal exposure, other risk features for breast cancer have been identified, but none with the kind of relative, attributable, or absolute risks associated with these three factors. Various differences in diets (including Asian agrarian vs modern economic) have been implicated as risk factors, although the role of diet in breast cancer etiology is controversial. Associative links exist between breast cancer risk and total caloric and fat intake, or even specific types of caloric intake, but the exact role of fat in the diet is unproven and may actually intersect with menstrual history and estrogenic exposure.

Central obesity, metabolic syndrome, and type 2 diabetes mellitus are all risk factors for occurrence and recurrence of breast cancer. Moderate alcohol intake also increases the risk by an unknown mechanism. Folic acid supplementation appears to modify risk in women who use alcohol but is not additionally protective in abstainers. Recommendations favoring abstinence from alcohol must be weighed against other social pressures and the possible cardioprotective effect of moderate alcohol intake. Depression is also associated with both occurrence and recurrence of breast cancer.

Certain benign breast pathologic findings, such as atypical hyperplasia and radial scars, are associated with higher risk of subsequent breast cancers. Prior radiation is a risk factor, but principally when delivered in adolescence or early child-bearing ages. Women who have been exposed before age 30 years to radiation in the form of multiple fluoroscopies (200–300 cGy) or treatment for Hodgkin's disease (>3600 cGy) have a substantial increase in risk of breast cancer, whereas radiation exposure after age 30 years appears to have a minimal carcinogenic effect on the breast. Radioactive iodine therapy for thyroid disease is not associated with increased risk of breast cancer, whereas mediastinal radiation in younger women for lymphoma is a powerful risk factor within the radiated field.

INHERITED GERMLINE SUSCEPTIBILITY FACTORS

Family history has long been recognized as a risk factor for breast cancer. A woman with a first-degree history (mother or sister) of breast cancer has an increased relative risk of approximately 30–50% (or one-third to one-half higher) over a woman with no family history. However, family history only accounts for 10–15% of all breast cancers. Most women who develop breast cancer do not have a strong family history. For women without an identifiable inherited genetic

abnormality, it is not clear whether the increased risk associated with family history is due to environmental causes or as yet unidentified genetic abnormalities.

The genetics of breast cancer require an understanding of the distinction between inherited, germline genetic differences among individuals and acquired, somatic genetic changes within cancers. The former are often called mutations but are more properly termed *single nucleotide polymorphisms* (SNPs). Some SNPs are synonymous, meaning they do not change the encoded amino acid in the affected protein product, and therefore are of no clinical significance. Some SNPs are nonsynonymous but may lead to a substituted amino acid that does not change the function of the protein, and they are likewise clinically insignificant. However, if an SNP leads to an amino acid substitution that alters the protein function or results in complete cessation of transcription or translation (a "stop" codon), it is considered deleterious and leads to higher susceptibility to developing cancer. In some cases, the significance of the SNP is unknown, and these are designated *variants of undetermined significance* (VUS).

The genes of interest serve, in the normal cell, to suppress expansion of a potentially malignant clone, either by repairing downstream randomly occurring somatic genetic abnormalities or, if not possible, by inducing programmed cell death, or apoptosis. Somatic genetic changes that are not inherited, including mutations, amplifications, insertions, deletions, translocations, and others, are responsible for the malignant behavior of a cancer, including unrestrained proliferation, as well as extravasation from one site and migration and establishment of metastases into another. As discussed below, some germline and somatic mutations can be exploited therapeutically (Table 79-1).

For most women, the increased risk associated with a family member who has had breast cancer appears to be related to both a weak, and probably multigene, germline susceptibility and similar exposure to environmental/lifestyle risk factors. Only approximately 10% of human breast cancers can be linked directly to a single inherited germline SNP. However, when one is present, the relative and absolute risks for that individual developing breast, and other, cancers in her lifetime are extraordinary.

The *BRCA1* and *BRCA2* genes, located on chromosomal loci 17q21 and 13q12, respectively, are the best characterized breast cancer susceptibility genes and have the greatest clinical importance in assessing genetic risk for breast cancer. Women who inherit mutated alleles of these genes from either parent have at least a 60–80% lifetime chance of developing breast cancer and about a 33% chance of developing ovarian cancer. The cancers that arise within a *BRCA1*-mutated patient are almost exclusively negative for ER, progesterone receptor (PgR), and HER2 (so-called "triple-negative" breast cancers). Men who carry a mutant allele of the gene have an increased incidence of breast and also prostate cancers, although the absolute risk of breast cancer in men with *BRCA2* germline SNPs is far lower than that for women who harbor them.

Overall, <1% of the general population and <5% of all patients with breast cancer harbor deleterious SNPs in *BRCA1* or *BRCA2*. Certain subgroups of women are more likely to have *BRCA1/2* mutations. The incidence is approximately 2% in women of Ashkenazi, Eastern European descent. Approximately 20% of women with triple-negative breast cancers will be positive for deleterious germline *BRCA1* SNPs, and genetic testing is warranted in most patients with triple-negative breast cancer even without a family history.

In contrast to those that arise in *BRCA1* carriers, cancers that arise in *BRCA2* contexts are more likely to be ER positive. The incidence of *BRCA2* mutations is much higher than *BRCA1* in men who develop breast cancer. However, most male breast cancer cases do not occur in *BRCA1/2*-mutated men, and the risk of breast cancer in men who do carry the *BRCA2* mutation is much lower than that in women with this genetic abnormality. Many other inherited germline mutations in known or putative tumor-suppressor genes, such as *p53* (which also accounts in part for the Li-Fraumeni familial cancer syndrome), *PTEN* (which accounts for Cowden's syndrome), and *PALB1,* have now been identified as important tumor-suppressor genes with clinical implications.

Inherited germline mutations are readily detected in blood tests of normal circulating leukocytes using so-called "panel" assays, which at present provide results from 30–45 different germline genes. However, because the rate of deleterious germline SNPS in these genes in the general population is quite low (well below 1%), germline panel genetic testing of the entire population of women is not recommended. Further, results are confounded by the presence of VUS in known tumor-suppressor genes, such as *BRCA1* and *BRCA2*, or deleterious variants or VUS in genes that are putative, but not proven, tumor-suppressor genes. Such results lead to confusion, anxiety, and inappropriate preventive strategies, such as prophylactic surgery, in individuals who may not actually be at higher risk.

Consensus guidelines on who should be tested include any woman with a family member who has been tested and found to harbor a deleterious SNP in a germline tumor-suppressor gene. Testing is indicated for any breast cancer patient with a triple-negative breast cancer, who is <40 years old, who has synchronous or metachronous contralateral breast cancers, who has a personal history of ovarian cancer, or who has a first-degree relative (mother, father, or sister) with breast or ovarian cancer. All males with breast cancer should be tested. Some guidelines suggest testing any breast cancer patient of Ashkenazi descent. Patients with these mutations should be counseled appropriately.

Some experts have recommended testing any patient diagnosed with breast cancer, both for genetic counseling but also because of the advent of effective therapies directed toward cancers that have deleterious *BRCA1/2* mutations (Table 79-1), although this strategy remains controversial. Regardless, any patient who is found to have inherited germline deleterious SNPs should receive formal genetic testing and counseling about special screening and prevention measures they might take.

PREVENTION OF BREAST CANCER

One major reason to determine risk would be to efficiently apply prevention and/or screening strategies, if either has been shown to be effective for the disease of interest. At present, although diet and exercise are certainly recommended approaches to healthy living, none has been proven to specifically decrease a woman's risk of breast cancer. Avoidance of combined estrogen/progestin HRT reduces the associated increased risk of breast cancer to that of an average woman not using HRT.

Prophylactic removal of the breasts is an effective, albeit drastic, preventive strategy. Bilateral prophylactic mastectomies reduce the risk of breast cancer incidence and mortality by >95%. Because breasts are not encapsulated organs, some normal breast tissue is always left behind, and therefore, women who elect to have prophylactic mastectomies should be counseled that they still have some risk of developing a new breast cancer. Prophylactic mastectomy is most often chosen by women with germline genetic risk, in whom there is evidence of mortality reduction. For women with average or only mildly elevated risks, such as diagnosis of a unilateral breast cancer, survival is not increased by prophylactic mastectomy, and, because of its obvious adverse effect on sexuality, cosmesis, and breast-feeding, this approach is not considered appropriate.

So-called "chemoprevention" to lower breast cancer risk can be achieved with therapies directed toward the ER/estrogen signaling pathway (Table 79-1). These include the selective estrogen receptor modulators (SERMs) as well as aromatase inhibition. The latter should only be applied in postmenopausal women, since aromatase inhibition can result in a paradoxical increase in circulating estrogen levels in women with functioning ovaries. Chemoprevention with SERMs or aromatase inhibition lowers risk of ER-positive breast cancer by approximately one-half, although it has no effect on the more lethal ER-negative breast cancers. Of interest, prophylactic bilateral oophorectomy and salpingo-oophorectomy, which are often performed in women with high genetic risk (such as those with inherited *BRCA1/2* deleterious SNPs), also reduce breast cancer in addition to ovarian cancer risk.

SCREENING FOR BREAST CANCER (FIG. 79-2)

Screening mammography results in earlier diagnosis and subsequent local and systemic therapy. Overviews of nine prospective randomized clinical trials demonstrate that screening mammography reduces breast cancer mortality by one-fifth to one-quarter in women aged ≥50 years. The relative reduction in breast cancer mortality for women between ages 40 and 50 years is similar, although the absolute numbers of women who benefit in this age group is smaller since the incidence of breast cancer is much lower in younger women. In addition to reducing breast cancer mortality, screening mammography and early detection are more likely to identify tumors at a stage more appropriate for conservative local therapy. Better technology, including digitized mammography, tomosynthesis, routine use of magnified views, and greater skill in interpretation, have all improved the accuracy of mammography. Magnetic resonance spectroscopy has higher sensitivity but lower specificity than mammography. Since none of these newer technologies has been shown to be superior to mammography in terms of mortality reduction, screening of women with standard risk by any technique other than mammography is not recommended.

The issue of screening breast imaging of any sort has been controversial. Although the prospective randomized clinical trials demonstrate a late reduction in breast cancer mortality, they do not demonstrate improvement in overall survival. Further, many authors have raised concern about diagnosis of cancers that may be biologically insignificant, raising the specter of overdiagnosis and overtreatment. Moreover, the substantial advances in both local and systemic therapies for breast cancer may have reduced the benefit of earlier diagnosis provided by screening. In contrast, in countries that have adopted widespread screening programs, nonrandomized, epidemiologic studies have demonstrated even greater magnitude reductions in breast cancer mortality than those seen in the randomized trials. Taken together, these data have led most guideline bodies to recommend annual screening for women aged 50–70 years. Many have also recommended screening for women in the 40- to 50-year-old range. For older women, caregiver and patient judgment should be used, taking into account comorbidities.

Magnetic resonance imaging (MRI) is recommended for women with particularly dense breasts, women whose first cancer was not detected by mammography, women with an axillary breast cancer presentation but no definable breast mass on physical exam or mammography, and those with high genetic risk, such as *BRCA1* or *BRCA2* carriers or those with Li-Fraumeni, Cowden's, or Bannayan-Riley-Ruvalcaba syndromes. MRI might also be considered for women with a history of radiation therapy to the chest between ages 10 and 30 years. In these women, the positive predictive value of MRI is higher because

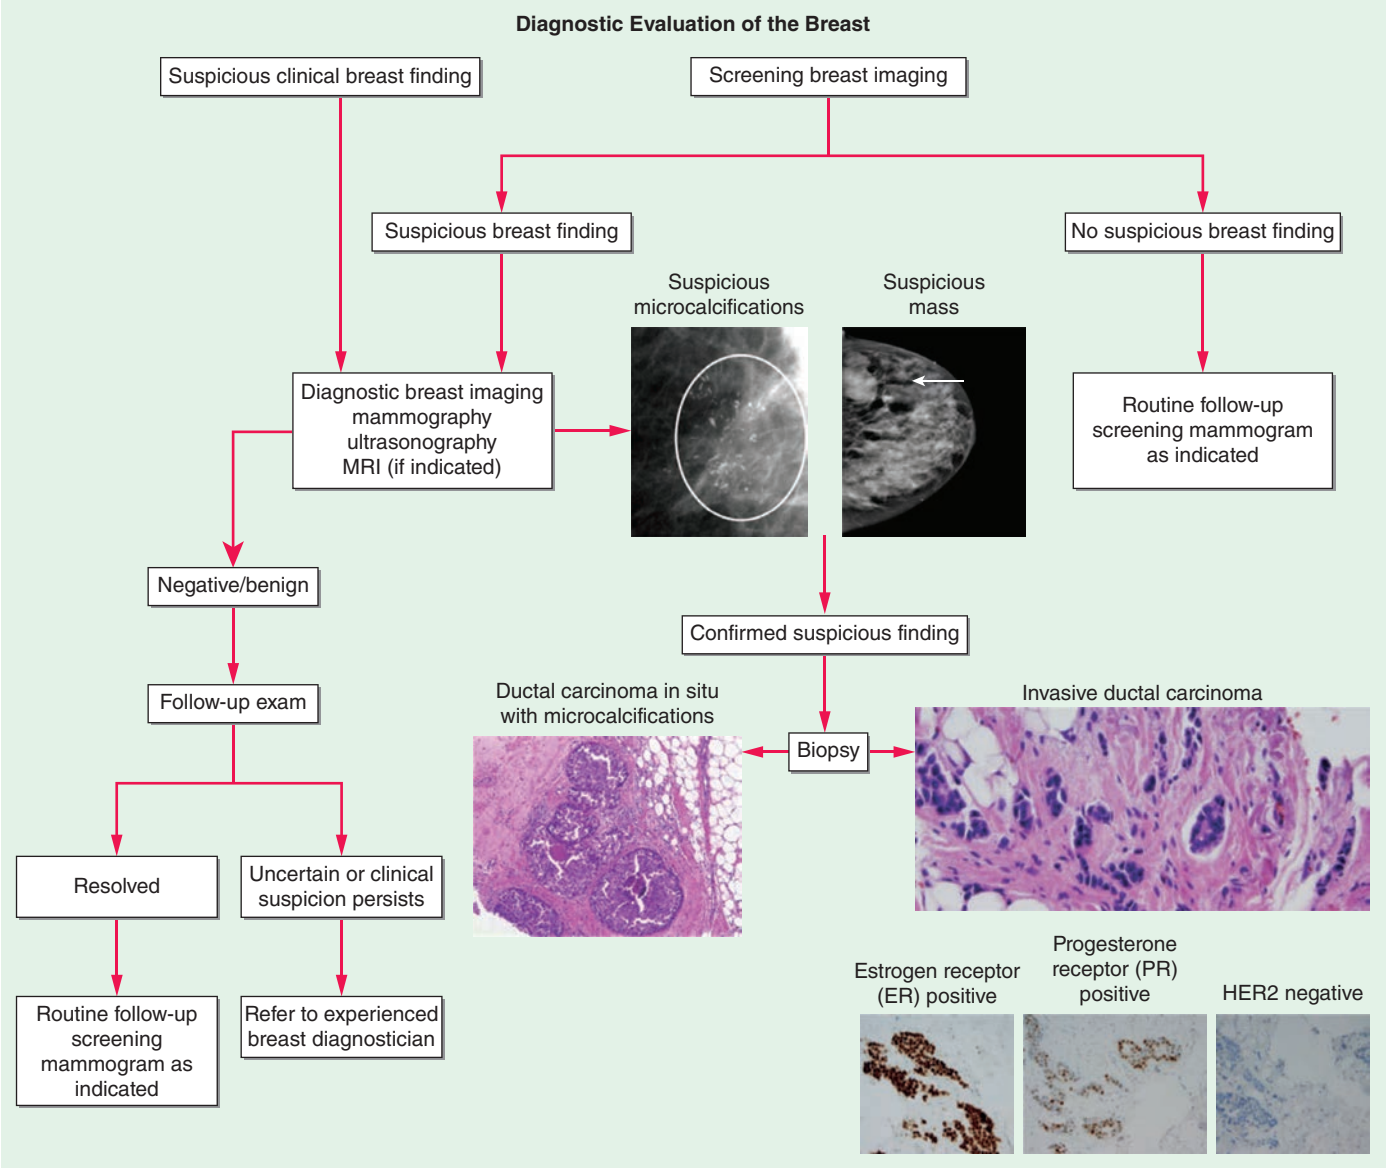

FIGURE 79-2 Evaluation and workup of breast lesions. For more extensive details, see *https://www.nccn.org/professionals/physician_gls/pdf/breast-screening.pdf. (Mammographic images courtesy of Drs. Mark Helvie and Colleen Neal, Department of Radiology, Michigan Medicine. Photomicrographs courtesy of Dr. Celina Kleer, Department of Pathology, Michigan Medicine.)*

of the higher incidence of cancer, and furthermore, many of them are considering prophylactic mastectomy as an alternative; therefore, the lower specificity and risk of a false-positive finding has been considered more acceptable.

Self-examination or physical breast examinations done by a health professional have poor sensitivity and specificity, and regular breast self-examination is not recommended. Nonetheless, all women should be familiar with how their breasts normally look and feel and report any changes to a health care provider right away. Because the breasts are a common site of potentially fatal malignancy in women, examination of the breast is an important part of a routine physical examination.

Screening breast imaging is not recommended for men, since it is so unusual and easily detected. It is important to note that unilateral lesions should be evaluated in the same manner as in women with an appropriately high index of suspicion.

EVALUATION OF BREAST MASSES (FIG. 79-2)

Virtually all breast cancer is diagnosed by biopsy of an abnormality detected either on a mammogram or by palpation. The presence or absence of any risk factors, such as age, family history, or menstrual history cannot be used to exclude more careful workup and, if indicated, a biopsy. Any woman with a persistent breast abnormality should be referred to an experienced breast diagnostician in order to avoid delay in diagnosis and therapy.

PALPABLE BREAST MASSES

Proper attention needs to be given to any abnormality either discovered by the patient or appreciated by the health care provider during examination. Most newly diagnosed breast cancers are asymptomatic. Lesions with certain clinical features, including firmness, irregularity, tethering or fixation to the underlying chest wall, and dermal erythema or peau d'orange (skin edema with pockmarking), are very worrisome for breast cancer. In contrast, painful masses and those that are cystic on physical examination are less likely malignant. However, none of these has a high positive or negative predictive value. Likewise, a negative mammogram in the presence of a persistent lump in the breast does not exclude malignancy and, again, deserves careful workup.

In premenopausal women, lesions that are either equivocal or nonsuspicious on physical examination should be reexamined in 2–4 weeks during the follicular phase of the menstrual cycle. Days 5–7 of the cycle are the best time for breast examination. A dominant mass in a postmenopausal woman or a dominant mass that persists through a menstrual cycle in a premenopausal woman requires further evaluation, likely including biopsy if appropriate.

ABNORMAL MAMMOGRAM

Diagnostic mammography, which is performed after a palpable abnormality has been detected, should not be confused with *screening mammography*, which is performed in an asymptomatic woman with no previously identified abnormalities.

Abnormalities that are first detected by physical exam and/or screening mammography should be evaluated by diagnostic mammography. Suspicious mammographic abnormalities include clustered, heterogeneous, linear, and branching microcalcifications; densities (especially if spiculated); and new or enlarging architectural distortion. For some lesions, ultrasound may be helpful either to identify cysts or to guide biopsy. If there is no palpable lesion and detailed mammographic studies are unequivocally benign, the patient should have routine follow-up appropriate to the patient's age. If a nonpalpable mammographic lesion has a low index of suspicion, mammographic follow-up in 3–6 months is reasonable. The presence of a breast lump and a negative mammogram does not rule out cancer, and if the physical finding persists or enlarges during follow-up, further evaluation and, if appropriate, a biopsy are indicated.

BREAST MASSES IN PREGNANCY OR LACTATION

Breast cancer develops in 1 of 3000–4000 pregnancies. The breast grows during pregnancy under the influence of estrogen, progesterone, prolactin, and human placental lactogen. After delivery and during lactation, breast tissue continues to be under the influence of unopposed prolactin. Therefore, breast examination during these times can be challenging. Nonetheless, development of a dominant mass during pregnancy or lactation should not be attributed to hormonal changes without appropriate diagnostic evaluation. Stage for stage, breast cancer in pregnant patients is no different from premenopausal breast cancer in nonpregnant patients. However, pregnant women often have more advanced disease because the significance of a breast mass was not fully considered and/or because of endogenous hormone stimulation.

PATHOLOGIC FINDINGS OF THE BREAST

BENIGN BREAST HISTOPATHOLOGY

Only ~1 in every 5–10 breast biopsies leads to a diagnosis of cancer, although the rate of positive biopsies varies in different countries and clinical settings due to variable interpretation, medico-legal considerations, and availability of mammograms. The vast majority of benign breast masses are due to fibrocystic changes, a descriptive term for small fluid-filled cysts and modest epithelial cell and fibrous tissue hyperplasia. Women with ductal or lobular cell proliferation (~30% of patients), particularly the small fraction (3%) with atypical hyperplasia, have a fourfold greater risk of developing breast cancer than women who have not had a biopsy, and the risk is even higher if they have an affected first-degree relative. Follow-up breast imaging should be continued, but not on an accelerated or more intense fashion than regularly indicated. Chemoprevention with antiestrogen therapy (SERM or aromatase inhibitor [AI]) should be considered for such patients. Prophylactic mastectomy is not normally indicated. By contrast, patients with a benign biopsy without atypical hyperplasia are at little increased risk and may be followed routinely.

NONINVASIVE BREAST NEOPLASMS

Breast cancer develops as a series of molecular changes in the epithelial cells that lead to ever more malignant behavior (Fig. 79-1). These changes range from malignant cells confined within the basement membrane of the lobule or duct, designated "noninvasive" or more commonly "in situ" carcinoma, to cancer cells that have invaded through the basement membrane into the surrounding normal tissue ("invasive" or "infiltrating" cancer). Increased use of mammography has led to more frequent diagnoses of noninvasive breast neoplasms. These lesions fall into two groups: ductal carcinoma in situ (DCIS) (Fig. 79-2) and lobular carcinoma in situ (LCIS; or lobular neoplasia in situ [LNIS]). The management of both entities is controversial.

Ductal Carcinoma In Situ Proliferation of cytologically malignant breast epithelial cells within the ducts is termed *ductal carcinoma in situ* (DCIS). Atypical hyperplasia may be difficult to distinguish from DCIS. In many ways, DCIS is really a "premalignant" condition, but probably at least one-third of patients with untreated DCIS develop invasive breast cancer within 5 years. However, many low-grade DCIS lesions do not appear to progress over many years; therefore, many patients are overtreated. Unfortunately, no reliable methods distinguish patients who require treatment from those who may be safely observed.

Mastectomy is nearly 100% effective in preventing a future breast cancer event in that breast and fundamentally can be considered prophylactic surgery, but is often not required for adequate treatment. No prospective randomized studies have directly compared breast-preserving therapy to mastectomy. However, the nearly 100% 10-year survival rates with the former suggest that it is a satisfactory strategy. Breast-preserving therapy refers to excisional surgery alone with or without breast radiation. However, although survival was identical in the two arms of a randomized trial comparing wide excision plus or minus irradiation, the latter caused a substantial reduction in the local recurrence rate as compared with wide excision alone. Addition of tamoxifen or an AI to any DCIS surgical/radiation therapy regimen further improves local control. However, in the largest trial comparing the two in DCIS, anastrozole did not improve distant disease-free or overall survival compared to tamoxifen.

Several prognostic features may help to identify patients at high risk for local recurrence after either lumpectomy alone or lumpectomy with radiation therapy and, therefore, might provide an indication for mastectomy. These include extensive disease within the breast; age <40; and cytologic features such as necrosis, poor nuclear grade, and comedo subtype with overexpression of *HER2*. In summary, it is reasonable to recommend breast-preserving surgery for patients who have a localized focus of DCIS with clear margins followed by breast irradiation and tamoxifen or anastrozole. Recently, a multifactorial gene expression assay has been shown to predict risk of recurrence in DCIS treated with breast-preserving surgery alone, but it is not clear that the in-breast risk recurrence rate in patients with low recurrence scores is sufficient to avoid radiation. The decision to irradiate such patients depends on the risk aversion to in-breast recurrence balanced against the risk associated with breast irradiation.

For patients with small, unicentric DCIS, axillary lymph node dissection is unnecessary. However, axillary sentinel lymph node (SLN) evaluation, which is discussed in greater detail below, may be indicated for widespread, larger, or poor grade DCIS or if microscopic invasion is identified on a core biopsy. In such cases, subsequent excision or mastectomy may demonstrate invasive disease on the larger specimen. Since SLN mapping is indicated in such patients, doing so at the time of excision or mastectomy avoids a further surgical procedure at a later date.

Lobular Carcinoma (Neoplasia) In Situ The presence of malignant cells within the lobules is termed *lobular carcinoma or neoplasia in situ* (LCIS). LCIS does not usually cause palpable breast masses, nor does it often induce suspicious findings on mammogram. Therefore, it usually is found as an incidental finding during pathologic examination of a breast biopsy performed for some other reason. Unlike DCIS, which is usually confined to a single area in a breast, LCIS is often spread throughout the breast, and it is frequently also found in the contralateral breast.

A diagnosis of LCIS itself does not confer a higher risk of mortality from breast cancer, but it does increase the risk of a subsequent breast cancer. Women with LCIS who do not undergo bilateral prophylactic mastectomy experience a new, invasive cancer in either breast at a rate of approximately 1% per year over at least the next 15–20 years, and probably lifelong. Therefore, LCIS is even more commonly considered a premalignant condition than DCIS, and aggressive local management seems unreasonable. Management options include careful observation with routine mammography and chemoprevention with either a SERM or an AI (for postmenopausal women) for 5 years. Beyond 5 years, such patients should be followed with subsequent annual mammography and semi-annual physical examinations. Bilateral prophylactic mastectomy is an alternative option, although it is no more effective in prolonging survival than the less aggressive approach, and it associated with substantial cosmetic, and perhaps emotional, morbidity.

INVASIVE BREAST CANCERS

Invasive breast cancers are of more concern than in situ lesions because they harbor the capacity to metastasize and cause substantial morbidity and mortality (Fig. 79-1). Eighty-five percent of invasive breast cancers are ductal in origin (Fig. 79-2), 10% are lobular or mixed ductal/lobular, and the other 5% are made up of so-called "special types" including mucinous or colloid (2.4%), tubular (1.5%), medullary (1.2%), and papillary (1%). Although not universally true, prognosis for the special types tends to be better than standard ductal or lobular cancers.

STAGING AND DIAGNOSTIC CONSIDERATIONS

Cancer staging has been traditionally based on the size of the tumor (T) and the presence or absence of regional nodal (N) and distant metastases (M). More recently, tumor grade and biological characteristics, such as expression of ER and HER2, have been incorporated into staging, making the system quite complex. Staging can be performed clinically or pathologically, before or after adjuvant systemic therapy. These are designated as a prefix before the stage as cTNM or pTNM if determined before or yTNM if determined after systemic (neoadjuvant) therapy. Although staging is an important part of the surgical evaluation and pathology reporting system, the specific elements that inform the clinician of both prognosis and likelihood of response to specific therapies have become more critical determinants of patient care than a simple stage designation. Importantly, imaging for detection of distant metastases is not needed in a patient with no signs or symptoms of widespread disease and who has a T3 or smaller tumor and fewer than four involved axillary lymph nodes, since the odds of finding distant metastases in such patients are low and the risk of false positives outweighs true-positive findings. Although finding bone marrow micrometastases or circulating tumor cells (cM0(i+)) has been associated with worse prognosis, how to integrate these into routine clinical care has not been determined, and their assessment is not recommended in patients with early-stage disease.

TREATMENT

Early-Stage Breast Cancer

GENERAL CONSIDERATIONS

Goals of Therapy The goal of therapy for breast cancer in patients who do not have obvious evidence of distant metastases (meaning outside the breast, chest wall, and regional lymph nodes) is cure, or at least substantial survival prolongation. For these patients, treatment strategies are divided into primary and systemic considerations. Primary therapies consist of surgical and radiation treatments directed toward the breast and locoregional lymph nodes. These approaches are designed to minimize the odds of locoregional recurrence while maintaining quality of life and cosmesis as much as possible by excising the cancer and sterilizing unaffected breast tissue as appropriate. Adjuvant systemic treatments, consisting of endocrine, anti-HER2, and/or chemotherapies, are given to treat micrometastases that may have already escaped to distant sites but are not yet detectable.

Prognostic and Predictive Factors All treatments for breast cancer are based on prognostic and predictive factors. Prognostic factors provide an indication of how likely a cancer will recur either locally or in distant organs in the future if a patient is not treated with the respective treatments. Predictive factors are used to determine if a given treatment is likely to work or not, assuming the patient's prognosis justifies treatment (or further treatment assuming the patient has been treated in some manner already).

Anatomic prognostic features include visual and physical examination findings of locally advanced breast cancer (T4 lesions: skin erythema ["inflammatory"] or edema ["peau d'orange"], nodules, or ulceration or tumor fixation to the chest wall). In patients without any of these findings, the most important prognostic features remain tumor size (T) and lymph node (N) status.

Biologic features, such as histologic tumor grade as well as ER, PgR, and HER2 status, are also prognostic. Indeed, gene expression patterns, or "signatures," have demonstrated that breast cancer is actually many different diseases and can be divided into a series of intrinsic subtypes. These subtypes are driven principally, although not exclusively, by expression of ER and HER2 and their respective associated pathways, as well as measures of cellular proliferation and other less important but still contributory biologic features. These intrinsic subtypes are important clinically, both in influencing natural history as well as in prognosis and therapeutic decision making. Four different intrinsic subtypes are recognized: luminal, HER2-like, basal, and claudin-low. Some, if not all, have been further divided into subgroups.

Luminal breast cancers are almost always positive for ER and negative for HER2 amplification. *Luminal A* tumors have the highest levels of ER and downstream related genes, are almost universally negative or low in HER2, are usually low grade, have low proliferative thrust, and have a generally favorable prognosis. They are most likely to respond to endocrine therapy and may appear

to be less responsive to chemotherapy. *Luminal B* breast cancers tend to be PgR negative, may express HER2 but at low levels, are usually higher grade, and have higher proliferative activity than luminal A tumors. Prognosis is somewhat worse than for luminal A cancers, and although not yet proven, they may be more sensitive to chemotherapy.

HER2-amplified breast cancers exhibit co-amplification and overexpression of other genes adjacent to *HER2*. Historically, the clinical prognosis of such tumors was poor, but it has markedly improved with the introduction of targeted anti-HER2 therapies.

Basal breast cancers are mostly negative for expression of ER/PgR and HER2. Tumors of this type are often called "triple-negative" malignancies, although this is a general term, and such cancers have been further subgrouped based on other genetic abnormalities. They tend to be high grade and express cytokeratins 5/6 and 17 as well as vimentin, p63, CD10, α-smooth muscle actin, and epidermal growth factor receptor (EGFR). Patients with germline *BRCA1* mutations also usually fall within this molecular subtype.

Normal breast-like and *claudin-low* cancers have also been distinguished, but at present, these designations have failed to have clinical significance.

Over the past decade, several multiparameter tests based on gene expression have been developed to determine prognosis in patients who have node-negative, ER-positive, and HER2-negative disease. These assays have been principally used to guide decisions regarding use of adjuvant chemotherapy, as discussed below. Predictive features are usually used to guide targeted systemic therapies. These include ER for endocrine treatments and HER2 for anti-HER2 therapies, such as trastuzumab, and more recently *BRCA1/2* and *PIK3CA* mutations for poly (ADP ribose) polymerase (PARP) inhibitors and PIK3CA inhibitors, respectively.

LOCAL (PRIMARY) TREATMENTS

In the 1980s, the Halsted radical mastectomy was replaced with the less disfiguring modified radical mastectomy, in which chest wall muscles are preserved and only a sampling of axillary lymph nodes are removed. Subsequently, breast-conserving treatments, consisting of surgical excision of the primary tumor (lumpectomy, quadrantectomy, or partial mastectomy) often followed by locoregional radiation, were introduced and shown to have equal if not slightly superior outcomes to those associated with mastectomy. For women undergoing breast conservation, postlumpectomy radiation is usually indicated, although it may be less necessary in older women with ER-positive, node-negative breast cancer, since their risk of subsequent in-breast recurrence is quite low with surgery and endocrine therapy only. When lumpectomy with negative tumor margins is achieved and radiation is delivered appropriately, breast conservation is associated with a recurrence rate in the breast of ≤5%.

Not all patients are candidates for breast-conserving therapy. Contraindications include large tumor to breast ratio, inability to achieve clear margins with adequate cosmesis after extensive surgery, multifocal cancers, extensive four-quadrant DCIS, and inability to receive radiation. The latter issue arises in women with dermal autoimmune disease (such as lupus erythematosus), prior radiation to the site, and/or lack of available radiation treatment facilities. Further, although not contraindicated, breast-conserving therapy may be less cosmetically acceptable than mastectomy with reconstruction if the nipple-areolar complex is involved with cancer and must be sacrificed. This is a personal choice, and some women prefer mastectomy, especially those with high genetic risks for second breast cancers.

Enigmatically, in spite of the supporting data, only approximately one-third of women in the United States are managed by lumpectomy. It appears that many women still undergo mastectomy who could safely avoid this procedure and probably would if appropriately counseled. Most patients should consult with an experienced breast surgeon and radiation oncologist before making a final decision concerning local therapy. Indeed, a multimodality clinic in which the surgeon, radiation oncologist, medical oncologist, and other caregivers cooperate to evaluate the patient and develop a treatment plan is usually considered a major advantage by patients.

For patients who do undergo mastectomy, nipple-areolar-sparing mastectomy preserves the dermis and epidermis of the nipple but removes the major ducts from within the nipple lumen and often provides more acceptable cosmesis when combined with reconstruction. This approach is often a preferable option for patients who are having prophylactic surgery or those with cancer who are candidates for immediate reconstruction. Nipple-sparing mastectomy is contraindicated in the presence of inflammatory breast cancer, clinical involvement of the nipple-areolar complex, nipple retraction, Paget disease, bloody nipple discharge, or multicentricity. The safety of nipple-sparing mastectomy is based on retrospective, nonrandomized cohort series. In a meta-analysis of 20 studies (5594 patients), overall and disease-free survival and locoregional recurrence rates appeared similar to those of patients undergoing modified radical mastectomy.

After mastectomy, breast reconstruction is an acceptable option. Breast reconstruction can be achieved by either placement of an exogenous implant (usually silicon) or by transferring autologous tissue from another site, such as the abdomen, latissimus dorsi, or gluteal areas, to the breast. Of note, patients should be aware that a reconstructed breast is usually insensate. Risks of reconstruction include surgical complications such as infection and hemorrhage. Reconstruction does not hinder detection of future recurrences, nor is silicone implant reconstruction associated with non-cancer-related syndromes, although on occasion, these can rupture and removal is required. Breast implant–associated anaplastic large cell lymphoma is an extraordinarily rare complication of textured silicone implants. Although occasionally associated with metastatic lymphoma, it is usually confined locally and highly curable. The optimal choice of implant reconstruction should be made with an experienced breast plastic surgeon.

Postmastectomy chest wall and regional nodal radiation reduces locoregional recurrence and improves survival. It is indicated for patients with high risk of locoregional recurrence, such as those with tumors ≥5 cm, four or more positive axillary lymph nodes, or postoperative positive margins. Postmastectomy radiation is not indicated in women with cancers <2 cm, negative lymph nodes, and negative margins. It is considered for women who fall into the areas between these (2–5 cm, one to three positive nodes, or close margins) and is usually recommended if a patient has one to three involved axillary lymph nodes. Many radiation oncologists and plastic surgeons prefer postmastectomy radiation before reconstruction.

The survival of patients who have recurrence in the breast after proper treatment (adequate surgery and radiation if indicated) is somewhat worse than that of women who do not have in-breast recurrences, but it is better than those who suffer locoregional recurrence after mastectomy. Thus, locoregional recurrence is a negative prognostic variable for long-term survival but not the *cause* of distant metastasis.

Evaluation and Treatment of the Axillary Lymph Nodes SLN mapping and biopsy (SLNB) is generally the standard of care for women with localized breast cancer and clinically negative axilla. This procedure involves injecting a dye or radioactive tracer into the involved breast and, a few hours (4–24) later, undergoing resection of the axillary node containing the dye or tracer. If that lymph node is negative for tumor, more extensive axillary surgery is not required, avoiding much of the risk of postdissection lymphedema. Even in the presence of sentinel lymph node involvement, further axillary surgery may not be required for selected patients, such as older women and those with ER-positive cancers.

ADJUVANT SYSTEMIC THERAPIES

The use of adjuvant systemic therapy is based on the concept that with increasing generations of cellular replication, genetic abnormalities accumulate. These mutations occur randomly and may lead to sensitivity or resistance to therapies, but of course, the latter

is of greater concern. Almost all patients with metastatic breast cancer are destined to die with, if not of, their cancer. However, treatment with the same therapies administered earlier, in the setting of micrometastatic disease only, is more effective than waiting until symptomatic, documented metastases occur and substantially improves survival. More than half of the women who would otherwise die of metastatic breast cancer remain disease-free and experience considerable survival advantage when treated with the appropriate adjuvant systemic regimen.

Prognostic and Predictive Variables Adjuvant systemic therapies are of three types: (1) chemotherapy; (2) endocrine therapy; and (3) anti-HER2 therapies. The decision of whether to apply adjuvant systemic therapy, and which type, depends on prognostic and predictive features as well as the combined judgment of the patient and caregiver.

Prognostic Factors As noted, prognostic factors help define who most likely needs, or perhaps more importantly does not need, adjuvant systemic therapy. In contrast, predictive factors help identify which therapies are likely to work, independent of prognosis (Table 79-1). The most important prognostic variables are provided by *tumor staging: tumor size (T), lymph node status (N), and detectable distant metastases (M)* **(Table 79-2)**. *Histologic grading* is also important. Tumors with a poor nuclear grade (grade 3) have a higher risk of recurrence than tumors with a good nuclear grade (grade 1). Infiltrating lobular cancer, which is almost always ER positive, has roughly the same prognosis as ER-positive infiltrating ductal cancer, although the lobular subtype may be slightly worse. Lobular cancers are harder to detect on mammography and within axillary lymph nodes than ductal cancers, and when they do metastasize, they often spread to unusual sites, such as mesothelial surfaces, the ovaries, and gastrointestinal organs. Among the special types of breast cancer, pure tubular and mucinous cancers are associated with very favorable prognoses. Medullary cancers are often triple negative with poor nuclear grade, but paradoxically, they have a heavy infiltrating lymphocyte component, and they also have a favorable prognosis. However, before treatment is directed toward these types of cancers, their histology should be confirmed by an experienced breast pathologist.

Adjuvant systemic therapy may not be needed at all for patients with very small (<1 cm) tumors and negative lymph nodes. However, every patient with invasive breast cancer has some risk of subsequent distant metastases. Most patients are more likely to accept endocrine therapy for a very small potential benefit than they would accept chemotherapy for the same calculated advantage because the former is much less often associated with either life-threatening or permanently life-changing toxicities.

The greatest controversy concerns the recommendation for adjuvant *chemotherapy*. Since no established factor predicts sensitivity or resistance for this class of treatments, the decision must be made on prognosis alone. Overall, chemotherapy reduces the risk of recurrence over the 10 years subsequent to primary diagnosis by approximately one-third. For patients with T4 cancers or many positive lymph nodes, the risk of distant recurrence (and thus not being cured) in the subsequent decade is 50% or higher. Therefore, a one-third reduction of a 50% risk of recurrence means that at least 15–20% (one-third × 50%) of women will be cured who would not have been cured in the absence of adjuvant chemotherapy. The life-threatening or permanently life-changing toxicities of adjuvant chemotherapy are ~1–2%, and therefore, almost all medical oncologists would recommend adjuvant chemotherapy in this setting.

In contrast, adjuvant chemotherapy is rarely justified in most women with tumors <1 cm in size whose axillary lymph nodes are negative. However, this decision is very much influenced by the expression of ER and HER2. For example, the risk of recurrence of a patient with a small, node-negative but triple-negative breast cancer over the succeeding 10 years without any adjuvant therapy is 15%. If chemotherapy reduces this risk by approximately one-third or more, then approximately 5% or more of patients will be cured who would otherwise have died of their disease. Likewise, a patient with ER- and PgR-negative but HER2-*positive* disease has a slightly worse prognosis, with a risk of recurrence over 10 years of approximately 20%. She will benefit not only from the adjuvant chemotherapy but also from anti-HER2 therapy, so that her potential absolute benefit is even higher. Many, but not all, clinicians would recommend adjuvant chemotherapy for such patients.

On the other hand, patients with ER-positive disease have a better prognosis than those with ER-negative breast cancer, and adjuvant endocrine therapy will further reduce the odds of recurrence by approximately one-half. Therefore, the same patient in the example above (<1 cm, node negative) but who has an ER-positive and HER2-negative cancer has a lower initial risk of recurrence (~10% over 10 years). She is very likely to accept adjuvant endocrine therapy, further lowering her estimated risk of recurrence to ~5%. Even if chemotherapy reduces this residual risk by approximately one-third, no more than 1–2% (one-third × 5%) of patients will benefit. This potential benefit is approximately the same as the number of patients who will suffer life-threatening or permanently life-changing toxicities from chemotherapy. Thus, in this case, most clinicians would recommend adjuvant endocrine therapy but not chemotherapy.

Multiparameter gene expression assays have refined prognostic determination, particularly in node-negative, ER-positive, and HER2-negative breast cancers. These tests include the 21-gene Oncotype DX, the 12-gene Endopredict, the 58-gene ProSigna, and the 2-gene Breast Cancer Index. Furthermore, several investigators have reported that analysis of ER, PgR, HER2, and Ki67 by immunohistochemistry (IHC4) also provides prognostic information in this group, but the analytical validity of this assay is quite variable among different pathologists. Assuming adequate adjuvant endocrine therapy, the prognosis of such patients whose tumors have low recurrence scores, which usually identifies luminal A type cancers, with one of these assays is so good they can safely forego adjuvant chemotherapy. Indeed, the same is true for such patients with intermediate Oncotype DX recurrence scores. In contrast, those with high recurrence scores (>25) appear to have luminal B cancers, and the benefits of adjuvant chemotherapy clearly outweigh the risks.

The largest data set for directing care has been generated using the 21-gene recurrence score. However, only one of these tests should be ordered for a single patient, since they do not always give the same results, and there are no data to determine which, in the case of discordance, might be "correct." Use of these assays to determine prognosis in patients with higher anatomic stage, such as T3b/T4 lesions, or multiple positive lymph nodes, especially if more than three, is still under investigation.

Several *measures of tumor growth rate* correlate with early relapse, but their use is problematic due to analytical variability. Of these, assessment using immunohistochemical (IHC) assays for the proliferation marker Ki67 is the most widespread. However, substantial lab-to-lab variability and disagreement regarding optimal cut points exist. At present, in standard practice outside of a highly skilled laboratory, Ki67 expression is not used to make clinical decisions.

Predictive Factors The two most important predictive factors in breast cancer are ER and HER2 expression, and they should be performed on all primary or metastatic cancer biopsy specimens (Table 79-1). Adjuvant endocrine therapy reduces the risk of recurrence by one-half or more in patients with ER-rich cancers, whereas no detectable benefit is noted in patients with ER-poor or -negative cancers. ER is expressed as the percentage of positive cells within the cancer after IHC staining. Endocrine therapy is recommended for any patient with ≥10% positive cells, but not for those whose cancers only have 0–1% staining. The evidence supporting benefit in cases with 1–9% expression is weak, but given the potential benefit and relatively low toxicities of endocrine therapy, it is recommended for such patients with a low threshold for discontinuation if side effects are intolerable.

The HER2 protein is the target for anti-HER2-directed therapies. Adjuvant trastuzumab therapy reduces the risk of distant recurrence and death in patients with HER2-positive breast cancer by one-third or more but has no discernable effect on HER2-negative cancers. HER2 status is determined using either IHC staining for protein overexpression or fluorescent in situ hybridization (FISH) for gene amplification. IHC staining of 3+ (on a scale of 0–3+) is considered positive, whereas 0–1+ is considered negative. For cases with 2+ staining, reflex FISH analysis is recommended. FISH can either be used as the initial evaluation or for additional evaluation in IHC 2+ cases. *HER2* is considered amplified if the ratio of HER2 to centromere signal on chromosome 17 is ≥2.0. FISH is unnecessary if IHC is 3+ or 0–1+, nor is there reason for IHC testing if FISH is ≥2.0

No reliable predictive factors exist for chemotherapy in general or for specific types of chemotherapies. It has been hypothesized that chemotherapy may be more active in ER-negative and/or HER2-positive cancers. Luminal B cancers may be more chemotherapy sensitive, whereas luminal A cancers are perceived to be relatively chemotherapy resistant. At present, none of the tests for intrinsic subtype should be used to determine not to give chemotherapy to patients with poor anatomic *prognosis*, such as those with T4 or multiple positive nodes, based on *prediction* of resistance. Attempts to identify reliable predictive factors for individual classes of chemotherapeutic agents (such as anthracyclines, alkylating agents, or taxanes) have been unsuccessful. The platin salts (carboplatin, cisplatin) may have higher activity in patients with triple-negative breast cancer and perhaps in patients with HER2-positive disease. The PARP inhibitors may be more active in patients whose tumors have defects in homologous recombination DNA repair, a group that includes those with *BRCA* mutations.

Adjuvant Regimens • **Endocrine Therapy** Adjuvant endocrine therapy is indicated for nearly all patients with a diagnosis of ER-positive breast cancer and never for those with ER-negative disease. Two adjuvant endocrine therapy strategies are proven: the SERM tamoxifen or estrogen ablation. In addition to being effective in preventing new cancers and reducing the risk of locoregional recurrences in patients with DCIS, tamoxifen reduces the risk of distant recurrence and death due to invasive breast cancer by ~40% over the decade following diagnosis. It is equally effective in pre- and postmenopausal women, although it may be slightly less effective in very young (<40 years) patients. Because tamoxifen is a SERM, it has mixed ER antagonism (in the breast and brain) and agonism (in the bone, liver, and uterus). Therefore, it is active against breast cancer in the prevention, adjuvant, and metastatic settings.

Side effects of tamoxifen are predictable based on ER antagonism, including frequent hot flashes as well as vaginal discomfort/sexual dysfunction and myalgias and arthralgias. The agonistic effect results in reduction of osteopenia/osteoporosis, especially in postmenopausal women, but it increases thrombosis risk and endometrial cancers due to this effect in the liver and uterus, respectively.

Estrogen depletion can be achieved surgically in premenopausal women by oophorectomy or ovarian suppression with a gonadotropin-releasing hormone (GnRH) superagonist, such as goserelin or leuprolide, which invoke a tachyphylactic response, or a GnRH antagonist, such as triptorelin. However, women with nonfunctioning ovaries, whether induced or by natural menopause, still produce small amounts of estrogen by adrenal synthesis of estrogen precursors (testosterone, dehydroepiandrosterone [DHEA]). These are converted to estradiol and estrone by aromatase activity in peripheral fat and possibly cancer cells. In postmenopausal women, circulating estrogen can be reduced to nearly imperceptible levels with the use of oral AIs: anastrozole, letrozole, and exemestane. The three AIs are not significantly different in activity or toxicity. All are slightly more effective than tamoxifen.

Toxicities of the AIs are predictable based on very low estrogen levels. These include hot flashes, musculoskeletal symptoms, and atrophic vaginitis/sexual dysfunction. They also induce or worsen osteoporosis and fractures, although this effect can be abrogated with bone-modifying agents, such as bisphosphonates or rank ligand antagonists (denosumab).

For both tamoxifen and the AIs, musculoskeletal symptoms mimicking osteoarthritis and arthralgias can be treated with physical therapy and nonsteroidal anti-inflammatory drugs. After a brief period of washout after discontinuation, switching from one AI to another relieves this symptom in approximately a third of patients. These symptoms can also be reduced with either acupuncture or the antidepressant duloxetine. If AIs cannot be tolerated, tamoxifen is a reasonable therapy, assuming no contraindications, such as a past history of thrombosis or high risk of cerebrovascular disease. Hot flashes from either class of drugs are alleviated in approximately one-half of patients with use of one of several different antidepressant drugs.

For premenopausal women, optimal endocrine therapy depends on prognosis and patient choice. Complete estrogen depletion is slightly more effective than tamoxifen alone, but it may also be associated with more bothersome side effects, such as hot flashes, vaginal dryness, and sexual dysfunction. Complete estrogen depletion, consisting of either oophorectomy or chemical suppression of gonadotropins coupled with an AI, is indicated for women with worse prognosis, in particular node positivity. For those with more favorable prognosis, tamoxifen alone or with ovarian suppression is adequate and produces better quality of life. The AIs should not be administered to women with functioning, or dormant, ovaries, since the negative hypothalamic-pituitary feedback can result in a rebound overproduction of ovarian estrogens.

The duration of adjuvant endocrine treatment is unclear. Formerly, the standard recommendation was at least 5 years of therapy, which clearly reduces the risk of recurrence during that time and for a few years after discontinuation. However, the annual risk of distant recurrence during the subsequent 15 years is 0.5–3%, depending on the initial T and N status. Extended adjuvant endocrine therapy with either tamoxifen or an AI for at least 5 more years continues to reduce this late risk of relapse. The decision of whether to continue adjuvant endocrine therapy or not after 5 years must therefore take into consideration initial risk (T, N, grade), current side effects and potential cumulative toxicities, and the patient's perception of the relative and absolute benefits and risks.

Chemotherapy Multiple-agent adjuvant chemotherapy is more effective than single-agent chemotherapy. Although chemotherapeutic agents are usually delivered in combination, sequential single-agent chemotherapy is as effective, and may be slightly less toxic, although it requires longer total duration to deliver. Administration of four to six cycles of chemotherapy appears to be optimal; one cycle is less effective than six, but more than six cycles have generally increased toxicity without further efficacy. Importantly, although chemotherapy is combined with anti-HER2 therapy in patients with HER2-positive cancers, concurrent endocrine therapy, in particular tamoxifen, is antagonistic with chemotherapy.

Therefore, they are administered sequentially, starting the endocrine therapy after completion of chemotherapy.

Several chemotherapeutic agents have activity in the adjuvant setting. These include alkylating agents (principally cyclophosphamide), anthracyclines (doxorubicin, epirubicin), antimetabolites (5-fluoruracil [5-FU], capecitabine, methotrexate), the taxanes (paclitaxel, docetaxel), and the platinum salts (cisplatin, carboplatin). Within classes, randomized trials have failed to demonstrate superiority of one agent versus another (e.g., doxorubicin vs epirubicin, or paclitaxel vs docetaxel). Escalation above an optimal dose is not more effective. The antineoplastic advantage of more frequent scheduling for most individual agents has been demonstrated in a well-done meta-analysis. Weekly or every-other-week paclitaxel is superior to every-3-week infusion, whereas, enigmatically, the opposite is true for docetaxel. Taken together, the data support giving adjuvant chemotherapy in a dose-dense fashion.

The oldest combination regimen consists of cyclophosphamide, methotrexate, and 5-FU (CMF). Addition of an anthracycline or substitution of an anthracycline for the antimetabolites improves outcomes slightly, albeit with slightly increased risk of heart failure and secondary leukemia. Addition of a taxane to an anthracycline-based regimen further modestly reduces the chances of distant recurrence and death. Likewise, addition of an anthracycline to a taxane-based regimen is also modestly more effective than a taxane plus cyclophosphamide alone.

Which regimen is appropriate for a patient must be individualized based on prognosis, comorbid conditions, and the perspective of the patient. For example, the modest relative improvement of giving an anthracycline, cyclophosphamide, and a taxane (AC-T) may not translate to a sufficiently large absolute improvement in survival in a patient with a relatively small (T2) tumor and negative nodes, whereas that same relative reduction in death may translate to a sufficiently large absolute benefit in a patient with a worse prognosis. Therefore, the former patient might best be served with a taxane/cyclophosphamide (TC) regimen alone, while the latter might wish to accept the added risk of congestive heart failure and leukemia associated with the anthracyclines.

Neoadjuvant Chemotherapy Preoperative, or "neoadjuvant," treatment involves the administration of adjuvant systemic therapy, most commonly chemotherapy, before definitive surgery and radiation therapy. Neoadjuvant endocrine therapy for patients with ER-positive disease is usually given preoperatively for 4–6 months. However, it is generally reserved for patients for whom a reason for surgical delay exists, such as comorbid conditions.

The objective partial and complete response rates of patients with breast cancer to neoadjuvant chemotherapy range from 10 to 75% depending on the intrinsic subtype of the cancer and the regimen used. Thus, many patients will be "downstaged" by neoadjuvant chemotherapy. In this circumstance, patients with locally advanced, inoperable cancers may become candidates for surgery, and approximately 15% of patients who are not considered eligible for breast-conserving surgery may become so due to shrinkage of their cancer. However, overall survival has not been improved using this approach as compared with the same drugs given postoperatively.

Patients who achieve a pathologic complete remission (pCR) after neoadjuvant chemotherapy have a substantially improved survival compared to those who do not. It is unknown if this observation implies that the latter group did not benefit or just had a worse initial prognosis, yet still gained some benefit. Delivering more therapy to patients who do not have a pCR is appealing. However, it is possible that these patients have chemotherapy-resistant disease, and therefore, more chemotherapy may not be of value. Clearly nonchemotherapeutic strategies, such as adjuvant endocrine therapy if they have an ER-positive breast cancer and adjuvant anti-HER2 therapy if their cancer is HER2 positive, are warranted.

Adding or changing systemic therapies may benefit selected groups of patients who do not have a pCR. Approximately 6 months of a postsurgical oral fluoropyrimidine, capecitabine, reduces distant metastases in patients with triple-negative breast cancer who have residual disease after non-fluoropyrimidine-containing neoadjuvant chemotherapy. Similarly, postoperative therapy with an antibody-drug conjugate consisting of trastuzumab and the antitubulin emtansine (ado-trastuzumab emtansine) is superior to continuing unconjugated trastuzumab in patients with HER2-positive breast cancer who did not achieve pCR with preoperative chemotherapy and trastuzumab.

Chemotherapy Toxicities Chemotherapy is associated with nausea, vomiting, and alopecia in nearly 100% of patients. Nausea and vomiting are usually well controlled with modern antiemetics. Small but convincing studies have suggested that the strategy of constricting blood flow to the scalp with various means of cooling is commonly effective in sparing hair loss, without evidence of increased scalp metastases.

More importantly, chemotherapy causes potential life-threatening or life-changing toxicities in 2–3% of all treated patients. These include neutropenia and fever, with a risk of infection of ~1%, which can be prevented with appropriate use of the growth factor filgrastim. Secondary myelodysplasia and leukemia occur in ~0.5–1% of patients treated with anthracyclines as well as with high cumulative doses of cyclophosphamide, usually occurring within 2–5 years of treatment. The anthracyclines cause cumulative dose-related congestive heart failure, which occurs in ~1% of patients treated with standard four to five cycles at 60 mg/m^2. Peripheral neuropathy is the major dose-limiting and life-changing toxicity of the taxanes. Neuropathy occurs during treatment in ~15–20% of patients, and permanent, chronic neuropathy persists in 3–5%. Many patients complain of cognitive dysfunction, so-called "chemo-brain." Although occasional cases of apparent organic chemotherapeutic toxic effects on cognitive function are noted, much of this syndrome may be due to anxiety, depression, and fatigue caused by the diagnosis itself or the treatment for it. Although not always, cognitive functioning usually returns to age-adjusted baseline several months after discontinuation of therapy.

Anti-HER2 Therapy The humanized anti-HER2 monoclonal antibody trastuzumab decreases both risk of recurrence and mortality in early-stage breast cancer. Trastuzumab is optimally delivered concurrently with chemotherapy, particularly in association with a taxane. Concurrent treatment with an anthracycline is generally avoided, since the main toxicity of trastuzumab is cardiac dysfunction, which appears more often when the agent is delivered simultaneously with doxorubicin. In patients with reasonably favorable prognosis (T1 or T2, node negative), single-agent paclitaxel plus trastuzumab is an adequate regimen. The addition of a second anti-HER2 monoclonal antibody, pertuzumab, in combination with trastuzumab is modestly superior to trastuzumab alone. When given in the neoadjuvant setting, this combination results in higher pCR rates than single-agent trastuzumab. At least in patients with poor prognostic features, such as positive axillary lymph nodes, the combination significantly reduces distant metastases and perhaps mortality. As noted, neoadjuvant studies have demonstrated that postoperative ado-trastuzumab emtansine is superior to trastuzumab in patients who do not achieve a pCR.

Trastuzumab is administered intravenously weekly or every 3 weeks. Twelve months of trastuzumab therapy are optimal with no additional benefit beyond 12 months. Treatment for 6 months is more effective than no trastuzumab therapy but is inferior to 12 months. A preparation of trastuzumab for subcutaneous injection has been approved by the U.S. Food and Drug Administration.

Selected anti-HER2 tyrosine kinase inhibitors have activity against HER2-positive breast cancer, but their benefit in the adjuvant setting is limited. Lapatinib does not add to trastuzumab therapy, and single-agent adjuvant lapatinib is inferior to single-agent trastuzumab. Another anti-HER2 tyrosine kinase inhibitor, neratinib, is modestly superior to no anti-HER2 therapy. Neratinib has

not been compared to trastuzumab either as a single agent or in combination.

Toxicities of Anti-HER2 Adjuvant Therapies In general, the anti-HER2 therapies are safe and effective. Occasionally patients experience allergic reactions to an initial cycle of trastuzumab, but these usually do not recur. Trastuzumab can cause cardiac muscle dysfunction, although it is rare to observe symptomatic congestive heart failure from adjuvant trastuzumab. Baseline and serial echocardiographic monitoring is indicated. Patients with a past history of cardiac abnormalities should not receive trastuzumab or should be followed and treated by a cardiologist with experience in this condition. Pertuzumab is associated with loose stools and diarrhea, which can usually be managed with antidiarrheal therapy, such as loperamide. The chemotherapy payload of ado-trastuzumab emtansine can cause thrombocytopenia and peripheral neuropathy.

Skeletal Strengthening Agents Bone-strengthening agents that are commonly used to treat osteoporosis, specifically the bisphosphonates, have some limited activity in preventing recurrent breast cancer to bone, particularly in postmenopausal women. In addition, bisphosphonate therapy also reduced breast cancer mortality in this subgroup. The benefit is not significantly associated with any specific bisphosphonate class, treatment schedule, ER status, nodal status, tumor grade, or concomitant chemotherapy. As expected, bone fractures are reduced (relative risk [RR] 0.85; 95% confidence interval [CI] 0.75–0.97; 2 $p = .02$). Joint guidelines from the American Society of Clinical Oncology and Cancer Care Ontario recommend "that, if available, zoledronic acid (4 mg intravenously every 6 months) or clodronate (1,600 mg/d orally) be considered as adjuvant therapy for postmenopausal patients with breast cancer who are deemed candidates for adjuvant systemic therapy. Further research comparing different bone-modifying agents, doses, dosing intervals, and durations is required." The rank-ligand inhibitor denosumab does not prevent relapse in bone or other sites, nor does it reduce mortality.

Novel Adjuvant Systemic Agents Other exciting adjuvant strategies are being tested (Table 79-1). These include PARP inhibitors (olaparib, talazoparib) in patients with known germline *BRCA1* or *BRCA2* mutations or those with triple-negative cancers that share similar defects in DNA repair in their etiology. Likewise, the mTOR inhibitor everolimus and the CDK4/6 inhibitors (palbociclib, ribociclib, abemociclib) are being tested in the adjuvant setting in combination with antiestrogen therapy. The remarkable results of immune checkpoint inhibitors in other cancers have led to studies of this approach in both metastatic and post-neoadjuvant chemotherapy settings. Their activity with chemotherapy in triple-negative disease appears promising.

STAGE III BREAST CANCER

Ten to 25% of patients present with so-called locally advanced or stage III breast cancer at diagnosis. Many of these cancers are technically operable (T3), whereas others, particularly cancers with chest wall involvement, inflammatory breast cancers, or cancers with large matted axillary lymph nodes (T4 or N2-3), cannot be managed with surgery initially. Neoadjuvant downstaging facilitates local therapy. Radiotherapy either to the chest wall after mastectomy or to the breast after tumor excision is almost always recommended, as is regional lymph node treatment. Adjuvant anti-HER2 and endocrine therapies are also used as appropriate. These patients should be managed in multimodality clinics to coordinate local and systemic therapies. Such approaches produce long-term disease-free survival in ~30–50% of patients.

SIMULTANEOUS NEW PRIMARY WITH DETECTABLE METASTASES

In the screening era, only a small fraction of patients (~5%) present with a new primary lesion and simultaneous metastases, detected either due to symptoms of distant disease or because they had staging scans due to locally advanced disease. Several retrospective single-institutional experiences have suggested that neoadjuvant systemic therapy followed by local therapy (breast surgery and radiation) is associated with prolonged survival. However, two prospective randomized trials have failed to demonstrate any survival benefit. Currently, local therapy for such patients is considered on a case-by-case basis depending on the response to systemic therapy and the patient's overall performance status and desires.

BREAST CANCER SURVIVORSHIP ISSUES

The odds of surviving breast cancer have increased dramatically over the past 35 years due to a combination of early detection and more effective therapies. Without these advances, >60,000 American women would have suffered breast cancer mortality in 2020, and over one-quarter million women are alive who would not have been otherwise. Coupled with the women who would have been cured even before the impressive advances of the past three decades, millions are breast cancer survivors. Thus, all clinicians, not just oncologists, need to be aware of survivorship issues in patients with previously diagnosed and treated breast cancer.

At present, no special follow-up procedures, such as serial circulating tumor biomarkers or systemic radiographic/scintigraphic imaging, are indicated in an asymptomatic patient with no physical findings of recurrence. Although randomized trials have demonstrated slightly higher incidence of detection of metastases with lead times of 3–12 months by surveillance of asymptomatic patients compared to no special follow-up, no evidence suggests that earlier detection improves overall survival. If anything, such surveillance may worsen quality of life due to higher anxiety levels associated with the testing and toxicities associated with earlier treatment in patients who were otherwise doing well at that time.

However, the risk of late metastases in breast cancer survivors is small but real, especially those who had ER-positive disease. These patients remain at risk for distant recurrence for at least 20 years after initial diagnosis, and probably lifelong. The annual risk is relentless, ranging from 0.5% per year for patients with initially negative lymph nodes and grade 1 tumors <1 cm to as high as 3% per year for those who initially had multiple positive lymph nodes. Therefore, especially in patients with prior ER-positive cancers, the physician must carefully assess and evaluate new symptoms, considering whether they might be due to the cancer, the treatment, or an unassociated condition. Judgment needs to be used to decide if blood tests or imaging are required in order to avoid missing a lesion for which appropriate treatment would improve the patient's quality of life but also to diminish overtesting, with associated inconvenience, anxieties, false-positive results, and cost. Serial echocardiography should be performed every 3 months for patients on adjuvant trastuzumab, but not after it is discontinued.

Several observations suggest that perhaps the recommendations not to do intensive surveillance in patients without signs or symptoms of recurrence might need to be reconsidered. First, the unrelenting annual incidence of long-term distant recurrence for patients with ER-positive disease demonstrates that none of these patients can ever be considered free of risk of metastases. Second, available diagnostic tests have become substantially more sophisticated in the past decade. These include the advent of liquid biopsies beyond just circulating protein markers, such as circulating tumor DNA and circulating tumor cells, as well as more sensitive and specific scintigraphic and imaging techniques, such as positron emission tomography. Finally, the identification of several highly effective targeted therapies, including new endocrine, anti-HER2, and other therapies, provides opportunities to deliver more beneficial and less toxic therapies than the few chemotherapeutic and endocrine agents that were available at the time the older randomized trials were performed (Table 79-1). Ongoing trials are addressing whether incorporating these new technologies and treatments might improve survival as opposed to waiting for emerging symptoms to initiate additional treatment strategies. At present, no clear answers are apparent.

Likewise, serial monitoring for long-term, life-threatening toxicities associated with chemotherapy, such as myelodysplastic syndromes or congestive heart failure, is not warranted since these are quite uncommon and likely to cause obvious symptoms requiring proper evaluation if they occur.

For patients on endocrine therapy, quality-of-life issues may be critical, including hot flashes, sexual difficulties, musculoskeletal complaints, and risk of osteoporosis. Although estrogen therapy, given orally, transdermally, or transvaginally, effectively reduces these side effects, careful consideration should be given for estrogen replacement therapy to these patients because it may counteract the efficacy of the endocrine therapy. Locally administered therapies are often very effective and likely less risky. Nonhormonal treatments, such as selected antidepressants for hot flashes and musculoskeletal symptoms, and counseling and water-based lubricants for sexual issues can be quite helpful. It is important to screen bone density in patients on an AI more frequently than is recommended for the average postmenopausal woman, since total estrogen depletion results in enhanced risk of osteoporosis and risk of fracture. All women should be counseled to take daily calcium and vitamin D replacement, and if osteoporosis is present or osteopenia is worsening, bone-strengthening agents should be administered.

METASTATIC DISEASE

Diagnostic Considerations (Fig. 79-3) About 15–20% of patients treated for localized breast cancer develop metastatic disease in the subsequent decade after diagnosis. Soft tissue, bone, and visceral (lung and liver) metastases each account for approximately one-third of sites of initial relapses. However, by the time of death, most patients will have bone involvement. Recurrences can appear at any time after primary therapy, but at least half occur >5 years after initial therapy, especially in patients with ER-positive disease. A variety of host factors can influence recurrence rates, including depression and central obesity, and these diseases should be managed as aggressively as possible.

For patients with no prior history of metastases, a biopsy of suspicious physical or radiographic lesions should be performed for confirmation that the lesion does represent recurrent cancer. One should not assume that an apparent abnormality is a breast cancer metastasis. Many benign conditions, such as tuberculosis, gallstones, sarcoidosis, hyperparathyroidism, or other nonmalignant diseases, can mimic a recurrent breast cancer and are of course treated much differently. Moreover, if biopsy is positive for metastases, re-evaluation of ER and HER2 is indicated, since these can differ between the primary and metastatic lesions in up to 15% of cases. Analysis for *PIK3CA* mutations should be performed if the cancer is ER positive. Predictors of immune checkpoint inhibitor susceptibility, such as PD-L1 expression, should be determined in triple-negative metastatic breast cancers (Table 79-1). Many experts are also recommending some form of next-generation sequencing of all metastatic cancers from any site, although this recommendation is controversial.

Once a recurrence/metastasis is established, some form of body imaging should be performed—either a scintigraphic bone scan and chest and abdomen CT scan or a positron emission tomography (PET)/CT scan, depending on caregiver's preference. Brain scanning (CT or MRI) is not indicated in the absence of any cognitive or neurologic signs or symptoms in most patients. However, because of increased risk of brain metastases in HER2-positive breast cancer, some experts do recommend central nervous system (CNS) imaging in such patients even in the absence of clinical indications. Regardless, body scans provide a perspective of extent of disease, which may guide therapeutic decisions, as well as the need for ancillary treatments, such as bone-modifying agents if skeletal metastases are present.

Considerations Regarding Goals of Therapy Although treatable, metastatic disease is rarely if ever cured. The median survival for all patients diagnosed with metastatic breast cancer is <3 years, but with remarkable variability depending on intrinsic subtype and treatment effects. Patients with triple-negative metastatic breast cancer have the shortest expected survival, whereas those with ER-positive disease can expect to live the longest. HER2 positivity was initially found to be a very poor prognostic factor in metastatic breast cancer, but the availability of several effective targeted treatments has improved the expected survival rates to at least those of ER-positive patients, if not better.

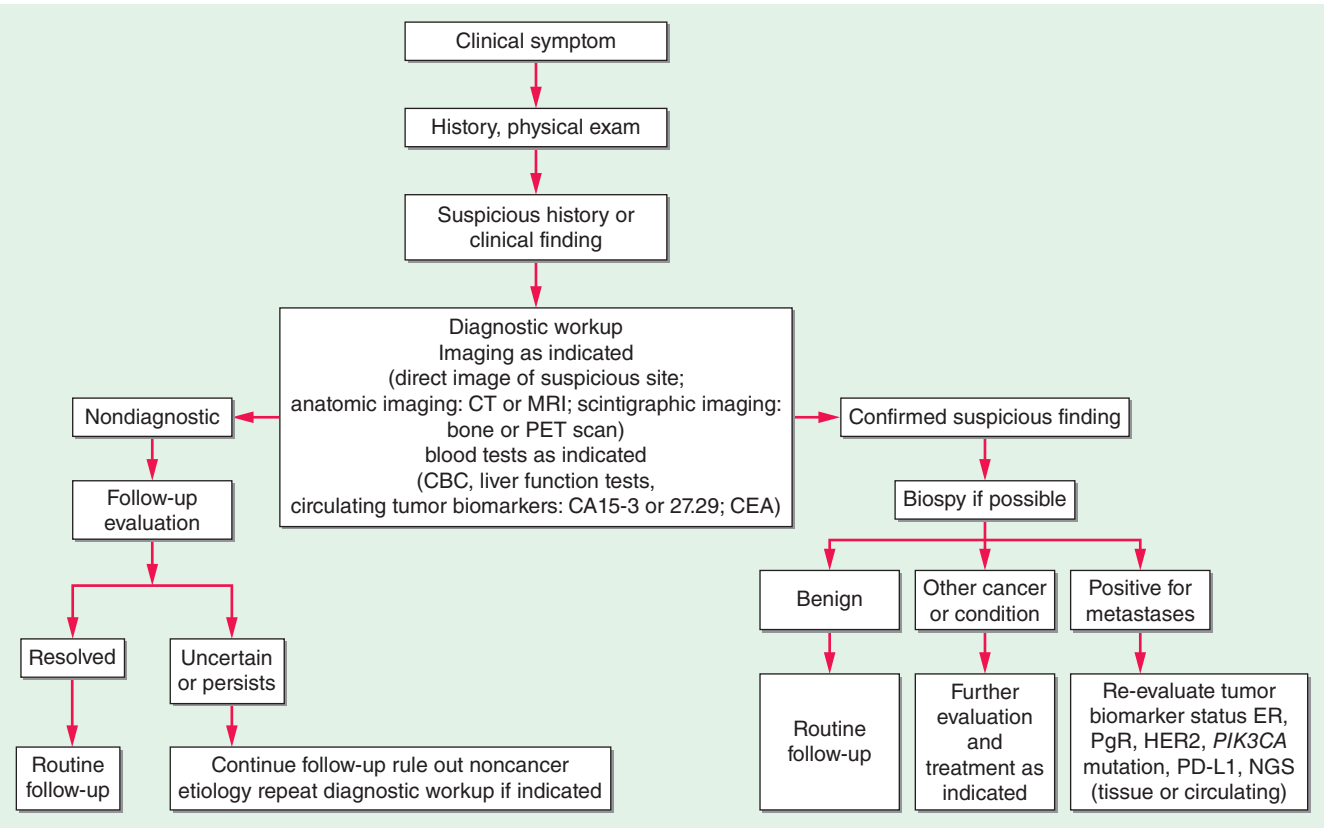

FIGURE 79-3 Evaluation of new signs or symptoms in a patient with prior history of early-stage breast cancer. See text for details. CBC, complete blood count; CEA, carcinoembryonic antigen; ER, estrogen receptor; NGS, next-generation sequencing; PET, positron emission tomography; PgR, progesterone receptor.

The overall goal of treatment of metastatic disease is palliation or, put simply, to "keep the patient feeling as well as she can for as long as she can." A secondary goal is improved survival. Overall survival has not been improved by advocating more aggressive or toxic therapies, such as high-dose or combination chemotherapy, but rather by using more selective and biologically based therapy, including endocrine or anti-HER2 therapies in patients with ER- or HER2-positive breast cancers, respectively.

Generally, a new treatment is continued until either progression or unacceptable toxicities are evident. These are both evaluated by serial history and physical examinations and periodic serologic evaluation for hematologic or hepatic abnormalities, as well as circulating tumor biomarker tests (assays for MUC1 [CA15-3 or CA27.29] and for carcinoembryonic antigen [CEA] and occasionally CA125). If all these evaluations fail to suggest progression, it is unlikely that imaging will contribute. However, if one or more of these suggest progression, whole-body imaging with whichever modality(ies) was used at baseline is indicated.

The choice of therapy requires consideration of local therapy needs, specifically surgical approaches to particularly worrisome long-bone lytic lesions or isolated CNS metastases. New back pain in patients with breast cancer should be explored aggressively on an emergent basis, usually with a spine MRI; to wait for neurologic symptoms is a potentially catastrophic error. Metastatic involvement of endocrine organs can occasionally cause profound dysfunction, including adrenal insufficiency and hypopituitarism. Similarly, obstruction of the biliary tree or other impaired organ function may be better managed with a local therapy than with a systemic approach. Radiation as an adjunct to or instead of surgery is an important consideration for particularly symptomatic disease in long or vertebral bones, locoregional recurrences, and CNS metastases. In many cases, systemic therapy can be withheld while the patient is managed with appropriate local therapy.

Aggressive local treatment, such as excision, radiation, radiofrequency ablation, or cryotherapy of metastases to the lung, liver, or other distant sites, does not improve survival. Although appealing, these strategies are associated with increased toxicity and cost and should be reserved for palliation.

Locoregional recurrence on the chest wall or surrounding lymph nodes is an exception to this principle. Some of these lesions may well represent new primary cancers, even in the case of prior mastectomy, since some residual at-risk normal tissue can remain. Regardless, rendering the patient disease-free by surgery and radiation, if appropriate, followed by adjuvant systemic therapy, such as endocrine therapy if the cancer is ER positive, or chemotherapy if ER negative, is indicated. Anti-HER therapy is also appropriate if the cancer is HER2 positive.

Selection of the systemic therapy strategy depends on the overall medical condition of the patient, the hormone receptor and HER2 status of the tumor, and clinical judgment. Because therapy of systemic disease is palliative, the potential toxicities of therapies should be balanced against expected response rates. Several variables influence the response to systemic therapy. For example, the presence of ER and PgR is a strong indication for endocrine therapy, even for patients with limited visceral (lung/liver) disease. On the other hand, patients with short disease-free intervals or rapidly progressive visceral disease (liver and lung) with end-organ dysfunction, such as lymphangitic pulmonary disease, are unlikely to respond to endocrine therapy.

Many patients with bone-only or bone-dominant disease have a relatively indolent course. Because the goal of therapy is to maintain well-being for as long as possible, emphasis should be placed on avoiding the most hazardous complications of metastatic disease, including pathologic fracture of the axial skeleton and spinal cord compression. Under such circumstances, systemic chemotherapy has a modest effect, whereas radiation therapy may be effective for long periods. Patients with bone involvement should receive concurrent bone-strengthening agents, such as bisphosphonates or the humanized monoclonal anti-RANK ligand antibody denosumab. These therapies have been proven to reduce bone pain, fractures, and hypercalcemia of malignancy.

Many patients are inappropriately treated with toxic regimens into their last days of life. Often, oncologists are unwilling to have the difficult conversations that are required with patients nearing the end of life, and not uncommonly, patients and families can pressure physicians into treatments with very little survival value. Although systemic therapy is designed to deliver palliation, formal palliative care consultation and realistic assessment of treatment expectations need to be reviewed with patients and families. We urge consideration of formal palliative care consultations for patients who have received at least two lines of therapy for metastatic disease.

SYSTEMIC TREATMENTS FOR METASTATIC BREAST CANCER

Endocrine Therapy (Table 79-1) Approximately 30–70% of patients with ER-positive breast cancer will benefit from endocrine therapy. Potential endocrine therapies are summarized in Table 79-1. Available strategies include SERMs (tamoxifen, toremifene), the AIs (anastrozole, letrozole, exemestane), and the selective estrogen receptor downregulator (SERD) fulvestrant. Additive endocrine therapies, including treatment with progestins and androgens and, enigmatically, pharmacologic doses of estrogens, are all active, but they may be associated with unacceptable side effects in many women and are rarely used. Tamoxifen withdrawal (as well as withdrawal of pharmacologic doses of estrogens) induces responses in ~15% of patients, but with the advent of so many other therapies for metastatic disease, this strategy is also rarely used in modern oncology.

The sequence of endocrine therapy is variable. Patients who respond to one endocrine therapy have at least a 50% chance of responding to a second endocrine therapy. It is not uncommon for patients to respond to two or three sequential endocrine therapies. Many, but not all, women with ER-positive breast cancer who suffer a recurrence will do so either while still taking or after recently discontinuing a prior adjuvant endocrine therapy (either tamoxifen or an AI). In most postmenopausal patients, if they have never received an AI or discontinued adjuvant AI many years before recurrence, the initial endocrine therapy should be an AI rather than tamoxifen. As noted, AIs are not used in women with functioning ovaries because their hypothalamus can respond to estrogen deprivation by producing gonadotropins that promote ovarian estrogen synthesis. Fulvestrant is usually used in sequence after AI therapy. Compared to single-agent therapy, combination endocrine therapies increase the chances of response, but they do not appear to increase the ultimate time to chemotherapy use or overall survival. Combinations of chemotherapy with endocrine therapy are not useful.

Over the past decade, several different targeted agents have been shown to enhance outcomes of patients with ER-positive metastatic breast cancer when combined with endocrine therapy (Table 79-1). Addition of an inhibitor of mTOR, everolimus, to endocrine therapy improves time to progression. Everolimus is commonly associated with mucositis, which can be prevented or alleviated by use of dexamethasone-containing mouthwash. Diarrhea is also a common side effect and can be lessened with antidiarrheal medications such as loperamide.

Inhibitors of CDK4/6 (palbociclib, ribociclib, abemaciclib) also substantially improve progression-free survival, and even overall survival when combined either with an AI or fulvestrant (Table 79-1). Most experts now recommend a CDK4/6 inhibitor with endocrine therapy as first-line therapy for ER-positive metastatic disease. They can cause dangerous neutropenia, although rarely to the extent seen with chemotherapy. Nonetheless, absolute neutrophil counts need to be monitored closely with appropriate adjustments in dose and schedule. Fatigue is also an occasional side effect, and abemaciclib frequently causes diarrhea. Similarly, an inhibitor of PIK3CA protein, alpelisib, prolongs progression-free survival in patients whose cancers harbor activating mutations of this gene. Like everolimus, it too causes mouth sores and diarrhea.

These targeted agents should not be given simultaneously but rather in sequence as appropriate.

Chemotherapy Unlike many other epithelial malignancies, breast cancer responds to multiple chemotherapeutic agents, including anthracyclines, alkylating agents, taxanes, and antimetabolites. Multiple combinations of these agents have been found to improve response rates somewhat, but they have had little effect on duration of response or survival. Unless patients have rapidly progressive visceral (lung, liver) metastases with end-organ dysfunction, single-agent chemotherapy is preferable, used in sequence as one drug fails going on to the next. Given the significant toxicity of most drugs, the use of a single-agent therapy will minimize toxicity by sparing the patient exposure to drugs that would be of little value. No method to select the drugs most efficacious for a given patient has been demonstrated to be useful.

Most oncologists use capecitabine, an anthracycline, or a taxane for first-line chemotherapy, either in a patient with ER-positive disease that is refractory to endocrine therapy or for a patient with ER-negative breast cancer. Within these general classes, one particular agent is no more preferable than another (such as doxorubicin vs epirubicin or paclitaxel vs docetaxel), and the choice has to be balanced with individual needs. Objective responses in previously treated patients may also be seen with gemcitabine, vinorelbine, and oral etoposide, as well as a newer class of agents, epothilones. Platinum-based agents have become far more widely used in both the adjuvant and advanced disease settings for some breast cancers, particularly those of the triple-negative subtype.

Anti-HER2 Therapy (Table 79-1) Initial use of a trastuzumab, either alone or with chemotherapy, improves response rate, progression-free survival, and even overall survival for women with HER2-positive disease. Indeed, anecdotal reports suggest that, on occasion, a few patients with HER2-positive metastatic breast cancer may be cured. Addition of pertuzumab to trastuzumab is more effective than trastuzumab alone. The antibody-drug conjugate, ado-trastuzumab emtansine, is effective after progression on trastuzumab. Another antibody-drug conjugate, fam-trastuzumab-deruxtecan-nxki, has been shown to be active even in patients who have progressed on multiple other anti-HER2 therapies, including ado-trastuzumab emtansine. A monoclonal antibody, margetuximab, has been engineered to specifically enhance antibody-dependent cell-mediated cytotoxicity against tumor cells overexpressing HER2. In a phase 3 trial, margetuximab plus chemotherapy improved overall survival by 1.8 months compared with trastuzumab plus chemotherapy.

Inhibitors of the HER2 tyrosine kinase domain also have activity against HER2-positive breast cancers. Lapatinib is effective when added to chemotherapy after patients progressed on trastuzumab. In addition, even after progression on trastuzumab, combination trastuzumab and lapatinib is superior to lapatinib alone. When added to oral capecitabine, neratinib is more effective than lapatinib in patients who received two or more prior anti-HER2-based regimens. In patients with heavily pretreated HER2-positive disease, including those with brain metastases, adding tucatinib to trastuzumab and capecitabine resulted in better progression-free survival and overall survival outcomes than adding placebo. Of interest, 2–3% of breast cancers that do not amplify or overexpress HER2 contain activating mutations in the gene encoding for it. Preclinical models and preliminary trials suggest that neratinib is particularly active against this mutation.

PARP Inhibitors (Table 79-1) PARP inhibitors induce synthetic lethality of cancer cells with inactive *BRCA1/2* or cancers that have *BRCA*-like biology by virtue of an ineffective homologous recombination DNA repair mechanism. Both olaparib and tolaparib have been approved for patients whose cancers have developed in the context of germline *BRCA1/2* mutations. Both agents, given as a single agent, are as effective as standard chemotherapy, but in general, they are less toxic. Unfortunately, responses are relatively short lived. PARP inhibitors are now being investigated in combination with chemotherapy and with immune checkpoint inhibitors. PARP inhibitors can cause mild nausea and occasional vomiting as well as fatigue.

Sacituzumab Govitecan (Table 79-1) An antibody-drug conjugate, sacituzumab govitecan, showed activity in a nonrandomized trial of patients with triple-negative metastatic breast cancer. Sacituzumab govitecan combines a humanized immunoglobulin G antibody targeted against TROP-2SN-38 with the active metabolite of irinotecan. In a single-arm, phase 2 trial, this agent elicited responses in one-third of such patients.

Immune Checkpoint Inhibitors (Table 79-1) These therapies permit immune effector cells to recognize and eliminate host cancer cells based on their recognition of neoantigen expression in tumor cells due to chromosomal instability and accumulated mutations. The excitement over immune checkpoint inhibitors has spread to metastatic breast cancer, especially of the triple-negative subtype. Atezolizumab in combination with nab-paclitaxel improves progression-free and perhaps overall survival, although exclusively against cancers with infiltrating immune cells that express PD-L1 (Table 79-1). The side effects of these agents can be life threatening, consisting of induction of inflammatory autoimmune responses in nearly every organ imaginable. These include thyroiditis, pneumonitis, myo- and pericarditis, esophagitis, gastritis and colitis, hepatitis, pancreatitis, hypophysitis, and dermatitis. The endocrine toxicities tend to be irreversible. Careful management should be handled by an experienced team.

Bone-Modifying Agents Bone-modifying agents, such as bisphosphonates or the anti-RANK antibody denosumab, are recommended for all patients with bone metastases. These agents substantially reduce the incidence of cancer-related skeletal events, such as bone pain, fracture, and hypercalcemia of malignancy. The bisphosphonates may cause myalgias and skeletal pain lasting a few hours to days after infusion. Both strategies have been associated with osteonecrosis of the jaw. The incidence of this complication is reduced by ensuring adequate dentition before treatment and by delivering treatment every 3 months, instead of monthly. The former has been shown to have equal efficacy.

BREAST CANCER IN PREGNANCY

As noted, breast cancer is unusual during pregnancy but does occur. Because of pregnancy-related physical breast changes, diagnosis is frequently delayed. Workup is the same as for non-pregnancy-related breast cancers, except radiographic staging should be limited or avoided, especially of the abdomen. Prognosis is similar, stage for stage, as that for age-matched women who are not pregnant. Pregnancy termination is usually not required. However, it is strongly advised that the patient be referred to a high-risk pregnancy program.

Remarkably, adjuvant chemotherapy including doxorubicin and cyclophosphamide can be safely given beyond the first trimester. Taxanes and the platinum salts may be administered safely. In contrast, anti-HER2 antibody therapies have resulted in unacceptable fetal malformations and pregnancy complications and should be avoided. Likewise, endocrine therapies should be delayed until after delivery. In general, a reasonable strategy is to deliver combination neoadjuvant chemotherapy with either concurrent or sequential single agents to permit sufficient embryogenesis followed by delivery and then breast primary therapy (surgery/radiation). Further adjuvant therapies, including additional chemotherapy and/or anti–HER2 and endocrine therapies can be delivered postoperatively. Breast feeding is discouraged, since these agents may cross into milk.

MALE BREAST CANCER

Breast cancer is ~1/150th as frequent in men as in women; ~2000 men developed breast cancer annually in the United States. Risk factors include inherited deleterious SNPs in *BRCA2*, as well as increased exposure to endogenous or exogenous estrogen. Men with Klinefelter's syndrome have two or more copies of the X chromosome and have higher levels of estrogen. Other conditions of hyperestrogenism, such as in hepatic failure and with exogenous

estrogen use in transgender situations, are also associated with higher risk of male breast cancers. However, the vast majority of men who present with breast cancer have none of these conditions.

Breast cancer usually presents in men as a unilateral lump in the breast and is frequently not diagnosed promptly. Given the small amount of soft tissue and the unexpected nature of the problem, locally advanced presentations are somewhat more common. Although gynecomastia may initially be unilateral or asymmetric, any unilateral mass in a man >40 years old should be biopsied. On the other hand, bilateral symmetric breast development rarely represents breast cancer and is almost invariably due to endocrine disease or a drug effect. Nevertheless, the risk of cancer is much greater in men with gynecomastia; in such men, gross asymmetry of the breasts should arouse suspicion of cancer.

Approximately 90% of male breast cancers contain ERs, and the disease behaves similarly to that in a postmenopausal woman. When matched to female breast cancer by age and stage, its overall prognosis is identical. Male breast cancer is best managed by mastectomy and axillary lymph node dissection or SLNB, although some men prefer breast-conserving therapy. Patients with locally advanced disease or positive nodes should also be treated with irradiation. No randomized studies have evaluated adjuvant therapy for male breast cancer, but extrapolation from treatment with women suggests it is indicated. If the cancer is ER positive, which is often the case, tamoxifen is usually the agent of choice. AIs are also effective in men. Anecdotal evidence supports use of gonadotropin-releasing hormones, such as leuprolide, in combination with an AI, since testosterone is a substrate for the aromatase enzyme. The sites of relapse and spectrum of response to chemotherapeutic drugs are virtually identical for breast cancers in either sex.

80 Upper Gastrointestinal Tract Cancers

David Kelsen

Cancers of the upper gastrointestinal tract include malignancies of the esophagus, stomach, and small bowel. Esophageal, gastroesophageal junction, and gastric cancers are among the most common of human malignancies, with 1.5 million global new cases diagnosed in 2018. In the United States, a lower risk area, it is estimated that in 2020, esophageal cancer will be diagnosed in 18,440 people and cause 16,170 deaths; for gastric cancer, 27,600 new cases will be diagnosed and 11,010 deaths will occur. Small intestine cancers are rare.

ESOPHAGEAL CANCER

INCIDENCE AND CAUSATIVE FACTORS

Two distinct forms of cancer with different epidemiologies, causative factors, and genomic profiles arise within the esophagus: squamous cell cancers, which occur more frequent in the upper and mid esophagus; and adenocarcinomas, which are almost always located in the lower esophagus and at the gastroesophageal junction. The incidence of esophageal cancer varies up to 20-fold based on geographic distribution: it is relatively uncommon in North America, but has a high incidence in Asia (especially China), the Normandy coast of France, and Middle Eastern countries such as Iran. This marked global variation is likely due to different causative factors in the development of the malignancy, leading to two different cancer types within the same tissue: squamous cell cancers are more common in high-incidence areas, usually with lower Human Development Index (HDI) scores (a measure of economic development that includes standard of living, health, and education). Overall, approximately 572,000 new cases of esophageal cancer were diagnosed globally in 2018; esophageal cancer was the seventh most common cause of malignancy and the third most common cause of cancer-related mortality, with an estimated 508,000 deaths.

The clearest high-risk factors for the squamous cell cancer subtype in Western countries are alcohol and tobacco abuse; concurrent alcohol and tobacco abuse further increases the risk. Ingestion of extremely hot substances (such as tea in Iran and mate [maté] in South America) has been proposed as a risk factor; in India, chewing the areca (betel) nut increases the risk of esophageal squamous cell cancers. Less common risk factors include chronic achalasia, radiation therapy (such as is delivered for treatment of Hodgkin's lymphoma or breast cancer), lye ingestion, and Plummer-Vinson (Patterson-Kelly) syndrome (iron deficiency anemia, glossitis, cheilosis, and the development of esophageal webs) **(Table 80-1)**. Adenocarcinoma of the lower esophagus and gastroesophageal junction has been the predominant histologic subtype in the United States and Western Europe for several decades, now making up >75% of all incident cases. Risk factors for adenocarcinoma **(Table 80-2)** include chronic reflux esophagitis leading to inflammation and the development of Barrett's esophagus (the finding of glandular gastric type mucosa extending into the esophagus). Although obesity increases the risk of reflux esophagitis, a substantial number of patients with newly diagnosed adenocarcinoma of the esophagus and gastroesophageal junction are younger and fit; Barrett's esophagus may still be found in these patients. In patients with adenocarcinoma of the lower esophagus in which Barrett's esophagus is not present, the disease may arise without Barrett's esophagus, or an extensive tumor found at diagnosis may obliterate previous areas of Barrett's. Genomic alterations may be identified even before the development of frank adenocarcinoma in patients with dysplasia associated with Barrett's esophagus. These include mutations of *TP53*, a gene critical in regulating uncontrolled cell division, and aneuploidy in dysplastic regions. Risk of progression of Barrett's esophagus to cancer is about 0.4–0.5% per year. Management of Barrett's esophagus is discussed in **Chap. 323**.

TABLE 80-1 Some Etiologic Factors Associated with Squamous Cell Cancer of the Esophagus
Excess alcohol consumption
Cigarette smoking
Other ingested carcinogens
Nitrates (converted to nitrites)
Smoked opiates
Fungal toxins in pickled vegetables
Mucosal damage from physical agents
Hot tea
Lye ingestion
Radiation-induced strictures
Chronic achalasia
Host susceptibility
Esophageal web with glossitis and iron deficiency (i.e., Plummer-Vinson or Paterson-Kelly syndrome)
Congenital hyperkeratosis and pitting of the palms and soles (i.e., tylosis palmaris et plantaris)
? Dietary deficiencies of selenium, molybdenum, zinc, and vitamin A

As opposed to other gastrointestinal malignancies, such as colorectal cancer, inherited cancer susceptibility genes are rarely associated with esophagus and gastroesophageal junction cancers. An exception is the rare inherited cancer susceptibility gene driving tylosis palmaris and plantaris; a mutation in the *RHBDF2* gene is associated with an increased risk for squamous cell cancers of the esophagus. Lynch syndrome modestly increases the risk of gastric and potentially gastroesophageal junction adenocarcinomas.

SCREENING AND SURVEILLANCE OF HIGHER RISK GROUPS

Because of its low incidence in North America and the absence of proven blood-based biomarker for esophageal cancer assays, screening of the asymptomatic general population using, e.g., upper endoscopy is not currently recommended in the United States. Periodic endoscopy is used for surveillance of higher risk patients, such as those with Barrett's esophagus and especially with dysplasia, based on expert opinion guidelines.

GENOMIC ALTERATIONS

Within a tissue, subtyping has revealed substantial genomic differences between adenocarcinomas and squamous cell cancers of the esophagus. An integrated analysis involving several different genomic platforms performed by The Cancer Genome Atlas (TCGA) Research Network investigators demonstrated that esophageal squamous cell cancers more closely resembled squamous cell carcinomas of other primary sites, such as the head and neck, than adenocarcinomas arising in the esophagus. Three molecular subclasses of squamous cell cancer were identified (of note, as opposed to squamous cell cancer of the head and neck, human papillomavirus was not identified in any of the three subgroups). Among other differences, the spectrum of genomic amplifications in squamous cell cancers are substantially different than that of adenocarcinomas. In adenocarcinomas, *ERBB2* (*HER2*) was frequently amplified, as were *VEGFA* and *GATA4/6*. The genomic profile for esophageal and gastroesophageal junction adenocarcinomas was very similar to the chromosomally unstable variant of gastric adenocarcinoma, suggesting that proximal gastric and gastroesophageal junction tumors may have a similar driving factor (see below). Other studies comparing transcriptomes of adenocarcinomas and squamous cell cancers across tissues (i.e., the same tumor histology arising in different organs, such as squamous cell cancers and adenocarcinomas from the esophagus, lung, and uterine cervix) found that histologies among the different organs showed more similarity than between the different histologies within the same organ. In addition to implications regarding driving factors in the initiation and progression of cancer, these genomic alterations are important for therapeutic decisions involving systemic agents given in the neoadjuvant or postoperative adjuvant setting or for advanced metastatic disease. For esophageal cancer, genomic abnormalities that should be considered in prescribing drug-based therapy include analysis for *HER2* amplification, PD-L1 expression, and hypermutated tumors\microsatellite instability (see below).

TABLE 80-2 Some Etiologic Factors Associated with Adenocarcinoma of the Esophagus
Chronic gastroesophageal reflux
Obesity
Barrett's esophagus
Male sex
Cigarette smoking

CLINICAL FEATURES

PRESENTING SYMPTOMS

The most common symptoms leading to suspicion of esophageal cancer are dysphagia or odynophagia and, less frequently, hematemesis or melena. More subtle symptoms include anorexia and weight loss, and fatigue and shortness of breath if anemia from gastrointestinal bleeding is present. Because the symptoms of dysphagia or odynophagia are usually not perceived by the patient until substantial obstruction of the esophageal lumen has occurred, the large majority of patients with esophageal cancer are found with locally advanced if not metastatic disease. Patients with symptoms of dysphagia and/or odynophagia should undergo upper endoscopy (rather than a barium contrast study) to determine the presence or absence of malignancy; biopsy should be performed at the same setting to determine histology. Depending on the tumor stage, molecular diagnostic or next-generation sequencing (NGS) analysis to assist in determine potential therapies would be performed. These studies should be done on all patients with metastatic disease as it will guide therapy. NGS requires adequate tumor cellularity, which is sometimes difficult to achieve from endoscopic biopsy. Some high-volume U.S. centers routinely perform NGS on all specimens, including from the primary tumor for patients without metastatic disease.

STAGING

Therapeutic strategy is based on the stage of the disease using a system such as the eighth edition of the American Joint Committee on Cancer (AJCC) tumor-node-metastasis (TNM) staging system. The T stage is based on the size of the tumor and depth of penetration through the esophageal wall (which for most of its course is not covered by serosa so that invasion through the muscle layer leads directly into periesophageal tissues) **(Fig. 80-1)**. Patients with regional lymph node metastases are still potentially curable. Metastatic disease is generally treated with palliative intent with rare exceptions. Because neoadjuvant (preoperative) therapy is widely employed for esophageal cancer in an effort to improve subsequent surgical outcomes, the AJCC TNM staging system includes clinical, pathologic (for patients undergoing initial surgery as first treatment), and ypTNM staging assessment for those treated with preoperative therapy. See **Table 80-3** for the TNM staging classification for gastric cancer, which is similar to esophageal cancer.

Determining tumor extent includes careful physical examination, which may reveal palpable lymphadenopathy or hepatomegaly; imaging studies including computed tomography (CT) and fluorodeoxyglucose (FDG) positron emission tomography (PET)/CT scan are used to assess for metastatic disease. If no metastatic disease is identified, endoscopic ultrasonography (EUS) is commonly performed to more definitively determine depth of penetration of the primary tumor (T) and regional lymph node involvement. For tumors of the mid and upper esophagus (5% of esophageal cancers are in the upper third of the esophagus, 20% in the middle third, and 75% in the lower third), bronchoscopy may be performed to rule out invasion of the tracheobronchial tree.

The finding of invasion of the trachea or bronchus rules out surgical intervention with curative intent. Regional lymph nodes may be biopsied under EUS guidance. If metastatic disease is suspected, biopsy to confirm tumor staging and to obtain adequate tissue for molecular and genomic alterations analysis should be performed. If systemic therapy is indicated as a portion of the treatment (for metastatic disease or for preoperative therapy for locally advanced cancers), serial FDG-PET/CT scans, using decrease in FDG avidity as a surrogate measure of effectiveness, are increasingly being used to guide whether the initial therapy should be continued or changed.

TREATMENT

Esophageal Cancer

Although the prognosis for patients with esophageal cancer (all stages) is still poor, a slow but steady improvement in 5-year survival has been noted. Because no effective early detection methods exist, the number of patients found to have very-early-stage cancers at the time of diagnosis has not markedly increased; the modest improvement in survival is probably a combination of somewhat improved systemic therapy as well as decreased operative morbidity and mortality when surgery is performed by high-volume surgeons at high-volume centers, as well as improvements in the delivery of external-beam radiation therapy.

For patients without evidence of metastatic disease, the goal of therapy is cure, usually by employing combined-modality therapies. Except for patients with early-stage esophageal cancer ,which might be treated by surgery alone (or for very-early-stage lesions, by endomucosal resection alone), systemic drug therapy plus external-beam radiation therapy is a standard of care option for esophageal cancers. For selected patients with gastroesophageal cancers, systemic therapy alone may be given before definitive surgical resection. For patients with squamous cell cancers of the upper and mid esophagus, combined chemotherapy plus concurrent radiation therapy is a standard of care option, with surgery reserved for patients not achieving a complete radiographic and endoscopic response. Chemotherapy plus concurrent radiation was superior to radiation therapy alone in several clinical trials. Increasingly, all systemic therapy given with curative intent is given before operation, although if surgery is the initial therapy and the patient is found to have more locally advanced cancer at pathology (e.g., regional lymph node metastasis), postoperative systemic therapy is used in the adjuvant setting. Adjuvant chemotherapy is more frequently indicated in patients with adenocarcinoma than squamous cell cancers.

For patients with metastatic disease, the goal of therapy is symptom palliation and life extension. No randomized trials of supportive care only versus systemic therapy plus best supportive care have been reported in patients with esophageal cancers. For gastric cancer (a similar histology as distal esophageal and gastroesophageal junction tumors as discussed above), clinical trials performed in the 1980s and 1990s indicated a modest improvement in 1- and 2-year survival when systemic therapy was initiated versus best supportive care only. While the cytotoxic chemotherapy regimens used for palliation have not changed dramatically over the past 10 years, subgroups of patients have been identified who benefit from therapies targeting specific genomic alterations. Approximately 20–25% of patients with adenocarcinoma of the esophagus or gastroesophageal junction are found to have amplified or overexpressed *HER2*; trastuzumab plus chemotherapy results in higher response rates and longer progression-free and overall survival compared to chemotherapy alone. Immune modulation therapy using PD-1 inhibitors is second-line palliative therapy for patients who have esophageal cancers expressing PD-L1 or having hypermutated or microsatellite-unstable genotype. Molecular diagnostic or genomic alteration analysis assays to identify these biomarkers should be performed routinely in patients with metastatic esophageal cancer to help guide therapy.

Supportive measures to improve nutrition and quality of life include placement of an endoluminal stent in the setting of high-grade obstruction; use of enteral nutrition can also be performed using a percutaneous gastrostomy. Photodynamic therapy and endoscopic laser therapy have been used to treat endoluminal obstruction.

TUMORS OF THE STOMACH

ADENOCARCINOMA OF THE STOMACH

Incidence and Causative Factors A century ago, gastric adenocarcinomas were among the most common of malignancies in the United States. Since the 1920s, the incidence of gastric cancer has steadily decreased; while the reason for this has not been definitively identified, it coincided with widespread use of refrigeration and a decreased need for food preservatives. In 2020, it is estimated that there will be 27,600 new cases of gastric cancer diagnosed in the United States; while now seen much less frequently, it remains a lethal disease, with 11,010 deaths. Globally, gastric cancer is still very common, with an overall global incidence of 1.03 million new cases per year and 780,000 deaths, making gastric cancer the third most common cause of cancer mortality. High-incidence areas, as is the case for esophageal cancers, include large Asian countries such as China, Korea, and Japan; South American countries such as Chile; and Eastern European countries.

While the number of new cases of body and distal gastric cancers has decreased in Western, high-HDI countries, the incidence of adenocarcinomas of the gastroesophageal junction has markedly increased in the same areas over the past several decades. The ingestion of high concentrations of nitrates found in dried, smoked, and salted foods may be a contributing factor. Bacteria such as *Helicobacter pylori* and ingestion of partially decayed bacterially contaminated food may lead to the generation of carcinogenic nitrites from nitrates **(Table 80-4)**. A causative factor is suspected to be chronic inflammation due to reflux of gastric contents into the esophagus, particularly in obese people. Obesity alone is not the cause, as a substantial number of these patients are fit and not overweight. Early-onset gastric cancers (gastric cancer occurring in patients under the age of 50), primarily proximal or gastroesophageal junction cancers, have also increased. A second cause of chronic inflammation, *H. pylori* infection, is a known driver in many cases of gastric cancer. While *H. pylori* is extremely common, occurring in approximately half of all humans, gastric cancer occurs in only a small subset of those infected. Higher cancer risk has been associated with certain strains of *H. pylori*; a specific human genetic predisposition has not yet been identified. Supportive evidence that *H. pylori* infection is a causative factor in the development of gastric cancer includes prospective studies demonstrating that treatment of *H. pylori* infection decreases the overall risk of gastric cancer. For example, patients with *H. pylori* infection who had at least one first-degree relative with a history of gastric cancer (increasing their own risk of stomach cancer) were randomly assigned to placebo or treatment for *H. pylori*. The group receiving *H. pylori* eradication showed a significant decrease in the incidence of gastric cancer (especially for

TABLE 80-4 Nitrate-Converting Bacteria as a Factor in the Causation of Gastric Carcinoma[a]

Exogenous sources of nitrate-converting bacteria:
Bacterially contaminated food (common in lower socioeconomic classes, who have a higher incidence of the disease; diminished by improved food preservation and refrigeration)
Helicobacter pylori infection
Endogenous factors favoring growth of nitrate-converting bacteria in the stomach:
Decreased gastric acidity
Prior gastric surgery (antrectomy) (15- to 20-year latency period)
Atrophic gastritis and/or pernicious anemia
? Prolonged exposure to histamine H_2-receptor antagonists

[a]Hypothesis: Dietary nitrates are converted to carcinogenic nitrites by bacteria.

those in whom *H. pylori* was successfully eradicated) compared to the control group. Earlier studies had demonstrated that treatment of *H. pylori* in Korean patients who had a prior very-early-stage gastric cancer decreased the incidence of a second gastric cancer. These data suggest that treatment of asymptomatic *H. pylori* gastric infection should be considered for patients who have a first-degree relative who has had gastric cancer or who themselves have a prior history of an early-stage gastric cancer.

In addition to chronic inflammatory conditions, inherited cancer susceptibility genes increase the risk of gastric cancer. These include mutations of *CDH1*, which encodes for the cell cohesion gene e-cadherin; germline *CDH1* mutations markedly increase the risk for the diffuse cell (signet cell) gastric cancer subtype (see below for discussion of histologic subtypes). Patients with an inherited deleterious *CDH1* mutation are considered for prophylactic gastrectomy. *CDH1* mutations also increase the risk for lobular breast cancer. Germline mutations in the mismatch repair pathway (Lynch syndrome) slightly increase the risk for gastric cancer. Other inherited cancer susceptibility genetic syndromes that increase the risk of gastric cancer include familial adenomatous polyposis, juvenile polyposis, and Peutz-Jeghers syndrome. Inherited cancer susceptibility genes such as *BRCA* mutations may not significantly increase risk for gastric cancer. Surveillance programs for the higher risk germline cancer susceptibility genes should be employed.

Gastric cancer stem cells originating in the bone marrow may play an important role in the development of gastric cancer. *H. pylori* may be an inciting factor for recruitment of such bone marrow gastric stem cells. If this hypothesis is confirmed, it may have important implications for therapy of gastric cancers.

Clinical Features • **SURVEILLANCE STRATEGIES** As is the case for esophageal cancer, the overwhelming majority of Western patients with gastric cancer are symptomatic at the time of diagnosis. Early detection programs, in Japan and Korea, where gastric cancer has been among the most common of malignancies (although its incidence has been decreasing), include upper endoscopy and, in Japan, upper endoscopy and serum pepsinogen; these programs have increased the number of patients found with early gastric cancer and decreased mortality rates. This strategy has not been cost effective in populations in which the incidence of gastric cancer is much lower, such as in the United States. In high-incidence areas, treatment of symptomatic *H. pylori* is a preventive measure. Exceptions to routine surveillance in the United States are asymptomatic patients with *CDH1* (and other cancer susceptibility gene) mutations who may be part of early detection programs and in whom prophylactic gastrectomy is a management option.

PRESENTING SYMPTOMS Presenting symptoms include vague upper abdominal discomfort, hematemesis or melena, anorexia and early satiety, and unexplained weight loss. For patients with esophagogastric junction cancers, dysphagia or odynophagia may be the presenting symptom. Anemia may be found due to occult bleeding. These symptoms and signs lead to upper (and if site of bleeding is uncertain, lower) endoscopy and biopsy (endoscopy has long replaced barium contrast radiography as an initial diagnostic step). Occasionally, imaging using CT performed to evaluate abdominal symptoms may identify gastric thickening or a gastric mass leading to upper endoscopy. Physical examination can reveal left supraclavicular adenopathy (Virchow's node), a periumbilical mass (Sister Mary Joseph nodule), a pelvic mass on rectal exam (Blumer's shelf), ascites, or an ovarian mass (Krukenberg tumor). More commonly, physical examination is unrevealing.

Upper endoscopy may reveal an ulcer or ulcerated mass, biopsy of which shows adenocarcinoma. For the diffuse subtype of gastric cancer, a mass or ulceration may not be seen, but rather, thickened gastric rugae may be noted. Initial biopsy may not reveal diffuse gastric cancer, which may track below the mucosal surface. In these patients, EUS may guide biopsy.

Histopathology Classification of Primary Gastric Adenocarcinomas The large majority (~85%) of gastric malignancies are adenocarcinomas or subtypes of adenocarcinoma. Other malignancies, discussed below, include neuroendocrine tumors (carcinoid tumors), primary gastric lymphomas, gastrointestinal stromal tumors (GISTs), and other rare malignancies. Using the Lauren classification, pathologists classify adenocarcinomas on the basis of histopathology as intestinal (more common) or diffuse subtype (~20%). As noted above, the diffuse subtype is associated with inherited *CDH1* mutations; in addition, in the TCGA genomic analysis of gastric cancer, approximately a third of diffuse subtype cases had somatic *CDH1* mutations. The intestinal subtype is associated with *H. pylori* infection and atopic gastritis. Histologic grade also influences the clinical course.

Genomic analysis performed by several groups has resulted in molecular classifications of gastric cancer that may, in the future, inform staging systems, provide a better understanding of the driving factors in the development of gastric cancer, and provide important information on treatment options **(Fig. 80-2)**. For example, the TCGA group reported the results of a multiplatform analysis of 295 patients with previously untreated gastric cancer; both Western and Asian patients were included in the analysis. Four subtypes of gastric cancer were identified: high Epstein-Barr virus burden, microsatellite unstable with hypermutation, genomically stable (associated with the diffuse subtype), and chromosomal unstable. The Asian Cancer Research Group (ACRG), studying primary tumors from 300 Korean patients, analyzed gene expression profiles and found four subtypes: mesenchymal, microsatellite unstable, microsatellite stable with *TP53* expressed, and microsatellite unstable with *TP53* mutated. Clinical outcome was correlated with genomic subtype in both studies, with microsatellite

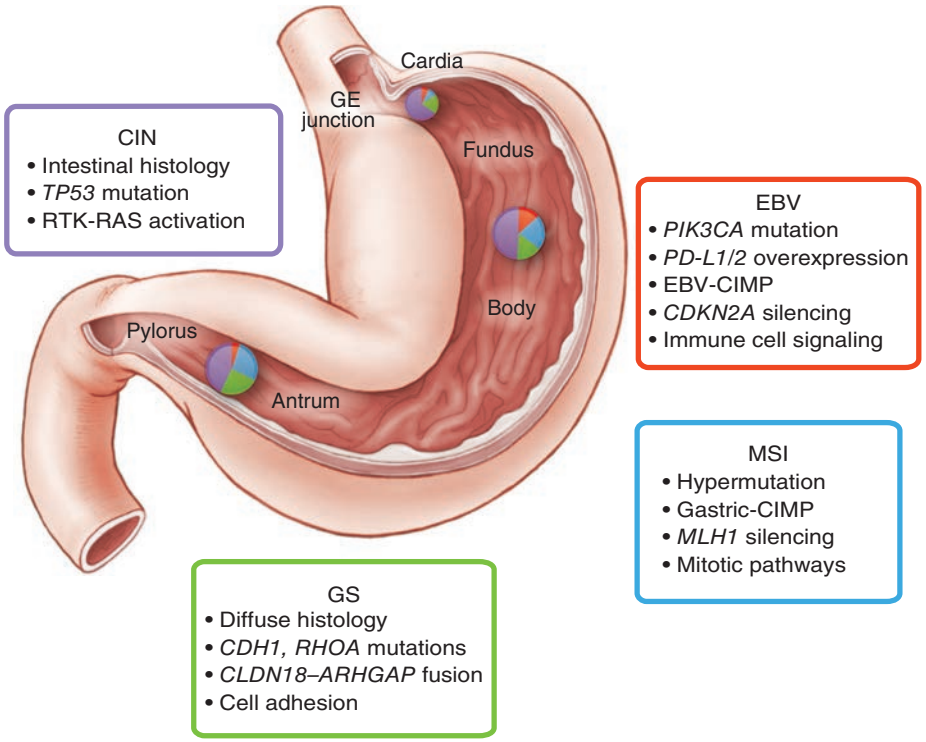

FIGURE 80-2 Molecular/genomic characterization of subtypes of gastric carcinomas. CIMP, CpG-island methylator phenotype; CIN, chromosomally unstable; EBV, Epstein-Barr virus-associated; GE, gastroesophageal; GS, genomically stable; MSI, microsatellite instability-associated.

unstable tumors having the best outcome and genomically stable (TCGA) and mesenchymal (ACRG) types the worst.

In addition to histopathology, molecular diagnostics (including NGS) are an important part of the pathology workup. The molecular subtypes have therapeutic implications; for example, ~20% of gastric cancer or gastroesophageal junction cancer patients' tumors have overexpression or amplification of *HER2*, which would lead to the addition of agents such as trastuzumab as part of systemic treatment for metastatic disease. Immune modulation therapy may be used in patients with hypermutated tumors, found by NGS or by polymerase chain reaction (PCR) for microsatellite instability (MSI). An evaluation for overexpression or amplification of *HER2*, quantification of PD-L1 by immunohistochemistry, and assessment of MSI by PCR or deficient mismatch repair protein (dMMRP) expression should be a routine part of the pathology workup of patients with metastatic gastric cancer. More controversial is whether these assays should also be routinely performed in patients with potentially operable gastric cancer because the addition of trastuzumab to neoadjuvant chemotherapy has not yet been shown to change outcome. In large-volume centers, NGS is routinely performed on pretreatment biopsies. Currently, the finding on pathologic assays of positive tumor Epstein-Barr virus (identified in 8–10% of gastric cancer patients) does not change therapeutic options.

Staging Once a diagnosis of a primary gastric adenocarcinoma is made, algorithms for clinical evaluation of stage include physical examination and imaging studies **(Fig. 80-3**; **Table 80-5)**. Tumor-related biomarkers such as carcinoembryonic antigen (CEA) or CA19-9 may be elevated but are nonspecific (may be elevated in a number of other gastrointestinal and other site cancers). Diagnostic CT scan of the chest, abdomen, and pelvis should be performed. If metastatic

disease is suspected on imaging, a biopsy of a metastatic site should be strongly considered to confirm stage IV disease, which changes the goals of care from potentially curative to palliative treatment. As is the case for esophageal cancer, FDG-PET/CT, which is more sensitive than diagnostic CT scan in identifying sites of metastatic disease, should be performed if the anatomic CT is negative for metastatic disease. Note, however, that FDG-PET may be noninformative (the primary tumor may not be FDG-avid, particularly in diffuse-type gastric cancer). If imaging does not reveal metastatic disease, EUS should be strongly considered to determine depth of penetration of the primary tumor and the presence or absence of regional lymphadenopathy suspicious for metastasis. Lymph node biopsy and, on occasion, biopsy of left hepatic parenchymal lesions found on EUS can be performed at the same setting. Endoscopic biopsies usually provide enough tumor tissue for molecular diagnostic pathology testing for *HER2*, MSI/MMRP, and PD-L1 assessment; it may not provide enough tissue for genomic alteration analysis. If neoadjuvant therapy is planned, laparoscopy should be considered to allow evaluation of the peritoneal cavity, with peritoneal washing for cytology if no peritoneal metastases are visible. The peritoneal cavity is a common site of metastases, especially from diffuse-type gastric cancer. The finding of peritoneal involvement either visibly or by positive cytology is staged as metastatic disease and diminishes the chance for curative resection.

The staging classification for gastric cancer is summarized in Table 80-5. Three staging classifications are provided: cTNM clinical staging (before any therapy has been given), pTNM pathologic staging (for patients not undergoing preoperative therapy), and a post-neoadjuvant therapy classification staging (ypTNM). The three components take into account current standard of care options for therapy in which the AJCC prognostic stage groups from clinical staging guide therapeutic decisions. For example, after clinical evaluation, a large percentage of newly diagnosed patients will be found to have higher-stage primary cancers (penetrating through the gastric wall [T3 or T4] or lymph node–positive tumors), in which case perioperative (neoadjuvant) systemic therapy may be chosen. Pathologic examination of the resected specimen for prognostic stage classification must take into account exposure to preoperative therapies that may lead to downstaging (thus, ypTNM staging). Nomograms have been developed for predicting outcome in patients undergoing surgery as initial treatment.

TREATMENT

Gastric Cancer

POTENTIALLY CURABLE GASTRIC CANCER: SURGERY

Surgical removal of the primary tumor with negative microscopic margins (an R0 resection) and with resection of regional lymph nodes is currently the only curative therapy; with surgery alone, 5-year survival rates are approximately 25%. If tumor cells are found at the margin of resection (R1) or if visible cancer is left at the time of surgical removal of the primary tumor (R2), surgery is palliative rather than curative. For patients with early-stage tumors (mostly clinical stage I), surgery without perioperative systemic therapy may be performed. For patients with more locally advanced tumors (clinical stages IIA, IIB, III), who compose approximately 70% of newly diagnosed operable patients, multimodality therapy (surgery and systemic chemotherapy) improves overall survival. Both neoadjuvant (preoperative) and postoperative systemic therapy are accepted approaches. If staging studies demonstrate a locally advanced cancer (T3/4 or node positive), preoperative treatment is recommended in a medically fit patient. If surgery is performed first and a locally advanced cancer is found, postoperative chemotherapy or chemotherapy plus chemoradiation is recommended. For selected very-early-stage gastric cancers (primary tumors that are ≤2 cm in diameter, are well to moderately differentiated, do not invade the deep submucosa, and do not show lymphovascular invasion or lymph node metastasis), which are not commonly found in the United States, endoscopic mucosal resection (EMR) or endoscopic submucosal dissection (ESD) may be performed by experienced gastroenterologists in place of surgical resection, with favorable results in studies in high-incidence areas such as Japan.

For patients in whom the primary tumor is in the distal stomach, a subtotal gastrectomy is the preferred surgical procedure. For tumors of the proximal stomach, the options for resection include total gastrectomy or, alternatively, proximal gastrectomy. Esophagogastrectomy is performed for tumors involving the gastroesophageal junction. In selected patients, a jejunostomy feeding tube may be placed if postoperative radiation therapy is part of the treatment plan.

As noted above, laparoscopy is commonly performed at high-volume centers before a final decision regarding the role of surgery. If staging has already demonstrated clinically suspicious lymph nodes or an advanced T stage tumor, but laparoscopy does not demonstrate peritoneal metastasis, perioperative chemotherapy is given before surgical resection.

Palliative resection of the primary tumor is usually performed only if symptoms such as uncontrollable bleeding or obstruction are present that cannot be relieved by other means.

As is the case for colorectal cancer, a correlation exists between the number of lymph nodes removed and sampled and outcome. Sentinel lymph node biopsy is not performed in gastric cancer outside of a research study setting. The goal is to examine at least 15 lymph nodes from the resected specimen; it is more controversial whether more extensive lymph node resection itself affects outcome; the extent of lymphadenopathy can be classified using a D0–D3 system with a higher number meaning more extensive lymphadenopathy. In the United States, a modified D2 (D1+)

resection preserving the spleen and avoiding pancreatectomy is recommended but should be performed by experienced surgeons at high-volume centers. Japanese investigators and others have used very extensive lymph node dissections, but studies have not demonstrated an advantage for a D3 resection. Both resection of the primary tumor and its regional lymph nodes can be performed laparoscopically in appropriate patients.

In the hands of experienced surgeons, operative mortality would be anticipated to be ≤2%.

NEOADJUVANT AND POSTOPERATIVE ADJUVANT THERAPY FOR RESECTABLE GASTRIC CANCER

The large majority of potentially resectable Western gastric cancer patients have locally advanced tumors (cTNM stage IIA/B or III). Multimodality therapy using systemic chemotherapy improves 5-year survival rates by 10–15% compared to surgery alone. A widely cited study, the MAGIC clinical trial, randomly assigned patients with potentially resectable disease to receive perioperative chemotherapy or to proceed directly to surgery. Five-year overall survival for patients undergoing surgery alone was 23%; for those receiving pre- and postoperative chemotherapy, it was 36%. On the basis of this and other clinical trials, for most medically fit patients with stage cTNM II and III resectable gastric cancers, preoperative systemic chemotherapy followed by resection and, if tolerable, postoperative chemotherapy is a standard of care. Chemoradiation as given for esophageal cancers is usually used for gastroesophageal junction tumors. Preoperative chemoradiation or preoperative chemotherapy followed by chemoradiation for gastric cancer, as opposed to esophageal or gastroesophageal junction cancers, has been studied but is still an investigational approach. For patients being treated with multimodality therapy, close interactions among the surgeon, medical oncologist, and radiation oncologist are essential.

Clinical trials have compared different cytotoxic chemotherapy regimens, most of which include a platinum compound—either cisplatin or oxaliplatin. Currently, a platinum compound plus a fluorinated pyrimidine, such as fluorouracil or capecitabine, given for three to four cycles before surgery is a standard of care option. Drug combinations are favored; an example is the FOLFOX regimen, which includes fluorouracil, leucovorin, and oxaliplatin. For very fit patients, a combination of fluorouracil, oxaliplatin, and docetaxel (FLOT) may be chosen. Addition of trastuzumab to chemotherapy has not improved outcomes for patients with HER2-positive cancers. Careful monitoring of chemotherapy-related toxicities with appropriate dose modifications is important. Several clinical trials have included both preoperative and postoperative systemic therapy; a substantial number of patients will have a slow postoperative recovery and not receive postoperative treatment. Maximizing the ability to give preoperative chemotherapy is an important consideration. For patients receiving preoperative systemic chemotherapy and undergoing a D2/D1+ dissection, postoperative chemoradiation therapy has not improved outcome.

For patients in whom the primary tumor has been resected and who did not receive preoperative chemotherapy, who are found to have stage II or III cancers, or who have <15 lymph nodes found in the resected specimen, postoperative chemoradiation is a treatment option. Chemoradiation therapy may also be given for unresectable cancers in selected patients.

PALLIATIVE THERAPY FOR INCURABLE GASTRIC CANCER

Patients with clinical stage IV gastric cancers with an adequate performance status should be offered systemic drug therapies. Small clinical trials performed in the 1980s and 1990s showed a survival benefit for systemic therapy compared to best supportive care only. The cytotoxic chemotherapy regimens most commonly employed are still based on a platinum compound and a fluorinated pyrimidine (e.g., FOLFOX, as is used in the perioperative setting). However, two subgroups of gastric cancer patients have been identified who benefit from the addition of noncytotoxic agents. Those whose tumors have overexpressed or amplified *HER2* should receive HER2-targeted agents such as trastuzumab plus cytotoxic chemotherapy because a modest survival advantage has been demonstrated. Additional HER2-targeted therapy using trastuzumab-deruxtecan, a monoclonal antibody-drug conjugate, has encouraging activity in patients whose tumors were refractory to trastuzumab. For patients with MSI/dMMRP gastric cancers, PD-1 inhibitors such as pembrolizumab should be used (currently approved in the second-line setting). Immune modulation therapy using PD-1 inhibitors such as pembrolizumab or nivolumab is also approved in gastric cancer with tumor specimens having ≥1% PD-L1 expression, with modest response rates. The development of more effective immune therapies and their combination with cytotoxic chemotherapy (and in combination with trastuzumab plus chemotherapy in *HER2*-positive patients) as initial treatment are areas of active investigation.

When disease progresses after first-line treatment, other therapies include the combination of a VEGF receptor–targeted agent, ramucirumab, either alone or in combination with paclitaxel. As noted above, immune modulation therapy may cause remissions in patients whose tumors have at least 1% PD-L1 expression. PD-1 inhibitors are the preferred option for patients whose tumors are microsatellite unstable. Several other cytotoxic agents have activity in the palliative setting including irinotecan and trifluridine-tipiracil. Best results from clinical trials indicate overall survival for treated patients with stage IV disease is still only 12–15 months.

Radiation therapy using shorter regimens may be employed to palliate bleeding. For patients with advanced incurable disease, other supportive measures include placement of a duodenal stent to relieve gastric outlet obstruction; in selected patients, surgical procedures for gastric outlet obstruction may be performed. Radiation therapy might be used if not previously given. Enteral feeding using a jejunostomy tube may support nutritional needs.

GASTRIC LYMPHOMAS

Lymphomas of the stomach are an uncommon (~3%) but important subgroup of gastric malignancies. They are extranodal non-Hodgkin's lymphomas (NHL). The gastrointestinal tract is the most common site for extranodal NHL, and the stomach is the most common site within the gastrointestinal tract. The presenting symptoms are similar to those of the much more common adenocarcinoma of the stomach described above, including pain, anorexia, and bleeding. Symptoms of fever and night sweats occur in 10–15% of patients with gastric NHL. Because the treatment options are so different, obtaining adequate tissue for definitive pathologic examination is crucial in diagnosing gastric lymphomas. On occasion, this may be challenging because, similar to diffuse subtype adenocarcinoma, lymphomas may track below the mucosal surface. Multiple deep biopsies and mucosal resection may be needed to provide enough tissue for definitive pathologic assessment.

Potential driving forces in the development of gastric lymphomas include active or prior *H. pylori* infection, which is associated with mucosa-associated lymphoid tissue (MALT) subtype gastric lymphomas. MALT lymphomas may develop in nearly any organ, but the stomach is the most frequent primary site, accounting for ~35% of all MALT lymphomas. Antibacterial therapy directed against *H. pylori* can be a highly effective treatment in these patients. Other forms of NHL may involve the stomach either as primary gastric lymphoma or as a secondary site of disease, including both B-cell (e.g., mantle cell lymphoma, Burkitt's lymphoma, and follicular lymphoma) and T-cell lymphomas (e.g., enteropathy-associated T-cell lymphoma, anaplastic large-cell lymphoma, and peripheral T-cell lymphoma).

Staging is performed in a fashion similar to gastric adenocarcinoma, but the staging classification is different (see below). In addition to a contrast-enhanced diagnostic-quality CT scan of the chest, abdomen, and pelvis, an FDG-PET/CT scan may be helpful. EUS may be used to determine depth of invasion in patients in whom no evidence of metastatic disease is noted. Examination of the peripheral blood and bone marrow aspirate should be considered as part of the workup.

In all patients with gastric lymphoma, *H. pylori* infection status should be evaluated. If *H. pylori* testing is negative by histopathology, noninvasive testing by either stool antigen test or urea breath test should be used. If rituximab will be part of the treatment plan (see below), hepatitis B testing should be performed.

STAGING

The TNM staging system is not employed for gastric lymphomas. The Lugano staging system for gastrointestinal lymphomas (a modification of the Ann Arbor staging system) divides patient groups into stages I, II, and IV. Stage I tumors are limited to the gastric wall; stage II tumors have regional lymph node involvement or invasion of local structures; stage IV tumors have either more extensive lymph node involvement or have distant metastasis, including to the bone marrow or other extranodal sites.

PATHOLOGIC CLASSIFICATION

The two most common histologic subtypes of gastric lymphoma are marginal zone B-cell lymphomas (gastric marginal zone B-cell lymphomas or MALT; ~40% of newly diagnosed patients) and diffuse large B-cell lymphomas (DLBCLs; ~55%). The distinction is critical because therapeutic options are different. As part of the pathologic evaluation, for patients with *H. pylori*–positive gastric lymphomas, the finding of a t(11;18) translocation identifies a subgroup less likely to respond to *H. pylori* eradication. This translocation may be detected using PCR or fluorescent in situ hybridization (FISH); it creates a chimeric protein composed of the amino terminal of *API1* (apoptosis inhibitor) and the carboxy terminus of *MALT1*, leading to activation of nuclear factor-κB signaling.

TREATMENT

Gastric Lymphoma

Unlike adenocarcinoma of the stomach, surgical resection has no role in the treatment of primary gastric lymphoma in the absence of complications of therapy such as perforation or uncontrollable bleeding. Resection of gastric lymphoma does not improve outcome.

For patients with MALT lymphoma, eradication of *H. pylori* with antibiotics is highly effective therapy. If tests for *H. pylori* are positive and t(11;18) translocation assay is negative, one of the currently accepted antibiotic regimens for treating *H. pylori* should be the initial therapy. *H. pylori* eradication is associated with high response rates including complete remissions in the majority of patients. The time to remission may be prolonged (in some studies averaging 15–16 months); therefore, careful monitoring is important before determining that a MALT tumor is not responding to anti–*H. pylori* therapy. For patients in whom the t(11;18) translocation assay is positive, options for therapy include anti–*H. pylori* antibiotic therapy plus involved-field radiation therapy or, if radiation is contraindicated, the use of single-agent rituximab, a monoclonal antibody targeting CD20. For patients who are *H. pylori* negative, moderate-dose (24–30 Gy) involved-site radiation therapy or single-agent rituximab is a treatment option. For selected, more advanced, stage IV MALT patients who have not responded to or who have progressed after receiving anti–*H. pylori* antibiotic therapy and/or rituximab, cytotoxic chemotherapy regimens such as R-CHOP (rituximab, cyclophosphamide, doxorubicin, vincristine, and prednisolone) or rituximab and lenalidomide may be considered.

DLBCL may be a result of transformation from more indolent MALT lymphoma or may arise de novo. De novo tumors are more likely to be BCL2 and CD10 positive. MALT lymphomas that have transformed to DLBCLs are more frequently BCL2 and CD10 negative.

For patients with DLBCL, earlier stage tumors may be treated by combination chemotherapy alone or chemotherapy plus involved-field radiation therapy. For more advanced gastric DLBCL tumors, chemotherapy using R-CHOP or R-EPOCH (rituximab, etoposide, prednisolone, vincristine, cyclophosphamide, and doxorubicin) regimens is standard of care. Some reports have suggested that eradication of *H. pylori* is effective treatment for early-stage DLBCL when the patient also has *H. pylori*.

UNCOMMON TUMORS OF THE ESOPHAGUS AND STOMACH

NEUROENDOCRINE TUMORS

Neuroendocrine tumors (NETs) of the esophagus are rare, accounting for <1% of gastrointestinal NETs. They may present with dysphagia and odynophagia similar to that of more common squamous cell or adenocarcinoma of the distal esophagus and gastroesophageal junction or with more nonspecific symptoms such as substernal discomfort or burning consistent with reflux esophagitis. A potential driving factor of higher grade NET is smoking. The initial diagnostic evaluation includes upper endoscopy and biopsy. Pathology may reveal a well-differentiated grade 1 or grade 2 NET with a low metastatic potential; at the other end of the spectrum are small-cell or large-cell NETs, which are fully malignant and frequently metastasize. EUS to assess depth of penetration and presence or absence of regional lymph node metastasis is usually performed. Imaging studies include CT or FDG-PET/CT scan to assess for metastatic disease, particularly in higher grade tumors. For lower grade tumors, somatostatin analog imaging studies such as gallium-68 DOTATATE may be performed if metastatic disease is suspected. For lower grade tumors, endoscopic resection including EMR or ESD may be performed. Small-cell or large-cell NETs that are not metastatic are usually treated with chemotherapy plus external-beam radiation therapy using chemotherapy regimens similar to those employed for small- and large-cell neuroendocrine cancers of the lung (Chap. 84). Systemic therapy for metastatic small- and large-cell esophagogastric NETs is also modeled on therapy for small- and large-cell thoracic NETs.

Gastric NETs (also called gastric carcinoid tumors) represent 7–9% of gastrointestinal NETs but <1% of gastric neoplasms. They are divided into three types (Chap. 84). For all gastric NETs, initial evaluation includes upper endoscopy and biopsy. EUS may be helpful in assessing depth of invasion for larger tumors and for assessing regional lymph node metastases in type 3 tumors. Somatostatin analog imaging using gallium-68 DOTATATE PET/CT scanning may be performed if metastatic disease is suspected. The finding of unresectable metastatic disease that is gallium-68 DOTATATE avid not only provides staging information but also guides potential therapy using somatostatin receptor–targeted therapy.

TREATMENT

Gastric Neuroendocrine Tumors

Type 1 tumors are usually treated endoscopically with polypectomy or endomucosal resection. For larger tumors (>2 cm) or tumors invading through the muscularis or to regional lymph nodes, surgical resection is recommended. Type 2 tumors have a higher risk for regional lymph node metastasis and are usually treated surgically, although selected patients may have a combination of endoscopic resection and limited surgical resection. Type 3 tumors are not associated with elevated gastrin levels and have a higher propensity for regional lymph node metastasis and distant metastasis. Surgery is the treatment of choice for localized type 3 tumors, although EMR has been used in selected patients. Adenocarcinoma of the stomach may be found in 5–10% of type 3 tumors.

GASTROINTESTINAL STROMAL TUMORS

Gastrointestinal stromal tumors (GISTs) are rare tumors of the gastrointestinal tract associated with somatic mutations in the c*KIT* (the majority) or *PDGFRA* genes, which are both driver mutations and targets for systemic therapy for metastatic disease; in a minority of cases, neither gene is mutated. GISTs arise from Cajal cells, which bridge between the autonomic nerves to the muscle layer of the bowel. The stomach is the most frequent primary site (~50%), followed by

the small bowel in about a third of cases. As endoscopy for other indications has become more widely used, otherwise asymptomatic and probably clinically insignificant small GISTs have been identified more frequently; it is not clear that the actual incidence has substantially increased. Symptoms associated with GISTs include acute gastrointestinal bleeding leading to melena and/or hematemesis. Anemia may be reflected in generalized weakness. With larger tumors, abdominal distention and pain may be presenting symptoms. At endoscopy, a nonspecific smooth bulging mass covered by normal mucosa is the most frequent finding. Initial biopsy may not reveal an epithelial neoplasm. EUS both to assess the extent of the neoplasm and to guide biopsy in order to obtain adequate tissue for histology and molecular pathology may be helpful.

Histologically, a spindle cell neoplasm is the most common subtype (~70%), with epithelioid cells making up 20%; 10% of cases are mixed histology. Immunohistochemical stains for the presence of c-kit or CD34 positivity and mutational analysis of *cKIT* and *PDGFRA* should be performed in all patients. These help to distinguish between GISTs and leiomyoma neoplasms. For nonmetastatic primary GISTs, laparoscopic surgical resection, if feasible, is the treatment of choice; because lymph node metastases are unusual, wedge or segmental resection is preferred. Endoscopic resection has been used in selected cases. Neither histology nor the presence of a c*KIT* or *PDGFRA* mutation distinguishes GISTs with clinically malignant phenotype from those that have a benign course. Higher risk tumors (larger size, higher mitotic index) may present with or develop metastatic or locally unresectable disease. For these patients, use of a c-kit tyrosine kinase inhibitor such as imatinib for tumors with *cKIT* mutations offers effective palliation. Avapritinib is used for tumors with certain *PDGFRA* mutations. However, resistance almost invariably develops, and the development of newer agents effective in tumors with secondary mutations is a high priority. For high-risk GISTs, adjuvant therapy with imatinib for 3 years improves relapse-free and overall survival.

SMALL-BOWEL NEOPLASMS

Although the number of new cases of small-bowel neoplasms is substantially less than that of gastric neoplasms (in 2020, there were an estimated 11,110 new cases in the United States, representing 3–4% of gastrointestinal malignancies), the spectrum of malignant tumors of the small bowel is similar and includes NETs (carcinoid), adenocarcinomas, lymphomas, and GISTs. Neuroendocrine cancers are slightly more frequent (40–45%) than adenocarcinomas (30–40%), with the remainder mostly lymphomas and ~8% GISTs. The duodenum is the most common portion of the small bowel in which malignancies develop (~50%), with ~30% occurring in the jejunum and 20% in the ileum. NETs are the most common benign and malignant tumors of the ileum. Risk factors for the development of adenocarcinoma include inflammatory bowel disease (Crohn's disease) and inherited germline mutation syndromes such as Lynch syndrome, familial adenomatous polyposis (FAP), and Peutz-Jeghers syndrome. Celiac disease is associated with a higher incidence of both small-bowel adenocarcinomas and T-cell lymphomas.

While an asymptomatic small-bowel primary adenocarcinoma might be found during surveillance in patients at high risk (such as someone with FAP), symptoms due to obstruction or bleeding (which may be occult) lead to the diagnosis of a small-bowel tumor in a substantial number of patients. Both adenocarcinoma and lymphomas might present with perforation. The development of anemia or obstructive symptoms in a patient with a germline cancer susceptibility gene mutation should lead to a high degree of suspicion for developing malignancy. Evaluation by diagnostic CT imaging may reveal an obstructing lesion. CT and/or MRI enterography can be helpful if the diagnostic CT is not informative. Endoscopy using techniques such as double balloon enteroscopy or video capsule endoscopy allows (for the former) tissue diagnosis as well as localization. Video capsule endoscopy is contraindicated in the setting of obstruction. For NETs, a gallium-68 DOTATATE scan may identify both the primary site as well as metastatic disease. Blood tumor biomarkers are nonspecific for the primary site (CEA or CA19-9 for adenocarcinoma or serum chromogranin for NET); these assays are better used to monitor response or progression of disease rather than for diagnosis.

Adenocarcinoma of the small bowel appears to be increasing in incidence. The median age for sporadic small-bowel tumors is in the seventh or eighth decade of life, but genetically predisposed patients and those with inflammatory bowel disease may be diagnosed at a much earlier age. African Americans have a higher incidence of small-bowel cancer than whites. While systemic therapies are usually modeled on agents used to treat colorectal cancer, genomic analyses have indicated that small-bowel adenocarcinoma has distinct genomic alterations compared to either colorectal or gastric cancers. Genomic alterations less frequent in small-bowel than in colorectal cancers include *TP53*, *BRAF* V600E, and *APC* mutations, whereas the rate of *KRAS* mutations is similar to colorectal cancer. Within small-bowel sites, the most striking difference is the higher rate of *ERBB2* alterations (of which a minority are amplifications) in duodenal cancers. Not surprisingly, because Lynch syndrome increases the risk of small-bowel adenocarcinoma, 15–20% of these tumors are MSI high or mismatch repair deficient; small-bowel adenocarcinoma associated with celiac disease also may have an increased rate of MSI-high tumors. MSI/MMRP status should be assessed in all patients with small-bowel adenocarcinoma. Somatic tumor genomic analysis may suggest a germline mutation, but appropriate genetic testing for a germline driver mutation should be performed in all patients with small-bowel adenocarcinoma.

Small-bowel adenocarcinoma has its own staging classification in the AJCC eighth edition.

TREATMENT

Small-Bowel Adenocarcinomas

Surgical resection with negative microscopic margins (R0), as is the case for other gastrointestinal tumors, is the best chance for cure. For duodenal adenocarcinomas, a Whipple procedure may be needed; for more distal duodenal cancers and jejunal adenocarcinomas, a segmental resection with adequate margins should be performed. Distal ileal tumors may require right hemicolectomy.

Small-bowel cancers are frequently found with locally advanced disease at the time of diagnosis. If the tumor is resectable, postoperative adjuvant systemic therapy is currently recommended for lymph node–positive patients, using regimens such as capecitabine-oxaliplatin. Benefit from adjuvant therapy has not yet been proven. Small-bowel cancers developing in patients with Lynch syndrome probably have a better prognosis; if colorectal cancer is a model, postoperative adjuvant therapy for patients with Lynch syndrome should be combination chemotherapy, not single-agent fluorinated pyrimidines. The value of immune modulation therapy is not established. For duodenal cancers, chemoradiation is considered if the resection margins are still positive.

For patients with advanced metastatic disease, in the absence of Lynch syndrome or a hypermutated tumor, similar cytotoxic regimens as deployed for gastric or colon cancers have been widely used. For tumors that are MSI high or dMMPR, immunotherapy is indicated; for tumors that are *HER2* amplified or *BRAF* mutated, targeted therapy may be useful.

SMALL-BOWEL GASTROINTESTINAL STROMAL TUMORS

Like small-bowel adenocarcinomas, small-bowel GISTs may present with obstruction or bleeding. Diagnostic techniques are those employed for other small-bowel neoplasms. While the pathological criteria for malignant potential are somewhat different than those used for gastric GISTs, postoperative management and treatment of metastatic disease are the same as those described above for gastric GIST.

CARCINOID (NEUROENDOCRINE) TUMORS OF THE SMALL BOWEL

Carcinoid tumors are the most common small-bowel neoplasms. For not yet identified reasons, the incidence of small-bowel carcinoid

tumors has markedly increased over the past several decades. Although known risk factors include inherited genetic cancer susceptibility genes such as *MEN1* and neurofibromatosis 1 (*NF1*), these are unlikely to be the cause of the increase **(Chap. 84)**. However, although the incidence has increased, small-bowel carcinoids are still uncommon, with an estimated incidence of approximately nine cases per million in the United States; the disease is more common in African Americans than whites.

Anatomically, the ileum is the most common part of the small bowel affected (~49%), followed by the duodenum and the jejunum. As is the case for gastric carcinoid tumors, grade is based on mitotic rate and/or Ki-67 immunohistochemistry. Histologic differentiation also uses the same criteria as in gastric carcinoid tumors.

In the absence of metastatic disease to the liver in the subgroup of patients whose tumors are functional (i.e., produce a hormone, usually serotonin; a duodenal NET may be a gastrinoma), presenting symptoms may be vague abdominal discomfort until or unless small-bowel obstruction occurs. Carcinoid syndrome may be found in patients whose tumors are diagnosed with already established hepatic metastasis. Because the liver is very efficient at clearing serotonin on first pass, carcinoid syndrome as a result of small-bowel carcinoid tumors usually does not occur in the absence of hepatic metastasis.

Clinical evaluation includes a diagnostic-quality CT or MRI of the abdomen and pelvis. For duodenal carcinoid tumors, upper endoscopy with EUS is also performed, and for jejunal or ileal carcinoid tumors, colonoscopy is performed. Small-bowel imaging may be performed by CT enterography; if an obstructing tumor is suspected, capsule endoscopy should be avoided. The diagnosis of a metastatic NET may be suspected from the radiographic appearance on CT imaging. Somatostatin analog imaging using gallium-68 DOTATATE is helpful in assessing extent of disease in patients whose tumors are somatostatin analog avid, as well as in identifying patients who may benefit from therapy targeting the somatostatin receptor. The AJCC eighth edition cancer staging manual has a specific small-bowel NET TNM stage classification.

The majority of patients present with locoregional disease, with approximately 40% having identified lymph node metastasis. Ten to 15% of patients have metastatic disease (usually to the liver) at the time of initial diagnosis.

Initial management should be surgical resection with curative intent; for patients with extensive adenopathy involving the root of the mesentery, vascular reconstruction may be required. Since small-bowel NETs may involve multiple tumors (15–30% of patients), the entire small bowel should be carefully examined. For patients with functional carcinoid tumors, somatostatin analog therapy using agents such as octreotide should be given before the induction of anesthesia to avoid a carcinoid crisis. For patients with hepatic metastasis, resection or regional therapy including ablation or hepatic artery embolization for functional tumors may provide effective palliation. Carcinoid syndrome may also be palliated by somatostatin receptor targeted therapy in the patients in whom gallium-68 DOTATATE scanning is positive (the majority of patients with carcinoid syndrome), including agents such as octreotide or lanreotide, or by peptide-directed radiation therapy using lutetium-177. Everolimus, an mTOR kinase inhibitor, has modest activity in metastatic small-bowel carcinoid tumors.

BENIGN NEOPLASMS OF THE SMALL BOWEL

As is the case for malignant small-bowel tumors, benign neoplasms of the small bowel are rare. In addition to cancers, the precursor lesion adenomas or hamartomas (from which cancers develop) may be driven by inherited cancer susceptibility genes (FAP, Lynch syndrome, Peutz-Jeghers syndrome, among others.). Other benign neoplasms include lipomas, leiomyomas, neurofibromas, and benign lymphoid nodular hyperplasia.

Patients with benign small-bowel neoplasms not associated with an inherited cancer susceptibility gene (in which case a benign tumor may be found during surveillance) are usually asymptomatic. A mass may be noted on an imaging study (usually a CT) ordered for another reason. Workup for occult or overt bleeding or intussusception of the bowel may lead to the discovery of a benign small-bowel neoplasm.

Diagnostic evaluation may include video capsule endoscopy and double balloon or push enteroscopy. In general, benign neoplasms, if found during surveillance, are removed endoscopically, if technically feasible, to decrease the risk of intussusception in Peutz-Jeghers syndrome. Mucosectomy may be used to treat bleeding hemangiomas.

81 Lower Gastrointestinal Cancers

Robert J. Mayer

Lower gastrointestinal cancers include malignant tumors of the colon, rectum, and anus.

COLORECTAL CANCER

INCIDENCE

Cancer of the large bowel is second only to lung cancer as a cause of cancer death in the United States: 149,500 new cases were identified in 2021, and 52,980 deaths were due to colorectal cancer. The incidence rate has decreased significantly during the past 30 years in individuals 50 years of age or older, likely due in large part to enhanced and more compliantly followed screening practices. Similarly, mortality rates in the United States in this age group have decreased by more than 30%, resulting largely from early detection and improved treatment. During the same period of time, however, the incidence rate for colorectal cancer in men and women <50 years of age, having no enhanced genetic risk factor or family history for the disease, has risen by 2% each year with the presence of symptoms in this age group often being initially attributed to other causes, resulting in a more advanced disease stage at the time of diagnosis being frequently observed. A corresponding increase in mortality rates from colorectal cancer in this young adult population is now evident while, simultaneously, the trend for a decreased death rate in older individuals has continued. No distinguishing etiologic or molecular factor or clinical characteristic to account for the rising incidence of colorectal cancer in younger men and women has yet been identified with lifestyle patterns, such as diet and obesity beginning at an earlier age, having been proposed.

POLYPS AND MOLECULAR PATHOGENESIS

Most colorectal cancers, regardless of etiology, arise from adenomatous polyps. A polyp is a grossly visible protrusion from the mucosal surface and may be classified pathologically as a nonneoplastic hamartoma (e.g., *juvenile polyp*), a hyperplastic mucosal proliferation (*hyperplastic polyp*), or an adenomatous polyp. Only adenomas are clearly premalignant, and only a minority of adenomatous polyps evolve into cancer. Adenomatous polyps may be found in the colons of ~30% of middle-aged and ~50% of elderly people; however, <1% of polyps ever become malignant. Most polyps produce no symptoms and remain clinically undetected. Occult blood in the stool is found in <5% of patients with polyps.

A number of molecular changes are noted in adenomatous polyps and colorectal cancers that are thought to reflect a multistep process in the evolution of normal colonic mucosa to life-threatening invasive carcinoma. These developmental steps toward carcinogenesis include, but are not restricted to, point mutations in the K-*ras* proto-oncogene; hypomethylation of DNA, leading to gene activation; loss of DNA (*allelic loss*) at the site of a tumor-suppressor gene (the adenomatous polyposis coli [*APC*] gene) on the long arm of chromosome 5 (5q21); allelic loss at the site of a tumor-suppressor gene located on chromosome 18q (the deleted in colorectal cancer [*DCC*] gene); and allelic loss at chromosome 17p, associated with mutations in the *p53* tumor-suppressor gene (see Fig. 71-2). Thus, the altered proliferative pattern of the colonic mucosa, which results in progression to a polyp and then to carcinoma, may involve the mutational activation of an oncogene followed by and coupled with the loss of genes that normally suppress tumorigenesis. It remains uncertain whether the genetic aberrations always occur in a defined order. Based on this model, however, cancer is believed to develop only in those polyps in which most (if not all) of these mutational events take place.

Clinically, the probability of an adenomatous polyp becoming a cancer depends on the gross appearance of the lesion, its histologic features, and its size. Polyps may be pedunculated (stalked) or sessile (flat-based), adenomatous or serrated. Invasive cancers develop more frequently in sessile, serrated (i.e., "flat") polyps. Histologically, adenomatous polyps may be tubular, villous (i.e., papillary), or tubulovillous. Villous adenomas, most of which are sessile, become malignant more than three times as often as tubular adenomas. The likelihood that any polypoid lesion in the large bowel contains invasive cancer is related to the size of the polyp, being negligible (<2%) in lesions <1.5 cm, intermediate (2–10%) in lesions 1.5–2.5 cm, and substantial (10%) in lesions >2.5 cm in size.

Following the detection of an adenomatous polyp, the entire large bowel should be visualized endoscopically because synchronous lesions are noted in about one-third of cases. Colonoscopy should then be repeated periodically, even in the absence of a previously documented malignancy, because such patients have a 30–50% probability of developing another adenoma and are at a higher-than-average risk for developing a colorectal carcinoma. Adenomatous polyps are thought to require >5 years of growth before becoming clinically significant; colonoscopy need not be carried out more frequently than every 3 years for the vast majority of patients.

ETIOLOGY AND RISK FACTORS

Risk factors for the development of colorectal cancer are listed in Table 81-1.

TABLE 81-1 Risk Factors for the Development of Colorectal Cancer

Diet: Animal fat, obesity
Hereditary syndromes
Polyposis coli
MYH-associated polyposis
Nonpolyposis syndrome (Lynch's syndrome)
Inflammatory bowel disease
Streptococcus bovis bacteremia
Tobacco use

Diet The etiology for most cases of large-bowel cancer appears to be related to environmental factors. The disease occurs more often in upper socioeconomic populations who live in urban areas. Mortality from colorectal cancer is directly correlated with per capita consumption of calories, meat protein, and dietary fat and oil as well as elevations in the serum cholesterol concentration and mortality from coronary artery disease. Geographic variations in incidence largely are unrelated to genetic differences because migrant groups tend to assume the large-bowel cancer incidence rates of their adopted countries. Furthermore, population groups such as Mormons and Seventh Day Adventists, whose lifestyle and dietary habits differ somewhat from those of their neighbors, have significantly lower-than-expected incidence and mortality rates for colorectal cancer. The incidence of colorectal cancer has increased in Japan since that nation has adopted a more "Western" diet. At least three hypotheses have been proposed to explain the relationship to diet, none of which is fully satisfactory.

ANIMAL FATS One hypothesis is that the ingestion of animal fats found in red meats and processed meat leads to an increased proportion of anaerobes in the gut microflora (the "microbiome"), resulting in the conversion of normal bile acids into carcinogens. This provocative hypothesis is supported by several reports of increased amounts of fecal anaerobes (*Fusobacterium nucleatum*, *Bacteroides fragilis*) in the stools of patients with colorectal cancer. Diets high in animal (but not vegetable) fats are also associated with high serum cholesterol, which is also associated with enhanced risk for the development of colorectal adenomas and carcinomas.

INSULIN RESISTANCE The large number of calories in Western diets coupled with physical inactivity has been associated with a higher prevalence of obesity. Obese persons develop insulin resistance with increased circulating levels of insulin, leading to higher circulating concentrations of insulin-like growth factor type I (IGF-I). This growth factor appears to stimulate proliferation of the intestinal mucosa.

FIBER Contrary to prior beliefs, the results of randomized trials and case-controlled studies have *failed* to show any value for dietary fiber or diets high in fruits and vegetables in preventing the recurrence of colorectal adenomas or the development of colorectal cancer.

The weight of epidemiologic evidence, however, implicates diet as being the major etiologic factor for colorectal cancer, particularly diets high in animal fat and in calories.

HEREDITARY FACTORS AND SYNDROMES

Up to 25% of patients with colorectal cancer have a family history of the disease, suggesting a hereditary predisposition. Inherited large-bowel cancers can be divided into two main groups: the well-studied but uncommon polyposis syndromes and the more common nonpolyposis syndromes (Table 81-2).

Polyposis Coli Polyposis coli (familial polyposis of the colon) is a rare condition characterized by the appearance of thousands of adenomatous polyps throughout the large bowel. It is transmitted as an autosomal dominant trait; the occasional patient with no family history probably developed the condition due to a spontaneous mutation. Polyposis coli is associated with a deletion in the long arm of chromosome 5 (including the *APC* gene) in both neoplastic (somatic mutation) and normal (germline mutation) cells. The loss of this genetic material (i.e., allelic loss) results in the absence of tumor-suppressor genes whose protein products would normally inhibit neoplastic growth. The presence of soft tissue and bony tumors, congenital hypertrophy of the retinal pigment epithelium, mesenteric desmoid tumors, and ampullary cancers in addition to the colonic polyps characterizes a subset of polyposis coli known as *Gardner's syndrome*. The appearance of malignant tumors of the central nervous system accompanying polyposis coli defines *Turcot's syndrome*. The colonic polyps in all these conditions are rarely present before puberty but are generally evident in affected individuals by age 25 years. If the polyposis is not treated surgically, colorectal cancer will develop in almost all patients aged <40 years. Polyposis coli results from a defect in the colonic mucosa, leading to an abnormal proliferative pattern and impaired DNA repair mechanisms.

TABLE 81-2 Heritable (Autosomal Dominant) Gastrointestinal Neoplasia Syndromes

SYNDROME	DISTRIBUTION OF POLYPS	HISTOLOGIC TYPE	MALIGNANT POTENTIAL	ASSOCIATED LESIONS
Familial adenomatous polyposis	Large intestine	Adenoma	Common	None
Gardner's syndrome	Large and small intestines	Adenoma	Common	Osteomas, fibromas, lipomas, epidermoid cysts, ampullary cancers, congenital hypertrophy of retinal pigment epithelium
Turcot's syndrome	Large intestine	Adenoma	Common	Brain tumors
MYH-associated polyposis	Large intestine	Adenoma	Common	None
Lynch syndrome (nonpolyposis syndrome)	Large intestine (often proximal)	Adenoma	Common	Endometrial and ovarian tumors (most frequently), gastric, genitourinary, pancreatic, biliary cancers (less frequently)
Peutz-Jeghers syndrome	Small and large intestines, stomach	Hamartoma	Rare	Mucocutaneous pigmentation; tumors of the ovary, breast, pancreas, endometrium
Juvenile polyposis	Large and small intestines, stomach	Hamartoma, rarely progressing to adenoma	Rare	Various congenital abnormalities

Once the multiple polyps are detected, patients should undergo a total colectomy. Medical therapy with nonsteroidal anti-inflammatory drugs (NSAIDs) such as sulindac and selective cyclooxygenase-2 inhibitors such as celecoxib can decrease the number and size of polyps in patients with polyposis coli; however, this effect on polyps is only temporary, and the use of NSAIDs has not been shown to reduce the risk of cancer. Colectomy remains the primary therapy/prevention. The offspring of patients with polyposis coli, who often are prepubertal when the diagnosis is made in the parent, have a 50% risk for developing this premalignant disorder and should be carefully screened by annual flexible sigmoidoscopy until age 35 years. Proctosigmoidoscopy is a sufficient screening procedure because polyps tend to be evenly distributed from cecum to anus, making more invasive and expensive techniques such as colonoscopy or barium enema unnecessary. Testing for occult blood in the stool is an inadequate screening maneuver. If a causative germline *APC* mutation has been identified in an affected family member, an alternative method for identifying carriers is testing DNA from peripheral blood mononuclear cells for the presence of the specific *APC* mutation. The detection of such a germline mutation can lead to a definitive diagnosis before the development of polyps.

MYH-Associated Polyposis MYH-associated polyposis (MAP) is a rare autosomal recessive syndrome caused by a biallelic mutation in the *MUT4H* gene. This hereditary condition may have a variable clinical presentation, resembling polyposis coli or colorectal cancer occurring in younger individuals without polyposis. Screening and colectomy guidelines for this syndrome are less clear than for polyposis coli, but annual to biennial colonoscopic surveillance is generally recommended starting at age 25–30 years.

Lynch Syndrome Lynch syndrome, previously known as hereditary nonpolyposis colon cancer, is another autosomal dominant trait. It is characterized by the presence of three or more relatives with histologically documented colorectal cancer, one of whom is a first-degree relative of the other two; one or more cases of colorectal cancer diagnosed before age 50 in the family; and colorectal cancer involving at least two generations. In contrast to polyposis coli, Lynch syndrome is associated with an unusually high frequency of cancer arising in the proximal large bowel. The median age for the appearance of an adenocarcinoma is <50 years, 10–15 years younger than the median age for the general population. Despite having a poorly differentiated, mucinous histologic appearance, the proximal colon tumors that characterize Lynch syndrome have a better prognosis than sporadic tumors from patients of similar age. Families with Lynch syndrome often include individuals with multiple primary cancers; the association of colorectal cancer with either ovarian or endometrial carcinomas is especially strong in women, and an increased appearance of gastric, small-bowel, genitourinary, pancreaticobiliary, and sebaceous skin tumors has been reported as well. It has been recommended that members of such families undergo annual or biennial colonoscopy beginning at age 25 years, with intermittent pelvic ultrasonography and endometrial biopsy for afflicted women; such a screening strategy has not yet been validated. Lynch syndrome is associated with germline mutations of several genes, particularly *hMSH2* on chromosome 2 and *hMLH1* on chromosome 3. These mutations lead to errors in DNA replication and are thought to result in DNA instability because of defective repair of DNA mismatches resulting in abnormal cell growth and tumor development. Testing tumor cells through molecular analysis of DNA for "microsatellite instability" or immunohistochemical staining for deficiency in mismatch repair proteins in patients with colorectal cancer and a positive family history for colorectal or endometrial cancer may identify probands with Lynch syndrome.

INFLAMMATORY BOWEL DISEASE

(Chap. 326) Large-bowel cancer is increased in incidence in patients with long-standing inflammatory bowel disease (IBD). Cancers develop more commonly in patients with ulcerative colitis than in those with granulomatous (i.e., Crohn's) colitis, but this impression may result in part from the occasional difficulty of differentiating these two conditions. The risk of colorectal cancer in a patient with IBD is relatively small during the initial 10 years of the disease, but then appears to increase at a rate of ~0.5–1% per year. Cancer may develop in 8–30% of patients after 25 years. The risk is higher in younger patients with pancolitis.

Cancer surveillance strategies in patients with IBD are unsatisfactory. Symptoms such as bloody diarrhea, abdominal cramping, and obstruction, which may signal the appearance of a tumor, are similar to the complaints caused by a flare-up of the underlying inflammatory disease. In patients with a history of IBD lasting ≥15 years who continue to experience exacerbations, the surgical removal of the colon can significantly reduce the risk for cancer and also eliminate the target organ for the underlying chronic gastrointestinal disorder. The value of such surveillance techniques as colonoscopy with mucosal biopsies and brushings for less symptomatic individuals with chronic IBD is uncertain. The lack of uniformity regarding the pathologic criteria that characterize dysplasia and the absence of data that such surveillance reduces the development of lethal cancers have made this costly practice an area of controversy.

OTHER HIGH-RISK CONDITIONS

***Streptococcus bovis* Bacteremia** For unknown reasons, individuals who develop endocarditis or septicemia from this fecal bacterium have a high incidence of occult colorectal tumors and, possibly, upper gastrointestinal cancers as well. Endoscopic or radiographic screening appears advisable.

Tobacco Use Cigarette smoking is linked to the development of colorectal adenomas, particularly after >35 years of tobacco use. No biologic explanation for this association has yet been proposed.

PRIMARY PREVENTION

Several orally administered compounds have been assessed as possible inhibitors of colon cancer. The most effective class of chemopreventive agents is aspirin and other NSAIDs, which are thought to suppress cell proliferation by inhibiting prostaglandin synthesis. Regular aspirin use reduces the risk of colon adenomas and carcinomas as well as death from large-bowel cancer; such use also appears to diminish the likelihood for developing additional premalignant adenomas following successful treatment for a prior colon carcinoma. This effect of aspirin on colon carcinogenesis increases with the duration and dosage of drug use. Emerging data linking adequate plasma levels of vitamin D with reduced risk of adenomatous polyps and colorectal cancer appear promising. The value of vitamin D as a form of chemoprevention is under study. Antioxidant vitamins such as ascorbic acid, tocopherols, and β-carotene are ineffective at reducing the incidence of subsequent adenomas in patients who have undergone the removal of a colon adenoma. Estrogen replacement therapy has been associated with a reduction in the risk of colorectal cancer in women, conceivably by an effect on bile acid synthesis and composition or by decreasing synthesis of IGF-I.

SCREENING

The rationale for colorectal cancer screening programs is that the removal of adenomatous polyps will prevent colorectal cancer, and that earlier detection of localized, superficial cancers in asymptomatic individuals will increase the surgical cure rate. Such screening programs are particularly important for individuals with a family history of the disease in first-degree relatives. The relative risk for developing colorectal cancer increases to 1.75 in such individuals and may be even higher if the relative was afflicted before age 60 years. The prior use of rigid proctosigmoidoscopy as a screening tool was based on the observation that 60% of early lesions are located in the rectosigmoid. For unexplained reasons, however, the proportion of large-bowel cancers arising in the rectum has been decreasing during the past several decades, with a corresponding increase in the proportion of cancers in the more proximal descending colon. As such, the potential for rigid proctosigmoidoscopy to detect a sufficient number of occult neoplasms to make the procedure cost-effective has been questioned.

Screening strategies for colorectal cancer that have been examined during the past several decades are listed in **Table 81-3**.

Many programs directed at the early detection of colorectal cancers have focused on digital rectal examinations and fecal occult blood (i.e., stool guaiac) testing. The digital examination should be part of any routine physical evaluation in adults aged >40 years, serving as a screening test for prostate cancer in men, a component of the pelvic examination in women, and an inexpensive maneuver for the detection of masses in the rectum. However, because of the proximal migration of colorectal tumors, its value as an overall screening modality for colorectal cancer has become limited. The development of the fecal occult blood test has greatly facilitated the detection of occult fecal blood. Unfortunately, even when performed optimally, the fecal occult blood test has major limitations as a screening technique. About 50% of patients with documented colorectal cancers have a negative fecal occult blood test, consistent with the intermittent bleeding pattern of these tumors. When random cohorts of asymptomatic persons have been tested, 2–4% have fecal occult blood-positive stools. Colorectal cancers have been found in <10% of these "test-positive" cases, with benign polyps being detected in an additional 20–30%. Thus, a colorectal neoplasm will not be found in most asymptomatic individuals with occult blood in their stool. Nonetheless, persons found to have fecal occult blood-positive stool routinely undergo further medical evaluation, including sigmoidoscopy and/or colonoscopy—procedures that are not only uncomfortable and expensive but also associated with a small risk for significant complications. The added cost of these studies would appear justifiable if the small number of patients found to have occult neoplasms because of fecal occult blood screening could be shown to have an improved prognosis and prolonged survival. Prospectively controlled trials have shown a statistically significant reduction in mortality rate from colorectal cancer for individuals undergoing annual stool guaiac screening. However, this benefit only emerged after >13 years of follow-up and was extremely expensive to achieve because all positive tests (most of which were falsely positive) were followed by colonoscopy. Moreover, these colonoscopic examinations quite likely provided the opportunity for cancer prevention through the removal of potentially premalignant adenomatous polyps because the eventual development of cancer was reduced by 20% in the cohort undergoing annual screening.

TABLE 81-3 Screening Strategies for Colorectal Cancer

Digital rectal examination
Stool testing
• Occult blood
• Fecal DNA
Imaging
• Contrast barium enema
• Virtual (i.e., computed tomography colonography)
Endoscopy
• Flexible sigmoidoscopy
• Colonoscopy

With the appreciation that the carcinogenic process leading to the progression of the normal bowel mucosa to an adenomatous polyp and then to a cancer is the result of a series of molecular changes, investigators have examined fecal DNA for evidence of mutations associated with such molecular changes as evidence of the occult presence of precancerous lesions or actual malignancies. Such a strategy has been tested in >4000 asymptomatic individuals whose stool was assessed for occult blood and for 21 possible mutations in fecal DNA; these study subjects also underwent colonoscopy. Although the fecal DNA strategy proved to be more effective for suggesting the presence of more advanced adenomas and cancers than did the fecal occult blood testing approach, the overall sensitivity, using colonoscopic findings as the standard, was <50%, diminishing enthusiasm for further pursuit of the fecal DNA screening strategy.

The use of imaging studies to screen for colorectal cancers has also been explored. Air contrast barium enemas had been used to identify sources of occult blood in the stool prior to the advent of fiberoptic endoscopy; the cumbersome nature of the procedure and inconvenience to patients limited its widespread adoption. The introduction of CT scanning led to the development of virtual (i.e., CT) colonography as an alternative to the growing use of endoscopic screening techniques. Virtual colonography was proposed as being equivalent in sensitivity to colonoscopy and being available in a more widespread manner because it did not require the same degree of operator expertise as fiberoptic endoscopy. However, virtual colonography requires the same cathartic preparation that has limited widespread acceptance in association with endoscopic colonoscopy, is diagnostic but not therapeutic (i.e., patients with suspicious findings must undergo a subsequent endoscopic procedure for polypectomy or biopsy), and, in the setting of general radiology practices, appears to be less sensitive as a screening technique when compared with endoscopic procedures.

With the appreciation of the inadequacy of fecal occult blood testing alone, concerns about the practicality of imaging approaches, and the wider adoption of endoscopic examinations by the primary care community, screening strategies in asymptomatic persons have changed. At present, the American Cancer Society, the American College of Gastroenterology, and the National Comprehensive Cancer Network recommend either fecal occult blood testing annually coupled with flexible sigmoidoscopy every 5 years or colonoscopy every 10 years in asymptomatic individuals with no personal or family history of polyps or colorectal cancer. In view of the emerging increase in the incidence of colorectal cancer in individuals <50 years of age, guidelines issued from these organizations have recently lowered the age at which to begin such screening from age 50 to age 45 years. The recommendation

for the inclusion of flexible sigmoidoscopy is strongly supported by the recently published results of three randomized trials performed in the United States, the United Kingdom, and Italy, involving >350,000 individuals, which consistently showed that periodic (even single) sigmoidoscopic examinations, after more than a decade of median follow-up, lead to an ~21% reduction in the development of colorectal cancer and a >25% reduction in mortality from the malignant disease. Less than 20% of participants in these studies underwent a subsequent colonoscopy. In contrast to the cathartic preparation required before colonoscopic procedures, which is only performed by highly trained specialists, flexible sigmoidoscopy requires only an enema as preparation and can be accurately performed by nonspecialty physicians or physician-extenders. The randomized screening studies using flexible sigmoidoscopy led to the estimate that ~650 individuals needed to be screened to prevent one colorectal cancer death; this contrasts with the data for mammography where the number of women needing to be screened to prevent one breast cancer death is 2500, reinforcing the efficacy of endoscopic surveillance for colorectal cancer screening. Presumably the benefit from the sigmoidoscopic screening is the result of the identification and removal of adenomatous polyps; it is intriguing that this benefit has been achieved using a technique that leaves the proximal half of the large bowel unvisualized.

It remains to be seen whether surveillance colonoscopy, which has gained increasing popularity in the United States for colorectal cancer screening, will prove to be more effective than flexible sigmoidoscopy in reducing mortality from this disease. Ongoing randomized trials being conducted in Europe are addressing this issue. Although flexible sigmoidoscopy only visualizes the distal half of the large bowel, leading to the assumption that colonoscopy represents a more informative approach, colonoscopy has been reported as being less accurate for screening the proximal rather than the distal colon, perhaps due to technical considerations but also possibly because of a greater frequency of serrated (i.e., "flat") polyps in the right colon, which are more difficult to identify. Furthermore, the vast majority of colorectal cancers that have appeared in younger adults have arisen in the left colon (i.e., distal to the splenic flexure), within the visible range of a flexible sigmoidoscopy. At present, colonoscopy performed every 10 years has been offered as an alternative to annual fecal occult blood testing with periodic (every 5 years) flexible sigmoidoscopy. Colonoscopy has been shown to be superior to double-contrast barium enema and also to have a higher sensitivity for detecting villous or dysplastic adenomas or cancers than the strategy using occult fecal blood testing and flexible sigmoidoscopy. Whether colonoscopy performed every 10 years beginning at age 45 is medically superior and economically equivalent to flexible sigmoidoscopy remains to be determined.

CLINICAL FEATURES

Presenting Symptoms Symptoms vary with the anatomic location of the tumor. Because stool is relatively liquid as it passes through the ileocecal valve into the right colon, cancers arising in the cecum and ascending colon may become quite large without resulting in any obstructive symptoms or noticeable alterations in bowel habits. Lesions of the right colon commonly ulcerate, leading to chronic, insidious blood loss without a change in the appearance of the stool. Consequently, patients with tumors of the ascending colon often present with symptoms such as fatigue, palpitations, and even angina pectoris and are found to have a hypochromic, microcytic anemia, indicative of iron deficiency. Because the cancers may bleed intermittently, a random fecal occult blood test may be negative. As a result, the unexplained presence of iron-deficiency anemia in any adult (with the possible exception of a premenopausal, multiparous woman) mandates a thorough endoscopic and/or radiographic visualization of the entire large bowel **(Fig. 81-1)**.

Because stool becomes more formed as it passes into the transverse and descending colon, tumors arising there tend to impede the passage of stool, resulting in the development of abdominal cramping, occasional obstruction, and even perforation. Radiographs of the abdomen often reveal characteristic annular, constricting lesions ("apple-core" or "napkin-ring") **(Fig. 81-2)**.

FIGURE 81-1 Double-contrast air-barium enema revealing a sessile tumor of the cecum in a patient with iron-deficiency anemia and guaiac-positive stool. The lesion at surgery was a stage II adenocarcinoma.

Cancers arising in the rectosigmoid are often associated with hematochezia, tenesmus, and narrowing of the caliber of stool; anemia is an infrequent finding. While these symptoms may lead patients and their physicians to suspect the presence of hemorrhoids, the development of rectal bleeding and/or altered bowel habits demands a prompt digital rectal examination and proctosigmoidoscopy.

Staging, Prognostic Factors, and Patterns of Spread The prognosis for individuals having colorectal cancer is related to the depth of tumor penetration into the bowel wall and the presence of both regional lymph node involvement and distant metastases. These variables are incorporated into a TNM classification method, in which T represents the depth of tumor penetration, N the presence of lymph node involvement, and M the presence or absence of distant metastases

FIGURE 81-2 Annular, constricting adenocarcinoma of the descending colon. This radiographic appearance is referred to as an "apple-core" lesion and is always highly suggestive of malignancy.

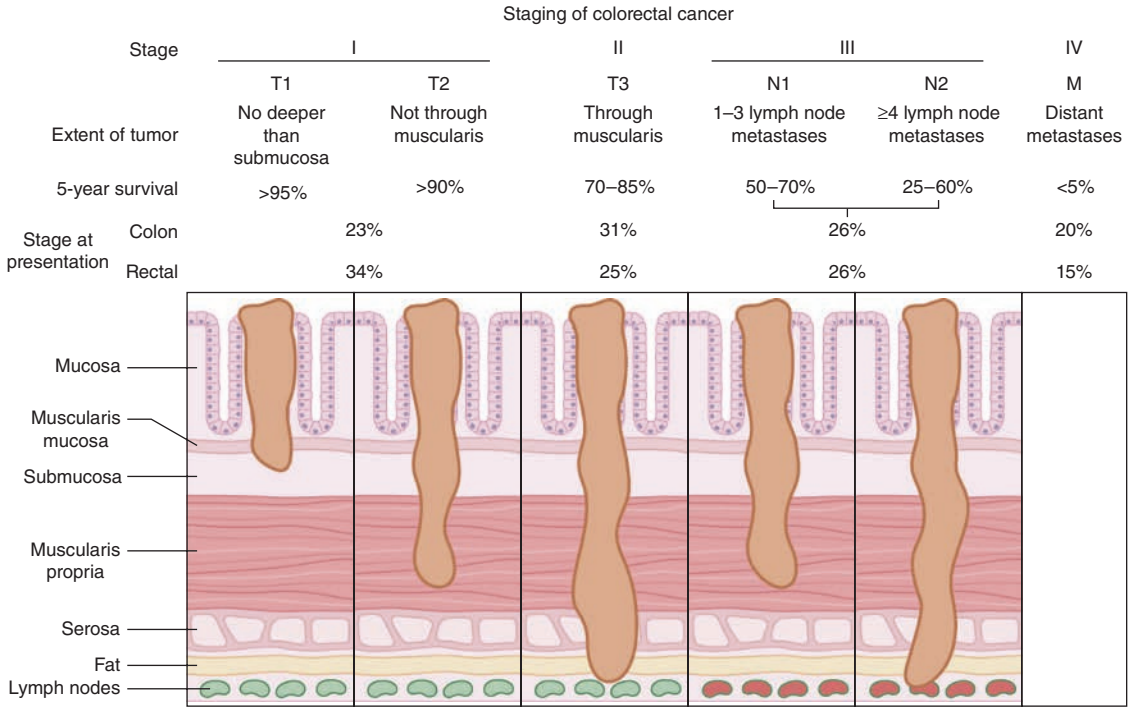

FIGURE 81-3 Staging and prognosis for patients with colorectal cancer.

(Fig. 81-3). Superficial lesions that do not involve regional lymph nodes and do not penetrate through the submucosa (T1) or the muscularis (T2) are designated as *stage I* (T1–2N0M0) disease; tumors that penetrate through the muscularis but have not spread to lymph nodes are *stage II* disease (T3-4N0M0); regional lymph node involvement defines *stage III* (TXN1-2M0) disease; and metastatic spread to sites such as liver, lung, or bone indicates *stage IV* (TXNXM1) disease. Unless gross evidence of metastatic disease is present, disease stage cannot be determined accurately before surgical resection and pathologic analysis of the operative specimens.

Most recurrences after a surgical resection of a large-bowel cancer occur within the first 4 years, making 5-year survival a fairly reliable indicator of cure. The likelihood for 5-year survival in patients with colorectal cancer is stage-related (Fig. 81-3). That likelihood has improved during the past several decades when similar surgical stages have been compared. The most plausible explanation for this improvement is more thorough intraoperative and pathologic staging. In particular, more exacting attention to pathologic detail has revealed that the prognosis following the resection of a colorectal cancer is not related merely to the presence or absence of regional lymph node involvement; rather, prognosis may be more precisely gauged by the number of involved lymph nodes (one to three lymph nodes ["N1"] vs four or more lymph nodes ["N2"]) and the number of nodes examined. A minimum of 12 sampled lymph nodes is thought necessary to accurately define tumor stage, and the more nodes examined, the better. Other predictors of a poor prognosis after a total surgical resection include tumor penetration through the bowel wall into pericolic fat, poorly differentiated histology, perforation and/or tumor adherence to adjacent organs (increasing the risk for an anatomically adjacent recurrence), and venous invasion by tumor (Table 81-4). Regardless of the clinicopathologic stage, a preoperative elevation of the plasma carcinoembryonic antigen (CEA) level predicts eventual tumor recurrence. The presence of specific chromosomal aberrations, particularly a mutation in the *b-raf* gene in tumor cells, appears to predict for a higher risk for metastatic spread. Conversely, the detection of microsatellite instability in tumor tissue indicates a more favorable outcome. Tumors arising in the left colon are associated with a better prognosis than those appearing in the right colon, likely due to differences in molecular patterns. In contrast to most other cancers, the prognosis in colorectal cancer is not influenced by the size of the primary lesion when adjusted for nodal involvement and histologic differentiation.

Cancers of the large bowel generally spread to regional lymph nodes or to the liver via the portal venous circulation. The liver represents the most frequent visceral site of metastasis; it is the initial site of distant spread in one-third of recurring colorectal cancers and is involved in more than two-thirds of such patients at the time of death. In general, colorectal cancer rarely spreads to the lungs, supraclavicular lymph nodes, bone, or brain without prior spread to the liver. A major exception to this rule occurs in patients having primary tumors in the distal rectum, from which tumor cells may spread through the paravertebral venous plexus, escaping the portal venous system and thereby reaching the lungs or supraclavicular lymph nodes without hepatic involvement. The median survival after the detection of distant metastases has increased during the last 30 years from 6–9 months (hepatomegaly, abnormal liver chemistries) to 27–30 months (small liver nodule initially identified by elevated CEA level and subsequent CT scan) with increasingly effective systemic therapy improving this prognosis further.

Efforts to use gene expression profiles to identify patients at risk of recurrence or those particularly likely to benefit from adjuvant therapy have not yet yielded practice-changing results. Despite a burgeoning literature examining a host of prognostic factors, pathologic stage at diagnosis remains the best predictor of long-term prognosis. Patients with lymphovascular invasion and high preoperative CEA levels are likely to have a more aggressive clinical course.

TABLE 81-4 Predictors of Poorer Outcomes Following Total Surgical Resection of Colorectal Cancer

Tumor spread to regional lymph nodes
Number of regional lymph nodes involved
Tumor penetration through the bowel wall
Poorly differentiated histology
Perforation
Tumor adherence to adjacent organs
Venous invasion
Preoperative elevation of CEA titer (>5 ng/mL)
Specific chromosomal deletion (e.g., mutation in the *b-raf* gene)
Right-sided location of primary tumor

Abbreviation: CEA, carcinoembryonic antigen.

Colorectal Cancer

Total resection of tumor is the optimal treatment when a malignant lesion is detected in the large bowel. An evaluation for the presence of metastatic disease, including a thorough physical examination, biochemical assessment of liver function, measurement of the plasma CEA level, and a CT scan of the chest, abdomen, and pelvis, should be performed before surgery. When possible, a colonoscopy of the entire large bowel should be performed to identify synchronous neoplasms and/or polyps. The detection of metastases should not preclude surgery in patients with tumor-related symptoms such as gastrointestinal bleeding or obstruction, but it often prompts the use of a less radical operative procedure. The necessity for a primary tumor resection in asymptomatic individuals with metastatic disease is an area of controversy. At the time of laparotomy, the entire peritoneal cavity should be examined, with thorough inspection of the liver, pelvis, and hemidiaphragm and careful palpation of the full length of the large bowel. Following recovery from a complete resection, patients should be observed carefully for 5 years by semiannual physical examinations and blood chemistry measurements. If a complete colonoscopy was not performed preoperatively, it should be carried out within the first several postoperative months. Some authorities favor measuring plasma CEA levels at 3-month intervals because of the sensitivity of this test as a marker for otherwise undetectable tumor recurrence. The value of periodically assessing plasma for the presence of circulating tumor DNA as a biomarker for residual or recurrent disease is under study. Subsequent endoscopic surveillance of the large bowel, probably at triennial intervals, is indicated, because patients who have been cured of one colorectal cancer have a 3–5% probability of developing an additional bowel cancer during their lifetime and a >15% risk for the development of adenomatous polyps. Anastomotic ("suture-line") recurrences are infrequent in colorectal cancer patients, provided the surgical resection margins were adequate and free of tumor. The value of periodic CT scans of the abdomen, assessing for an early, asymptomatic indication of tumor recurrence, while uncertain, has been recommended annually for the first 3 postoperative years.

Radiation therapy to the pelvis is recommended for patients with rectal cancer because it reduces the 20–25% probability of regional recurrences following complete surgical resection of stage II or III tumors, especially if they have penetrated through the serosa. This alarmingly high rate of local disease recurrence is believed to be due to the fact that the contained anatomic space within the pelvis limits the extent of the resection and because the rich lymphatic network of the pelvic side wall immediately adjacent to the rectum facilitates the early spread of malignant cells into surgically inaccessible tissue. The use of sharp rather than blunt dissection of rectal cancers (*total mesorectal excision*) appears to reduce the likelihood of local disease recurrence to ~10%. Radiation therapy, either administered pre- or postoperatively, further reduces the likelihood of pelvic recurrences but does not appear to prolong survival. Combining radiation therapy with 5-fluorouracil (5-FU)-based chemotherapy, preferably prior to surgical resection, lowers local recurrence rates and improves overall survival. Radiation therapy alone is not effective as the primary treatment of colon cancer.

Systemic therapy for patients with colorectal cancer has become more effective. 5-FU remains the backbone of treatment for this disease. Partial responses are obtained in 15–20% of patients. The probability of tumor response appears to be somewhat greater for patients with liver metastases when chemotherapy is infused directly into the hepatic artery, but intraarterial treatment is costly and toxic and does not appear to appreciably prolong survival. The concomitant administration of folinic acid (leucovorin [LV]) improves the efficacy of 5-FU in patients with advanced colorectal cancer, presumably by enhancing the binding of 5-FU to its target enzyme, thymidylate synthase. 5-FU is generally administered intravenously but may also be given orally in the form of capecitabine (Xeloda) with seemingly similar efficacy.

Irinotecan (CPT-11), a topoisomerase 1 inhibitor, has been added to 5-FU and LV (e.g., FOLFIRI) with resultant improvement in response rates and survival of patients with metastatic disease. The *FOLFIRI regimen* is as follows: irinotecan, 180 mg/m^2 as a 90-min infusion on day 1; LV, 400 mg/m^2 as a 2-h infusion during irinotecan administration; immediately followed by 5-FU bolus, 400 mg/m^2, and 46-h continuous infusion of 2.4–3 g/m^2 every 2 weeks. Diarrhea is the major side effect from irinotecan. Oxaliplatin, a platinum analogue, also improves the response rate when added to 5-FU and LV (FOLFOX) as initial treatment of patients with metastatic disease. The *FOLFOX regimen* is as follows: 2-h infusion of LV (400 mg/m^2 per day) followed by a 5-FU bolus (400 mg/m^2 per day) and 22-h infusion (1200 mg/m^2) every 2 weeks, together with oxaliplatin, 85 mg/m^2 as a 2-h infusion on day 1. Oxaliplatin frequently causes a dose-dependent sensory neuropathy that often but not always resolves following the cessation of therapy. FOLFIRI and FOLFOX are equal in efficacy. In metastatic disease, these regimens may produce median survivals of 2 years.

Monoclonal antibodies are also effective in patients with advanced colorectal cancer. Cetuximab (Erbitux) and panitumumab (Vectibix) are directed against the epidermal growth factor receptor (EGFR), a transmembrane glycoprotein involved in signaling pathways affecting growth and proliferation of tumor cells. Both cetuximab and panitumumab, when given alone, have been shown to benefit a small proportion of previously treated patients, and cetuximab appears to have therapeutic synergy with such chemotherapeutic agents as irinotecan, even in patients previously resistant to this drug; this suggests that cetuximab can reverse cellular resistance to cytotoxic chemotherapy. The antibodies are not effective in the ~65% subset of colon tumors that contain mutations in *ras* or *b-raf* genes and appear to be less likely to prove beneficial in the treatment of tumors arising from the right rather than left colon. The use of both cetuximab and panitumumab can lead to an acne-like rash, with the development and severity of the rash being correlated with the likelihood of antitumor efficacy. Inhibitors of the EGFR tyrosine kinase such as erlotinib (Tarceva) or sunitinib (Sutent) do not appear to be effective in colorectal cancer.

Bevacizumab (Avastin) is a monoclonal antibody directed against the vascular endothelial growth factor (VEGF) and is thought to act as an antiangiogenesis agent. The addition of bevacizumab to irinotecan-containing combinations and to FOLFOX appears to significantly improve the outcome observed with chemotherapy alone. The use of bevacizumab can lead to hypertension, proteinuria, and an increased likelihood of thromboembolic events.

Emerging data suggest that the use of checkpoint inhibitors (i.e., PD-1 and PD-2) as immunotherapy is more effective than chemotherapy in the subset (15%) of patients with metastatic colorectal cancer whose tumors are mismatch repair protein deficient (i.e., microsatellite unstable). Patients with solitary hepatic metastases without clinical or radiographic evidence of additional tumor involvement should be considered for partial liver resection, because such procedures are associated with 5-year survival rates of 25–30% when performed on selected individuals by experienced surgeons.

The administration of 5-FU and LV for 6 months after resection of tumor in patients with stage III disease leads to a 40% decrease in recurrence rates and 30% improvement in survival. The likelihood of recurrence has been further reduced when oxaliplatin has been combined with 5-FU and LV (e.g., FOLFOX). Reducing the duration of such oxaliplatin-containing therapy from 6 months to 3 months in patients with less invasive tumors ($T_{2\text{-}3}N_1$) has been shown to result in a similar therapeutic benefit with reduced side effects (i.e., neurotoxicity) whereas 6 months of such therapy continues to be recommended for optimally treating patients with more advanced stage III tumors (T_4 and/or N_2). Unexpectedly, the addition of irinotecan to 5-FU and LV as well as the addition of either bevacizumab or cetuximab to FOLFOX did not significantly enhance outcome.

Patients with stage II tumors do not appear to benefit appreciably from adjuvant therapy, with the use of such treatment generally restricted to those patients having biologic characteristics (e.g., perforated tumors, T4 lesions, lymphovascular invasion) that place them at higher likelihood for recurrence.

In rectal cancer, the delivery of preoperative or postoperative combined-modality therapy (5-FU or capecitabine plus radiation therapy) reduces the risk of recurrence and increases the chance of cure for patients with stage II and III tumors, with the preoperative approach being better tolerated.

CANCERS OF THE ANUS

Cancers of the anus account for 1–2% of the malignant tumors of the large bowel. Most such lesions arise in the anal canal, the anatomic area extending from the anorectal ring to a zone approximately halfway between the pectinate (or dentate) line and the anal verge. Carcinomas arising proximal to the pectinate line (i.e., in the transitional zone between the glandular mucosa of the rectum and the squamous epithelium of the distal anus) are known as *basaloid*, *cuboidal*, or *cloacogenic* tumors; about one-third of anal cancers have this histologic pattern. Malignancies arising distal to the pectinate line have squamous histology, ulcerate more frequently, and constitute ~55% of anal cancers. The prognosis for patients with basaloid and squamous cell cancers of the anus is identical when corrected for tumor size and the presence or absence of nodal spread.

The development of anal cancer is associated with infection by human papillomavirus, the same organism etiologically linked to cervical and oro-pharyngeal cancers. The virus is sexually transmitted. The infection may lead to anal warts (condyloma acuminata), which may progress to anal intraepithelial neoplasia and on to squamous cell carcinoma. The risk for anal cancer is increased among homosexual males, presumably related to anal intercourse. Anal cancer risk is increased in both men and women with AIDS, possibly because their immunosuppressed state permits more severe papillomavirus infection. Vaccination against human papilloma viruses appears to reduce the eventual risk for anal cancer. Anal cancers occur most commonly in middle-aged persons and are more frequent in women than men. At diagnosis, patients may experience bleeding, pain, sensation of a perianal mass, and pruritus.

Radical surgery (abdominal-perineal resection with lymph node sampling and a permanent colostomy) was once the treatment of choice for this tumor type. The 5-year survival rate after such a procedure was 55–70% in the absence of spread to regional lymph nodes and <20% if nodal involvement was present. An alternative therapeutic approach combining external beam radiation therapy with concomitant chemotherapy (5-FU and mitomycin C) has resulted in biopsy-proven disappearance of all tumor in >80% of patients whose initial lesion was <3 cm in size. Tumor recurrences develop in <10% of these patients, meaning that ~70% of patients with anal cancers can be cured with nonoperative treatment and without the need for a colostomy. Surgery should be reserved for the minority of individuals who are found to have residual tumor after being managed initially with radiation therapy combined with chemotherapy. The use of checkpoint immunotherapy (i.e., PD-1 inhibition) has been beneficial in some patients with recurrent disease.

82 Tumors of the Liver and Biliary Tree

Josep M. Llovet

Liver cancer is the sixth most common cancer worldwide, the fourth leading cause of cancer-related deaths, and the leading cause of death among cirrhotic patients. Liver cancer comprises a heterogeneous group of malignant tumors with different histologic features and unfavorable prognosis that range from hepatocellular carcinoma (HCC; 85–90% cases), intrahepatic cholangiocarcinoma (iCCA; 10%), and other malignancies accounting for <1% of tumors, such as fibrolamellar HCC, mixed HCC-iCCA, epithelioid hemangiothelioma, and the pediatric cancer hepatoblastoma. The burden of liver cancer is increasing globally in almost all countries, and it is estimated to reach 1 million cases by 2025.

HEPATOCELLULAR CARCINOMA

EPIDEMIOLOGY AND RISK FACTORS

Overall, liver cancer accounts for 7% of all cancers (~850,000 new cases each year), and HCC represents 90% of primary liver cancers. The highest incidence rates of HCC occur in Asia and sub-Saharan Africa due to the high prevalence of hepatitis B virus (HBV) infection, with 20–35 cases per 100,000 inhabitants. Southern Europe and North America have intermediate incidence rates (10 cases per 100,000), whereas Northern and Western Europe have low incidence rates of <5 cases per 100,000 inhabitants. In the United States, liver cancer is ranked number one in terms of increased mortality during the past two decades, with an incidence of 35,000 cases per year **(Fig. 82-1)**. HCC has a strong male preponderance with a male-to-female ratio estimated to be 2.5. The incidence increases with age, reaching a peak at 65–70 years old. In Chinese and in black African populations (where vertical transmission of HBV occurs), the mean age is 40–50 years. By contrast, in Japan, mean age in men is now around 75 years.

The risk factors for HCC are well established (Fig. 82-1). The main risk factor is cirrhosis—and associated chronic liver damage caused by inflammation and fibrosis—of any etiology, which underlies 80% of HCC cases worldwide and results from chronic infection by HBV or hepatitis C virus (HCV) infection, alcohol abuse, metabolic syndrome, and hemochromatosis (associated with *HFE1* gene germline mutations). Cirrhotic patients represent 1% of the human population, and one-third of them will develop HCC during their lifetime. Long-term follow-up studies have established an annual risk of HCC development of 3–8% in HBV- or HCV-infected cirrhotic patients. HCC is less common (1–3% per year) in cirrhosis associated with alcohol, nonalcoholic steatohepatitis (NASH), α_1 antitrypsin deficiency, autoimmune hepatitis, Wilson's disease, and cholestatic liver disorders. Predictors of liver cancer development among cirrhotic patients have been associated with liver disease severity (platelet count of <100,000/μL, presence

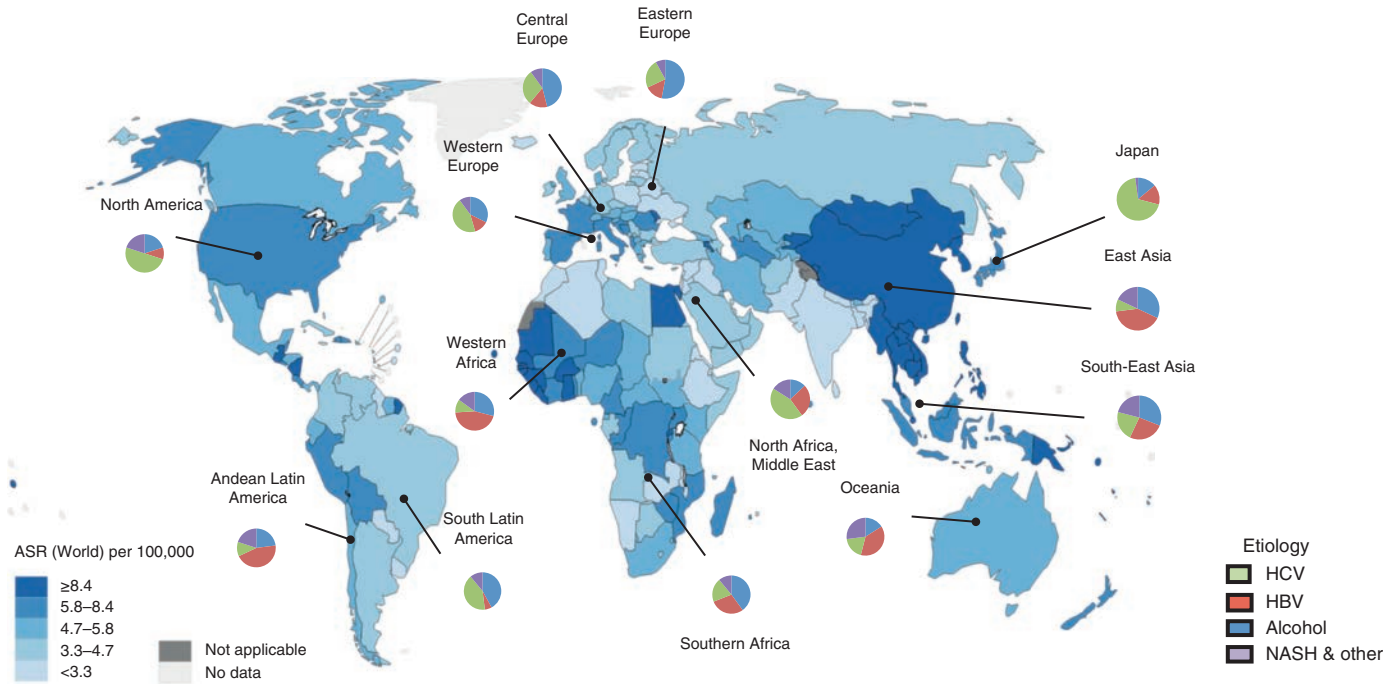

FIGURE 82-1 Distribution of hepatocellular carcinoma incidence according to geographical area and etiology. HBV, hepatitis B virus; HCV, hepatitis C virus; NASH, nonalcoholic steatohepatitis. *(Reproduced with permission from JM Llovet et al: Hepatocellular carcinoma. Nat Rev Disease Primers 6:7, 2021.)*

of portal hypertension), the degree of liver stiffness as measured by transient elastography, and liver gene signatures capturing the *cancer field effect*.

In terms of attributable risk fraction, HBV infection—a DNA virus that can cause insertional mutagenesis and affects 400 million people globally—accounts for ~60% of HCC cases in Asia and Africa and 20% in the Western world. Among patients with HBV infection, a family history of HCC, HBeAg seropositivity, high viral load, and genotype C are independent predictors of HCC development. Chronic treatments with effective antiviral HBV therapies are able to significantly decrease the risk of cancer. HCV infection—an RNA virus that affects 170 million people—is responsible for ~30% of cases and is the main cause of HCC in Europe and North America. Among patients with HCV infection, HCC occurs almost exclusively when relevant liver damage is present (either advanced fibrosis—Metavir F3 [Metavir is a scoring system for hepatic histology that grades fibrosis from 0 to 4 with higher numbers indicating more fibrosis]—or cirrhosis), particularly if associated with HCV genotype 1b. In addition, a polymorphism that activates *EGFR*, the epidermal growth factor receptor, is associated with HCV-HCC in several studies. Antiviral therapies with interferon regimens are able to prevent cirrhosis development and HCC occurrence. Direct-acting antiviral agents (DAA) induce sustained virologic response, i.e., clearance of HCV infection, in most of cases, thus resulting in 50–80% reduction in HCC risk.

Alcohol consumption and metabolic syndrome due to diabetes and obesity are responsible for ~30% of cases. NASH is becoming the leading cause of cirrhosis in developed countries and currently represents ~15–20% of HCC cases in the West. The annual incidence of HCC in NASH-related cirrhosis (1–2%/year) justifies including patients at risk in surveillance programs. Nonetheless, it has to be taken into account that 25–30% of NASH-associated HCC occurs in the absence of cirrhosis. A *PNPLA3* polymorphism is strongly associated with fatty and alcoholic chronic liver diseases and HCC occurrence. Other cofactors contributing to HCC development are tobacco and aflatoxin B1, a fungal carcinogen present in food supplies that induces *TP53* mutations. Finally, infection with adeno-associated virus 2 is associated with HCC in individuals without cirrhosis. Aside from the associations described above, genome-wide association studies have not yet confirmed polymorphisms predisposing to HCC development.

MOLECULAR PATHOGENESIS

HCC development is a complex multistep process that starts with precancerous cirrhotic nodules, so-called low-grade dysplastic nodules (LGDNs) that evolve to high-grade dysplastic nodules (HGDNs) that can transform into early-stage HCC. Molecular studies support the pivotal role of adult hepatocytes as the cell of origin, either by directly transforming to HCC or by de-differentiating into hepatocyte precursor cells. Alternatively, progenitor cells also give rise to HCC with progenitor markers.

Genomic analysis has provided a clear picture of the main drivers responsible for HCC initiation and progression. This tumor results from the accumulation of around 40–60 somatic genomic alterations per tumor, of which 4–8 are considered driver cancer genes. HCC is a prototypical inflammation-associated cancer, where immune microenvironment and oxidative stress present in chronically damaged livers play pivotal roles in inducing mutations. In preneoplastic HGDN, mutations in telomere reverse transcriptase (*TERT*) gene (20% of cases) and gains in 8q have been described. Oncogenic transformation occurs upon additional genomic hits including Wnt/β-catenin pathway activation, reexpression of fetal genes, deregulation of protein folding machinery, and the response to oxidative stress. Genomic studies and next-generation sequencing conducted during the past decade have enabled a description of the landscape of mutations, signaling pathways, and molecular classification of the disease. Nonetheless, none of these data have yet translated into actual clinical benefits for any specific molecularly based subgroups.

Molecular Drivers The landscape of mutational drivers in HCC identified by deep-genome sequencing is detailed in **Table 82-1**. The most common mutations are in the *TERT* promoter (56%), *TP53* (27%), *CTNNB1* (26%), *ARID2* (7%), *ARID1A* (6%), and *AXIN1* (5%) genes. These mutated genes participate in cell-cycle control and senescence (*TERT* and *TP53*), cell differentiation (*CTNNB1* and *AXIN1*), and chromatin remodeling (*ARID2* and *ARID1A*). Genes commonly mutated in other solid tumors such as *EGFR*, *HER2*, *PIK3CA*, *BRAF*, or *KRAS* are rarely mutated in HCC (<5%). Overall, only ~20–25% of HCCs have at least one actionable mutation. Some risk factors have been associated with specific molecular aberrations. HBV integrates into the genome of driver genes, such as the *TERT* promoter, *MLL4*, and cyclin E1 (*CCNE1*). Alcohol abuse and HCV infection have been

TABLE 82-1 Molecular Aberrations Common in Hepatocellular Carcinoma (HCC)[a]

[a]Recurrent mutations, focal amplifications, or homozygous deletions in HCC based on next-generation sequencing analyses.

associated with *CTNNB1* mutations. *TP53* mutations are the most frequent alterations with a specific hotspot of mutation (R249S) in patients with aflatoxin B1 exposure.

Studies assessing copy number alterations in HCCs have consistently identified: (1) high-level amplifications at 5–10% prevalence containing oncogenes in 11q13 (*CCND1* and *FGF19*) and 6p21 (*VEGFA*), *TERT* focal amplification, and homozygous deletion of *CDKN2A*; and (2) common amplifications containing *MYC* (8q gain) and *MET* genes (focal gains of 7q31). Activation of the FGF19-FGFR4 pathway mediated by epigenetic mechanisms (~20%) or high-level amplifications of 11q13 (6%) or *VEGFA* gains (high-level gains of 6p21) are also potential therapeutic targets.

Signaling Pathways Several signaling pathways have been implicated in HCC progression and dissemination. Activation of these pathways can result from structural alterations (mutations and amplifications/losses) or epigenetic modifications. In brief, (1) TERT overexpression occurs in 90% of cases, particularly related to promoter *TERT* mutations or amplifications; (2) inactivation of p53 and alterations of cell cycle are major defects in HCC, particularly in cases related to HBV infection; (3) Wnt/β-catenin pathway activation occurs in 50% of cases, either as a result of β-catenin or *AXIN1* mutation or overexpression of Frizzled receptors or inactivation of E-cadherin; (4) PI3K/PTEN/Akt/mTOR pathway is activated in 40–50% of HCCs due to mutation and focal deletion of the tuberous sclerosis complex (*TSC)1/TSC2* genes, *PTEN*, or ligand overexpression of EGF or insulin-like growth factor (IGF) upstream signals; (5) Ras MAPK signaling is activated in half of early and almost all advanced HCCs, and activation results from upstream signaling by EGF, IGF, and MET activation; (6) insulin-like growth factor receptor (IGFR) signaling is activated in 20% of cases through overexpression of the oncogenic ligand IGF2; (7) dysregulation of the c-MET receptor and its ligand HGF, critical for hepatocyte regeneration after liver injury, is a common event in advanced HCC (50%); (8) vascular endothelial growth factor (VEGF) signaling is the cornerstone of angiogenesis in HCC, along with activated angiogenic pathways such as Ang2 and FGF signaling; and (9) chromatin remodeling complexes and epigenetic regulators are frequently altered in HCC due to *ARID1A* and *ARID2* mutations.

Molecular and Immune Classes Genomic studies have revealed two molecular subclasses of HCC, each representing ~50% of patients. The proliferative subclass is enriched by activation of Ras, mTOR, and IGF signaling and *FGF19* amplification and is associated with HBV-related etiologies, overexpression of α-fetoprotein, and poor outcomes. By contrast, the so-called nonproliferative subclass contains a subtype characterized by *CTNNB1* mutations and better outcome. Another classification based on immune status has been proposed. It defines an immune HCC class in ~25% of cases characterized by immune infiltrate with expression of PD-1/PD-L1, enrichment of T cell activation, and better outcome and an immune excluded class with activation of pathways related with immune escape (i.e., Wnt signaling) or absence of T cell infiltrate. This excluded class has been proposed to be associated with resistance to immune checkpoint inhibitors, although direct translation of molecular subclasses into clinical decision making has yet to be achieved.

PREVENTION AND EARLY DETECTION

Prevention Primary prevention of HCC can be achieved by vaccination against HBV and effective treatment of HBV and HCV infection. Studies assessing the impact of universal vaccination against HBV infection have reported a significant decrease of the incidence of HCC. HBV vaccination is recommended to all newborns and high-risk groups, following World Health Organization guidelines. Vaccination is also recommended in people with risk factors for acquiring HBV infection, such as health workers, travelers to areas where HBV infection is prevalent, injection drug users, and people with multiple sex partners.

Effective antiviral treatments for patients with chronic HBV infection—achieving undetectable viral titers (circulating HBV-DNA)—reduce the risk of HCC development. Evidence of this effect is supported by one randomized trial and several cohort studies. Treatment of HCV has dramatically advanced with the new DAAs, which yield >90% sustained virologic response (SVR) rates after 12 weeks of treatment. This effect has a direct implication in reducing HCC incidence in patients with cured chronic HCV infection. Once cirrhosis is established, the incidence of HCC is lower for patients with SVR than for those with active viral disease, although they continue to have persistent HCC risk (>1% per year). Additional putative chemopreventive agents have been proposed to reduce HCC incidence in at-risk populations. Aspirin is associated with HCC cumulative incidence reduction in large studies from 8% to 4%. Similarly, compelling cohort and case-control studies demonstrated a dose-dependent relationship between coffee consumption and reduced HCC incidence. As a result, coffee consumption is recommended as a chemoprevention strategy in patients with chronic liver disease.

Surveillance The aim of surveillance is to obtain a reduction in disease-related mortality. This is usually achieved through early detection that enhances the applicability and cost-effectiveness of curative therapies. U.S. and European guidelines recommend surveillance for patients at high risk for HCC on the basis of cost-effectiveness analyses. As a general rule, high-risk populations are considered those presenting an incidence cutoff >1.5% for patients with cirrhosis and 0.2% for patients with chronic hepatitis B. However, the strength of evidence supporting surveillance is modest and is based on two randomized studies conducted in China and a meta-analysis of observational studies. Overall, these studies conclude that surveillance identifies patients with smaller tumors who are more likely to undergo curative procedures. Because of lead time bias and length time bias, it cannot be concluded that surveillance ultimately reduces HCC-related mortality.

Surveillance is recommended for cirrhotic patients due to any cause, those with HCV-related advanced fibrosis (Metavir score of F3), and patients with chronic HBV infection if Asian and aged >40 years, if African and aged >20 years, if there is a family history of HCC, or if the

patient has sufficient risk by risk scores such as PAGE-B. In terms of liver dysfunction, the presence of advanced cirrhosis (Child-Pugh class C) prevents potentially curative therapies from being employed, and thus surveillance is not recommended. As an exception, patients on the waiting list for liver transplantation, regardless of liver functional status, should be screened for HCC in order to detect tumors exceeding conventional criteria and to define priority policies for transplantation. Complex scoring systems to identify at-risk populations are not yet recommended by guidelines.

Ultrasonography every 6 months, with or without serum α fetoprotein (AFP) levels, is the recommended method of surveillance. It has a sensitivity of 65–80% and a specificity of >90% for early detection. A 3-month interval does not enhance outcomes, and survival is lower with 12-month compared with 6-month intervals. A shorter follow-up interval (every 3–4 months) is recommended when a nodule of <1 cm has been detected. Computed tomography (CT) and magnetic resonance imaging (MRI) are not recommended as screening tools due to lack of data on accuracy, high cost, and possible harm (i.e., radiation with CT). Exceptionally, these techniques can be considered in patients with obesity and fatty liver, where visualization with ultrasound is difficult. Accurate tumor biomarkers for early detection need to be developed. Use of AFP levels as a stand-alone method identifies patients with HCC with 60% sensitivity but has high false-positive results. One main limitation of AFP is that only a small proportion of early tumors (~20%) present with abnormal AFP serum levels. Combining AFP with ultrasound might increase the HCC detection rate from 8–30% compared to ultrasound and depending on the performance by experienced personnel as a stand-alone method. The accuracy of other serum biomarkers proposed, such as des-γ-carboxyprothrombin (DCP) and the L3 fraction of AFP (AFP-L3), in early detection is not known.

Despite the fact that surveillance is cost-effective in HCC, the global implementation of such programs is estimated to engage ~50% of the target population in Europe and ~30% in the United States. Public health policies encouraging the implementation of such programs should lead to an increase in early tumor detection.

Diagnosis HCC is generally diagnosed at early or intermediate stages in Western countries but at advanced stages in most Asian (except Japan) and African countries. A surveillance program yields early diagnosis in 70–80% of cases. At these stages, the tumor is asymptomatic, and diagnosis can be made by noninvasive (radiologic) or invasive (biopsy) approaches. Without surveillance, HCC is discovered either as a radiologic finding or due to cancer-related symptoms. If symptoms are present, the disease is already at an advanced stage with a median life expectancy <1 year. Symptoms include malaise, weight loss, anorexia, abdominal discomfort, or signs related to advanced liver dysfunction.

NONINVASIVE (RADIOLOGIC) DIAGNOSIS Patients enrolled in a surveillance program are diagnosed by identification of a new liver nodule on abdominal ultrasound. Noninvasive diagnostic criteria can only be applied to cirrhotic patients and are based on imaging techniques obtained by four-phase multidetector CT scan (four phases are unenhanced, arterial, venous, and delayed) or dynamic contrast-enhanced MRI. A flowchart of diagnosis and recall policy recommended by U.S. and European guidelines is summarized in Fig. 82-2. Radiologic diagnosis is achieved with a high degree of confidence if the lesion is ≥1 cm in diameter and shows the *radiologic hallmarks of HCC* by one imaging technique. Using contrast-enhanced imaging techniques, the typical hallmark of HCC consists of vascular uptake of the nodule in the arterial phase with washout in the portal venous or delayed phases. This radiologic pattern captures the hypervascular nature characteristic of

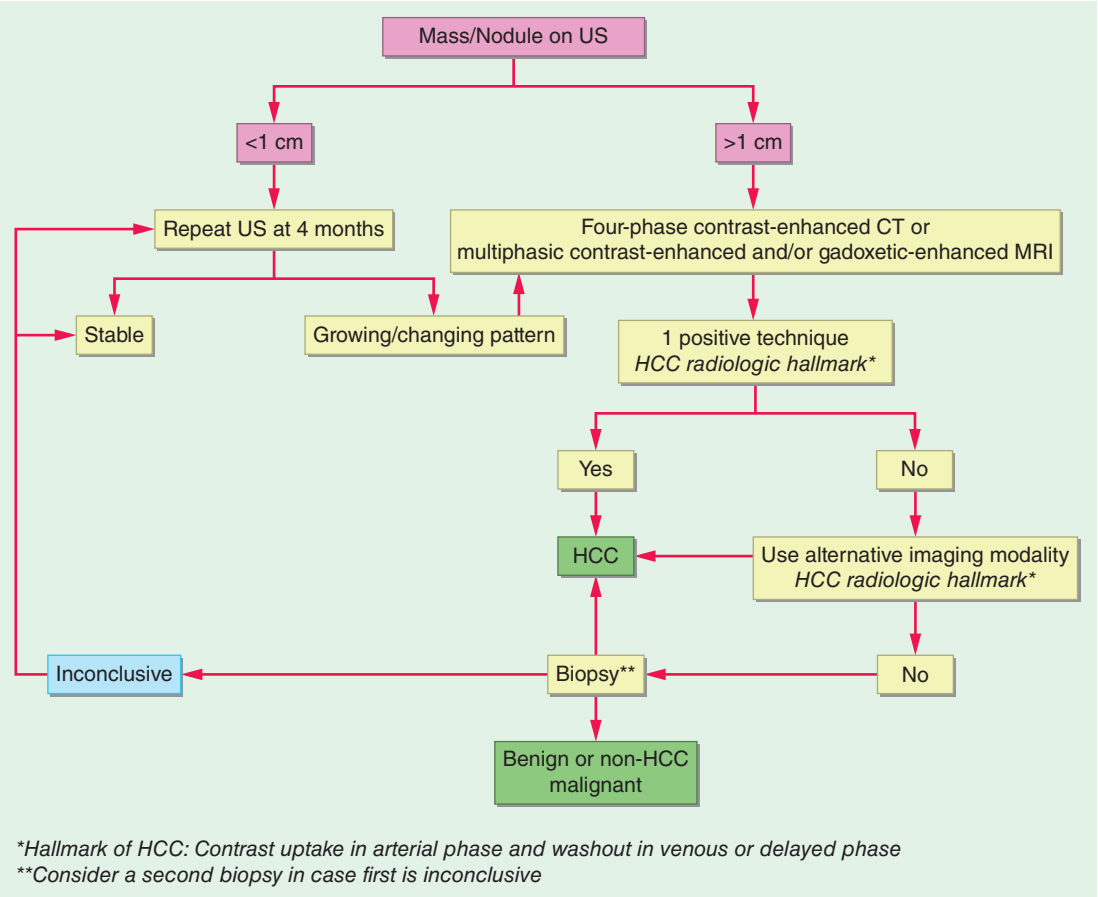

FIGURE 82-2 Recall diagnosis schedule for hepatocellular carcinoma (HCC) from the European Association for the Study of Liver Disease (EASL). ***Pink color:*** Size of the tumor at the time of detection by ultrasound (US). ***Yellow color:*** If a nodule of <1 cm is detected, repeated US at 4 months is recommended. If a nodule of >1 cm is detected, CT or MRI will be performed. Presence of *radiological hallmarks of HCC* by one imaging technique will suffice for diagnosis. This might require using one or two imaging techniques. If no diagnosis is established, then tissue biopsy would be recommended. ***Green color:*** Final diagnosis could be either HCC, benign tumor or non-HCC malingnant. ***Blue color:*** If after 2 biopsies the is no conclusive diagnosis then consider follow-up with US at 4 months. *(Reproduced with permission from European Association for the Study of the Liver: EASL Clinical Practice Guidelines: Management of hepatocellular carcinoma. J Hepatology 69:182-236, 2018.)*

HCC. In these scenarios, the diagnostic specificity is ~95–100% and a biopsy is not necessary. Nodules <1 cm in size are unlikely to be HCC and would be very difficult to diagnose; thus, ultrasound follow-up at 3–4 months is recommended. MRI with liver-specific contrast agents is accepted as a diagnostic tool (Fig. 82-2). Contrast-enhanced ultrasound and angiography are less accurate for HCC diagnosis. Positron emission tomography (PET) scan performs poorly for early diagnosis. AFP levels ≥400 ng/dL are highly suspicious, but not diagnostic, of HCC according to guidelines.

The Liver Imaging Reporting and Data System (LI-RADS) has been proposed as a way of classifying radiologic findings. Essentially, nodules >10 mm visible on multiphase exams are assigned category codes reflecting their relative probability of being benign, HCC, or other hepatic malignant neoplasms. LI-RADS-1 lesions have a 0% probability of HCC, whereas lesions assigned to the LI-RADS-5 category have a 96% probability of HCC. LI-RADS-M category comprises lesions with malignant radiologic features but are not HCC malignancies in >50% of cases.

PATHOLOGIC DIAGNOSIS Pathologic diagnosis is required in two scenarios: (1) in patients without cirrhosis and (2) if imaging is not typical in at least one of two imaging techniques (CT and MRI). This occurs mainly with early-stage HCC lesions. Biopsy has not been used as the gold standard in clinical practice because of variation introduced by sampling and complications. Nonetheless, with the advent of molecular therapies and precision oncology, some guidelines advocate obtaining tissue samples in the setting of all research studies in HCC, even if radiologic criteria are met. Sensitivity of liver biopsies ranges between 70 and 90% for all tumor sizes but decreases to <50% in tumors 1–2 cm in size. The risk of complications such as tumor seeding and bleeding after liver biopsy is ~3%. Biopsies should be assessed by an expert hepatopathologist. The use of special stains may help to resolve diagnostic uncertainties. Positive staining in two of four markers (glypican 3 [GPC3], glutamine synthetase, heat shock protein 70 [HSP70], and clathrin heavy chain) is highly specific for HCC. Gene expression blueprints (glypican 3, LYVE1, and survivin) are also able to differentiate HGDNs from early HCC. Additional staining can be considered to detect progenitor cell features (K19 and EpCAM) or assess neovascularization (CD34). A negative biopsy does not eliminate the diagnosis of HCC. A second biopsy is recommended in case of inconclusive findings or if growth or change in enhancement pattern is identified during follow-up (Fig. 82-2).

TREATMENT

Overview The landscape of management of HCC has substantially changed during the past decade. Several treatments have been adopted as standard of care according to clinical practice guidelines. For early stages, resection, liver transplantation, and local ablation have substantially improved life expectancy, with median overall survival (OS) times beyond 5 years (Fig. 82-3). For intermediate stages, transarterial chemoembolization (TACE) has improved OS from 16 months (natural history) to 20–30 months. Finally, systemic drugs for advanced tumors (atezolizumab plus bevacizumab, sorafenib, lenvatinib, regorafenib, cabozantinib, and ramucirumab) have improved median survival times from 8 months to 19 months in first-line settings and 10 months in second-line settings. Currently, several unmet needs, such as adjuvant therapies after resection or local ablation and improving outcomes at intermediate/advanced stages with combination therapies including immunotherapies, are being addressed in the setting of phase 3 investigations (Fig. 82-3).

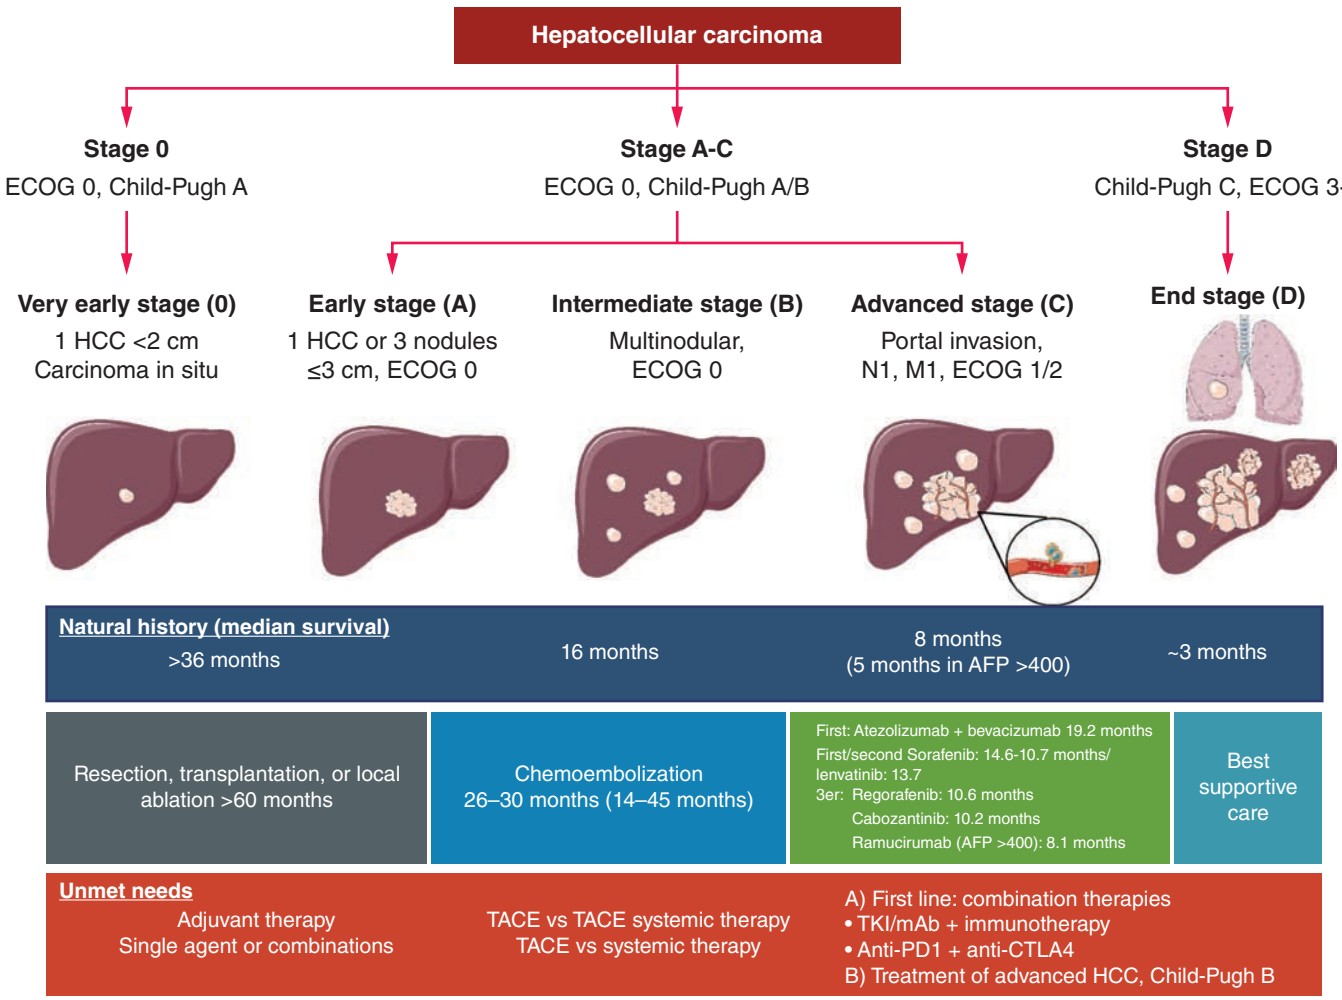

FIGURE 82-3 Natural history, impact of therapies, and unmet needs in hepatocellular carcinoma (HCC). AFP, α fetoprotein; ECOG, Eastern Cooperative Oncology Group performance status; mAb, monoclonal antibody; TACE, transarterial chemoembolization; TKI, tyrosine kinase inhibitor.

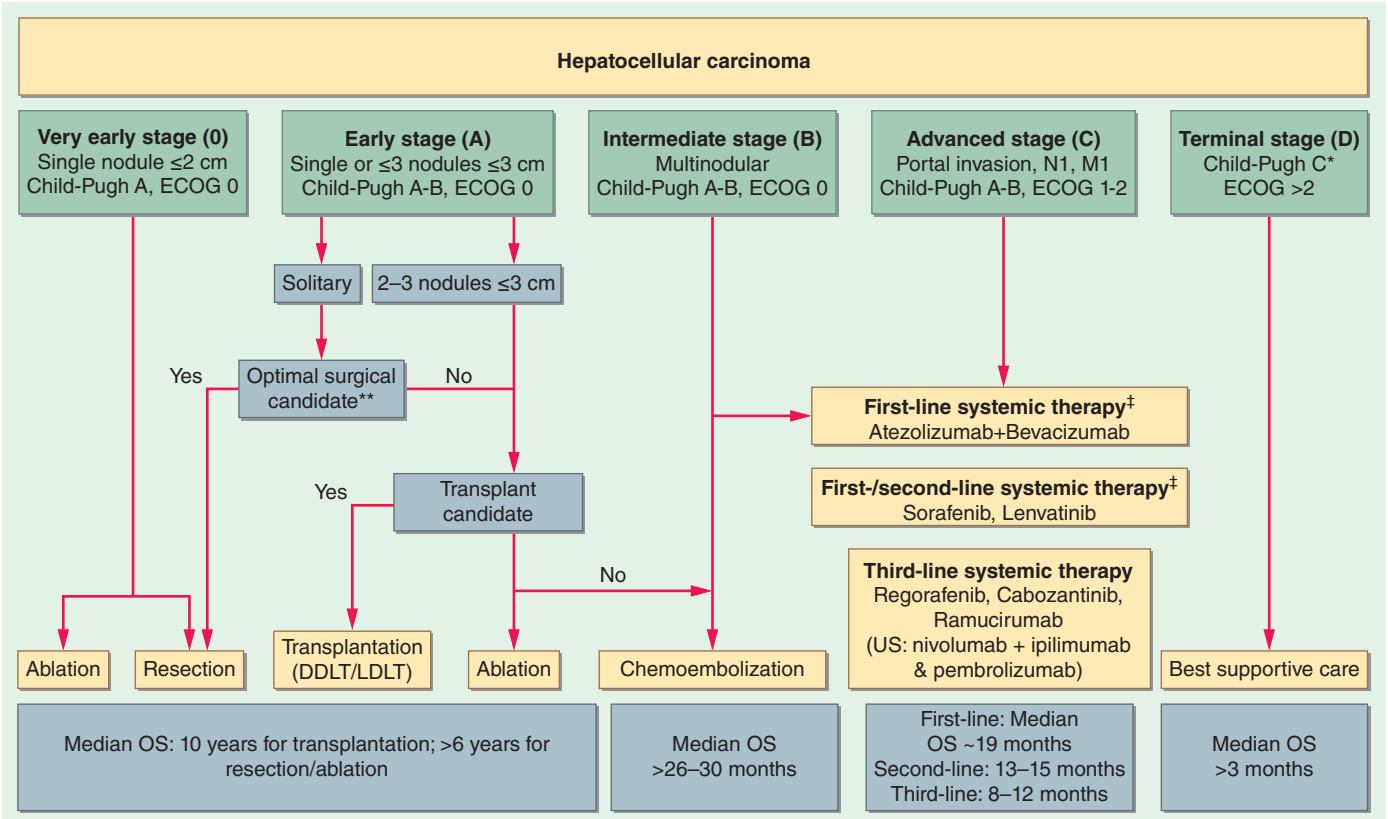

FIGURE 82-4 Staging system and therapeutic strategy. Barcelona Clinic Liver Cancer (BCLC) classification comprises five stages that select the best candidates for therapies according to evidence-based data. Patients with asymptomatic early tumors (stages 0–A) are candidates for radical therapies (resection, transplantation, or local ablation). Asymptomatic patients with multinodular hepatocellular carcinoma (HCC) (stage B) are suitable for transcatheter arterial chemoembolization (TACE), whereas patients with advanced symptomatic tumors and/or an invasive tumoral pattern (stage C) are candidates to receive systemic therapies. End-stage disease (stage D) includes patients with poor prognosis who should be treated by best supportive care. *Patients with end-stage liver disease if Child-Pugh class C should first be considered for liver transplantation. ‡Atezolizumab plus bevacizumab has been approved as new first-line treatment for advanced HCC. Nonetheless, sorafenib and lenvatinib are still considered first line options when there is a contraindication for the combination treatment. DDLT, deceased donor liver transplantation; ECOG, Eastern Cooperative Oncology Group performance status; LDLT, living donor liver transplantation; OS, overall survival. *(Reproduced with permission from JM Llovet et al: Trial Design and Endpoints in Hepatocellular Carcinoma: AASLD Consensus Conference 73:158, 2021.)*

Staging Systems and Treatment Allocation Staging systems are aimed at stratifying patients according to prognostic factors and outcome and allocating the best available therapies according to evidence. The most accepted staging system is the Barcelona Clinic Liver Cancer (BCLC) Classification, which is endorsed by U.S. and European clinical practice guidelines **(Fig. 82-4)**. This staging system defines five prognostic subclasses and allocates specific treatments for each stage. The BCLC staging system has been externally validated by numerous studies. It is an evolving system that allows incorporation of new therapies and treatment-dependent variables as new evidence emerges. Ten treatments have been shown to improve survival in HCC and thus have been incorporated in the therapeutic algorithm: surgical resection, liver transplantation, radiofrequency (RF) ablation, chemoembolization, and systemic therapies (atezolizumab-bevacizumab, sorafenib, lenvatinib, regorafenib, cabozantinib, and ramucirumab). The BCLC assigns each patient to a given treatment allocation. Treatment stage migration is also applied by this scheme, meaning that if patients are not candidates for the selected therapy, the next effective therapy at more advanced stages can be given.

In HCC, three parameters are relevant for defining treatment strategy: tumor status, cancer-related symptoms, and liver dysfunction. The BCLC staging captures all three variables and allocates patients to treatments according to evidence. Since >80% of patients have two diseases, HCC and cirrhosis, a clear measurement of liver dysfunction should be in place. The prognosis of chronic liver disease is commonly assessed using the Child-Pugh score, which uses five clinical measures—total bilirubin, serum albumin, prothrombin time, ascites severity, and hepatic encephalopathy grade—to classify patients into one of three groups (A–C) of predicted survival rates. In brief, Child-Pugh class A reflects well-preserved liver function, Child-Pugh class B indicates moderate liver dysfunction with a median life expectancy of ~3 years, and Child-Pugh class C indicates severe liver dysfunction with life expectancy of ~1 year. At early BCLC stages, more granular criteria to define patients with very-well-preserved liver function (Child-Pugh hyper-A class; those patients with normal bilirubin and without portal hypertension) need to be in place to select candidates for resection. Modifications of Child-Pugh scoring or the Model for End-Stage Liver Disease (MELD) score have not been adopted for treatment allocation, except for prioritization on the waiting list for liver transplantation (MELD score). The ALBI score, which is based only on serum albumin and bilirubin levels, has been shown to accurately stratify patients with HCC, particularly those with less severe liver dysfunction. Performance status is assessed using the Eastern Cooperative Oncology Group (ECOG) performance scale (a 5-point system where higher numbers indicate greater disability), and the presence of cancer-related symptoms (ECOG 1–2) is considered a sign of advanced stage. Patients with severe liver dysfunction (Child-Pugh class C) or performance status impairment (ECOG 3–4) are offered supportive care management.

Considering all of these prognostic and predictive variables and evidence-based treatment efficacy, five BCLC stages have been defined (Fig. 82-4). Patients with liver-only neoplastic disease, no symptoms (ECOG 0), and mild to moderate liver dysfunction (Child-Pugh A-B) can be classified as very early (stage 0) or early (stage A) or intermediate (stage B) stages depending on tumor size and number. Very early HCC (BCLC 0) is defined by single tumors ≤2 cm (if pathology is available, they should be well differentiated with absence of microvascular invasion or satellites). Early HCC (BCLC A) includes either single tumors or a maximum of three nodules of ≤3 cm in diameter. Intermediate stage (BCLC B) is defined by all other liver-only tumors. Conversely, HCC is considered at advanced stages (BCLC C) when patients present with cancer-related symptoms (ECOG 1–2) or tumors with macrovascular invasion (of any type, including branch, hepatic, or portal vein), lymph node involvement, or extrahepatic spread. Finally,

end-stage disease (BCLC D) is considered in cases of several impairment of quality of life/cancer-related symptoms (ECOG 3–4) or severe liver dysfunction (Child-Pugh C).

Around 40% of patients are diagnosed at stages 0 and A and, hence, are eligible for potentially curative therapies, resection, transplantation, or local ablation. These treatments provide median survival rates of 60 months and beyond, which are in sharp contrast with outcomes of 36 months reported in historical controls (Fig. 82-3, Table 82-2). No adjuvant therapy is recommended. Patients at intermediate stage (stage B) with preserved liver function have a documented natural history of around 16 months. These patients benefit from TACE as reported in two randomized studies and one meta-analysis and achieve an estimated survival of 25–30 months. None of the combination therapies with TACE have shown outcome advantages. Patients progressing on TACE or at advanced stage (stage C) benefit from systemic treatments. Sorafenib extends survival by ~3 months compared to placebo (from 7.9 to 10.7 months), whereas lenvatinib showed noninferiority compared to sorafenib (13.6 months vs 12.3 months, respectively). Atezolizumab (an anti-PD-L1 antibody) plus bevacizumab showed superiority compared to sorafenib (median survival 19.2 months vs 13.4 months). Three additional targeted therapies have shown improved survival compared to placebo in patients with HCC progressing on sorafenib: regorafenib, cabozantinib, and ramucirumab (only in patients with AFP >400 ng/mL). Therefore, these treatments have been adopted by guidelines and incorporated into the treatment algorithm. Patients with end-stage disease (BCLC D) should be considered for nutritional and psychological support and proper management of pain.

Although the BCLC establishes validated stages and treatment assignment according to evidence, clinical practice is not always aligned with this classification. In large cohort studies and surveys, only half of patients, or even less in Asia, are treated accordingly. Alternative staging or scoring systems have been proposed, but none of them has acquired global consensus. In contrast to BCLC, some proposed systems capture the standard of practice in Asia, such as the Hong Kong classification or the Japan Integrated Staging score. These systems capture extended indications for resection and TACE applied in clinical practice in Asia. Finally, the tumor-node-metastasis (TNM) staging system is not used in HCC since it does not incorporate the main prognostic variables related to liver function and performance status.

Due to the complexities of HCC diagnosis and management, it is recommended that patients be sent to a referral center where all the armamentarium of therapies can be offered. In principle, patient management and outcome benefit from liver cancer multidisciplinary programs that include a hepatologist, oncologist, hepatobiliary and transplant surgeons, interventional and body imaging radiologist, hepatopathologist, and specialized nurses.

SURGICAL THERAPIES

Resection Surgical resection is the first-line option for noncirrhotic patients with early-stage HCC (BCLC 0 or A) with solitary tumors (Fig. 82-4). In cirrhotic patients, ablation competes with resection for BCLC 0 tumors (<2 cm in diameter). Which treatment is better is not defined. Cost-effectiveness approaches report a benefit for local ablation with RF. For single tumors >2 cm (BCLC A), resection remains the mainstay of treatment in patients with Child-Pugh hyper-A class, i.e., those patients with normal bilirubin and absence of portal hypertension (portal hypertension is defined by hepatic venous pressure gradient ≥10 mmHg). Surrogate measures of portal hypertension are presence of esophageal varices or platelet count <100,000/μL associated with splenomegaly. Anatomic resections following the functional segments of the liver are recommended to spare uninvolved

TABLE 82-2 Summary of Key Results of Randomized and Cohort Studies in the Management of Hepatocellular Carcinoma

TREATMENT OF EARLY- AND INTERMEDIATE-STAGE HCC				
TREATMENTS	**HCC STAGE**	**TREATMENT ARMS**		**OUTCOMES (OS)**
Treatment for early HCC				
Resection	Early	Optimal (single nodule; no portal hypertension)		5 years: 50–70%
		Suboptimal (multinodular or portal hypertension)		5 years: 35–55%
Liver transplantation	Early	Milan (1 nodule <5 cm, 2–3 nodules ≤3 cm, no MVI, no EHS)		5 years: 70–80%
	Early/intermediate	Downstaged (1 nodule ≤6.5 cm, ≤3 nodules ≤4.5 cm and total diameter ≤8 cm, no MVI, no EHS)		5 years: 60–70%
Ablation	Early	RFA		Median: 50–60 months
Treatments for intermediate HCC				
Transarterial therapies	Intermediate	TACE		Median: 20–32 months
TREATMENT OF ADVANCED-STAGE HCC				
STUDY	**TREATMENT**	**MEDIAN OS, MONTHS (HR, 95% CI)**	**MEDIAN PFS, MONTHS (HR, 95% CI)**	**ORR: MRECIST/RECIST**
First-line therapies				
IMbrave150	Atezolizumab-bevacizumab	19.2 (HR 0.66, 0.52–0.85)	6.9 (HR 0.65, 0.53–0.81)	35.4%/29.8%

REACH-2	Ramucirumab	8.5 (HR 0.71, 0.53–0.95)	2.8 (HR 0.45, 0.34–0.6)	NA/5%

Abbreviations: CI, confidence interval; EHS, extrahepatic spread; HCC, hepatocellular carcinoma; HR, hazard ratio; MRECIST, Modified Response Evaluation Criteria in Solid Tumors; MVI, microvascular invasion; NA, not available; NE, not evaluable; ORR, overall response rate; OS, overall survival; PFS, progression-free survival; RECIST, Response Evaluation Criteria in Solid Tumors; RFA, radiofrequency ablation; TACE, transarterial chemoembolization.

liver parenchyma and to remove satellite tumors. Predictors of recurrence are tumor size and number and presence of microsatellites or microvascular invasion at the specimen analysis. Outcomes in suboptimal candidates lead to 5-year survival rates of ~35–55%, as opposed to 60–70% for ideal candidates (Table 82-2). Macrovascular invasion, extrahepatic involvement, and liver dysfunction (Child-Pugh B-C) are major contraindications for resection.

ADJUVANT TREATMENTS Tumor recurrence represents the major complication of resection (and local ablation) and occurs in 70% of cases at 5 years. Most recurrences are intrahepatic metastases, but at least one-third are considered de novo tumors, new clones developing in the cirrhotic carcinogenic field. The type of recurrence can only be defined by molecular studies. So far, no adjuvant therapies have been proven to improve outcome or prevent recurrence after resection/ablation. Randomized trials testing adjuvant sorafenib, retinoids, chemotherapies, or chemoembolization have been negative, and thus, no adjuvant therapy recommendation has been established for patients after resection or local ablation.

Liver Transplantation Liver transplantation is the first treatment choice for cirrhotic patients with single tumors ≤5 cm and portal hypertension (including Child-Pugh B and C) or with small multinodular tumors (≤3 nodules, each ≤3 cm) (Fig. 82-4). These so-called Milan criteria have been validated over the years, and a meta-analysis reported 5- and 10-year survival rates of ~70 and ~50%, respectively, similar to outcomes achieved in non-HCC transplantation indications. Perioperative mortality rates have been reduced to <3%. Transplantation simultaneously cures the tumor and the underlying cirrhosis, and it is associated with a low risk of recurrence, around 10–15% at 5 years. No immunosuppressive regimens or antitumor therapies after transplantation have demonstrated any preventive effect on recurrence. Milan criteria are integrated in the treatment strategy (BCLC 0 and A) and have also been adopted by the United Network for Organ Sharing (UNOS) pretransplant staging for organ allocation in the United States (stage T2). Aside from size and number, conventional contraindications for organ transplantation procedures (e.g., ABO incompatibility, comorbidities) are applied in this setting.

Liver transplantation has a couple of factors, such as cost and donor availability, that limit this procedure to <5% of HCC cases. The scarcity of donors represents a major drawback of liver transplantation. Donor scarcity varies geographically, and deceased liver donation is almost zero in some Asian countries. Due to the shortage of donors, median waiting times in Western programs is ~6–12 months, leading to 20% of candidates dropping off the list due to tumor progression before receiving the procedure. Predictors of dropout are neoadjuvant treatment failure, baseline AFP >400 ng/mL, and steady increase of AFP level >15 ng/mL per month. Several strategies have been proposed to overcome this limitation. First, apply neoadjuvant therapies in patients on the waiting list. Neoadjuvant treatments such as TACE or RF ablation have been assessed in the setting of cohort and cost-effectiveness studies. In principle, the use of these therapies is recommended when the waiting time exceeds 6 months, even though impact on long-term outcome is uncertain. Second, a priority policy has been established for patients enlisted. UNOS has implemented a scoring system based on the dropout risk.

The Milan criteria are universally used as the basis for transplant eligibility, and adherence to these criteria yields good posttransplant survival. Modest expansion of Milan criteria applying the "up-to-seven" criterion (i.e., those HCCs having the number 7 as the sum of the size of the largest tumor and the number of tumors) in patients without microvascular invasion achieves competitive outcomes. These pathologically defined criteria are being used in clinical practice to predict the expected outcome after transplantation. Similarly, *downstaging to Milan criteria* is currently defined as the reduction of HCC burden by locoregional treatments to achieve Milan staging before transplantation. This strategy leads to long-term 10-year survival rates of ~50%. Since policies for enhancing organ donation have reached a ceiling during the past several years, alternatives to donation have emerged. Living donor liver transplantation represents a plausible alternative that accounts of ~5% of total transplantations performed globally. Outcomes reported are similar to those with deceased liver donors, and it is recommended as an alternative option in patients on a waiting list exceeding 6 months. The risks and benefits of this procedure should take into account both donor (death is estimated in 0.3%) and recipient, a concept known as *double equipoise*. Due to the complexity of this treatment, it must be restricted to centers of excellence in hepatobiliary surgery and transplantation.

LOCOREGIONAL THERAPIES

LOCAL ABLATION RF ablation is recommended as the primary ablative technique (Fig. 82-4). The energy generated by RF ablation (heating of tissue at 80°–100°C) induces coagulative necrosis of the tumor, producing a *safety ring* in the peritumoral tissue, which might eliminate small undetected satellites. Treatment consists of one or two sessions performed using a percutaneous approach, although in some instances, ablation with laparoscopy is needed. RF ablation is more effective in response rate and time to recurrence compared with the once-conventional percutaneous ethanol injection. HCC patients treated by RF ablation have 5-year survival rates of ~60% (Table 82-2). In tumors <2 cm, RF ablation achieves complete responses in >90% of cases with good long-term outcome and is competitive with resection in cost-effectiveness as first-line option. For BCLC A cases, RF ablation is the first-line treatment for single tumors 2–5 cm or up to three nodules, each ≤3 cm in diameter, unsuitable for surgery.

The failure rate of RF ablation increases in tumors >3 cm because of the heat loss due to perfusion-mediated tissue cooling within the area ablated. In tumors 3–5 cm in diameter, complete pathologic tumor necrosis of <50% has been reported. In particular, ~10–15% of tumors with difficult-to-treat locations, such as a subcapsular location or adjacent to the gallbladder, have a higher risk of incomplete ablation or major complications and can be approached by ethanol injection. Several approaches have been proposed to enhance the antitumor activity of RF ablation. Microwave ablation is the most widely used local image-guided technique alternative to RF. Theoretically, it provides major efficacy but higher complication rates in tumors >3 cm. Randomized trials comparing both techniques are needed. Other treatments, such as high-intensity focused ultrasound or stereotactic body radiotherapy for small tumors, have been studied in early clinical trials and are under investigation.

Chemoembolization TACE is the most widely used primary treatment for unresectable HCC worldwide and the first-line indication for patients with intermediate BCLC B stage (Fig. 82-4). Conventional chemoembolization (c-TACE) consists of the local hepatic artery administration of chemotherapy (either doxorubicin 50 mg/m^2 or cisplatin) mixed with an emulsion of lipiodol followed by obstruction of the feeding artery with sponge particles. c-TACE mainly benefits patients with liver-only disease, Child-Pugh A class or B class without ascites, good performance status (ECOG 0), and absence of branch or trunk vascular invasion. Median survival is ~20 months (compared to 16 months for pooled control arms). The best randomized phase 3 investigations have provided median survivals for TACE of 20–30 months in properly selected populations. Median objective response rates are 50–70%. In randomized studies, the treatment is either performed at a regular schedule of 0, 2, and 6 months (median number of sessions: 3) or on demand according to tumor response. TACE procedures should be stopped upon tumor progression or any other contraindication. Exceptionally, occurrence of a new small untreated nodule as the only progression feature can be considered for treatment. Around 50% of patients present with a limited postembolization syndrome of fever and abdominal pain related to ischemic injury and release of cytokines. Less than 5% of patients present with major complications (liver abscess, ischemic cholecystitis, or liver failure), and in <2% of cases, treatment-related death occurs.

Applicability of c-TACE in patients at intermediate stage is limited to half of cases, mostly as a result of the presence of liver failure (Child B or ascites or encephalopathy), technical contraindications to the procedure (i.e., impaired portal vein blood flow), or infiltrative/massive tumor burden (i.e., generally main tumor size >10 cm). Super-selective

TACE minimize the ischemic insult to nontumor tissue. According to guidelines, treatment-stage migration allows performing TACE on patients at early stages not suitable for surgical or ablative therapies. In selective studies, median survival times of 5 years have been reported in patients with single HCC treated by super-selective TACE. On the other hand, TACE performed beyond guidelines as a conventional practice in patients with advanced HCC yields poor outcomes.

Drug-eluting bead chemoembolization (DEB-TACE) differs from c-TACE in the use of more standardized embolic spheres of regular size embedded with chemotherapy. This strategy ensures drug release over a 1-week period, resulting in an enhancement of drug concentration within the tumor. DEB-TACE achieves similar antitumor activity (objective responses of ~60%) as c-TACE and is associated with significantly less systemic cytotoxic effects and better tolerance, but with no clear differences in clinical outcomes. Phase 2 and 3 studies have compared DEB-TACE with the combination of DEB-TACE plus sorafenib, orantinib, or brivanib, which are VEGF receptor inhibitors. Median survival in both arms of these international trials was 25–30 months.

Radioembolization and Other Intraarterial Therapies

Radioembolization using beads coated with yttrium-90 (Y-90)—an isotope that emits short-range β radiation—is the most promising alternative to TACE. Several phase II studies reported objective responses and overall outcome with a safe profile. Due to the lack of phase III trials, this treatment is currently not recommended in guidelines. Radioembolization requires prevention of severe lung shunting and intestinal radiation before the procedure. Around 20% of patients present with liver-related toxicity and 3% experience treatment-related death. Due to the minimally embolic effect of Y-90 microspheres, treatment can be safely used in patients with portal vein thrombosis, a setting where survival results in phase II were encouraging. However, three randomised controlled trials, including two head-to-head trials against sorafenib and one trial combining radioembolization plus sorafenib versus sorafenib alone, did not show OS endpoint superiority. Thus, these treatments are not indicated in the advanced-stage scenario.

TACE should be distinguished from other intraarterial therapies, such as chemo-lipiodolization, which involves the delivery of an emulsion of chemotherapy mixed with lipiodol; bland transcatheter embolization, where no chemotherapeutic agent is delivered; and intraarterial chemotherapy, where no embolization is performed. None of these approaches is recommended due to the lack of survival benefit.

SYSTEMIC THERAPIES

Conventional systemic chemotherapy and radiotherapy have not produced survival advantages. Randomized studies also failed to show benefit with antiestrogen therapies and vitamin D derivatives. External-beam liver-directed radiotherapy (stereotactic body radiotherapy) efficacy is currently being tested with and without sorafenib in phase III trials. In 2007, a phase III trial demonstrated survival benefits for patients with advanced-stage disease treated with sorafenib, and lenvatinib showed similar effects to sorafenib in first-line treatment. Recently, the combination of atezolizumab with bevacizumab demonstrated survival benefits in the advanced setting when compared to sorafenib and has now become the standard first-line treatment. Three additional therapies, regorafenib, cabozantinib, and ramucirumab (only in patients with AFP >400 ng/mL), have been shown to benefit patients progressing on sorafenib (Fig. 82-5).

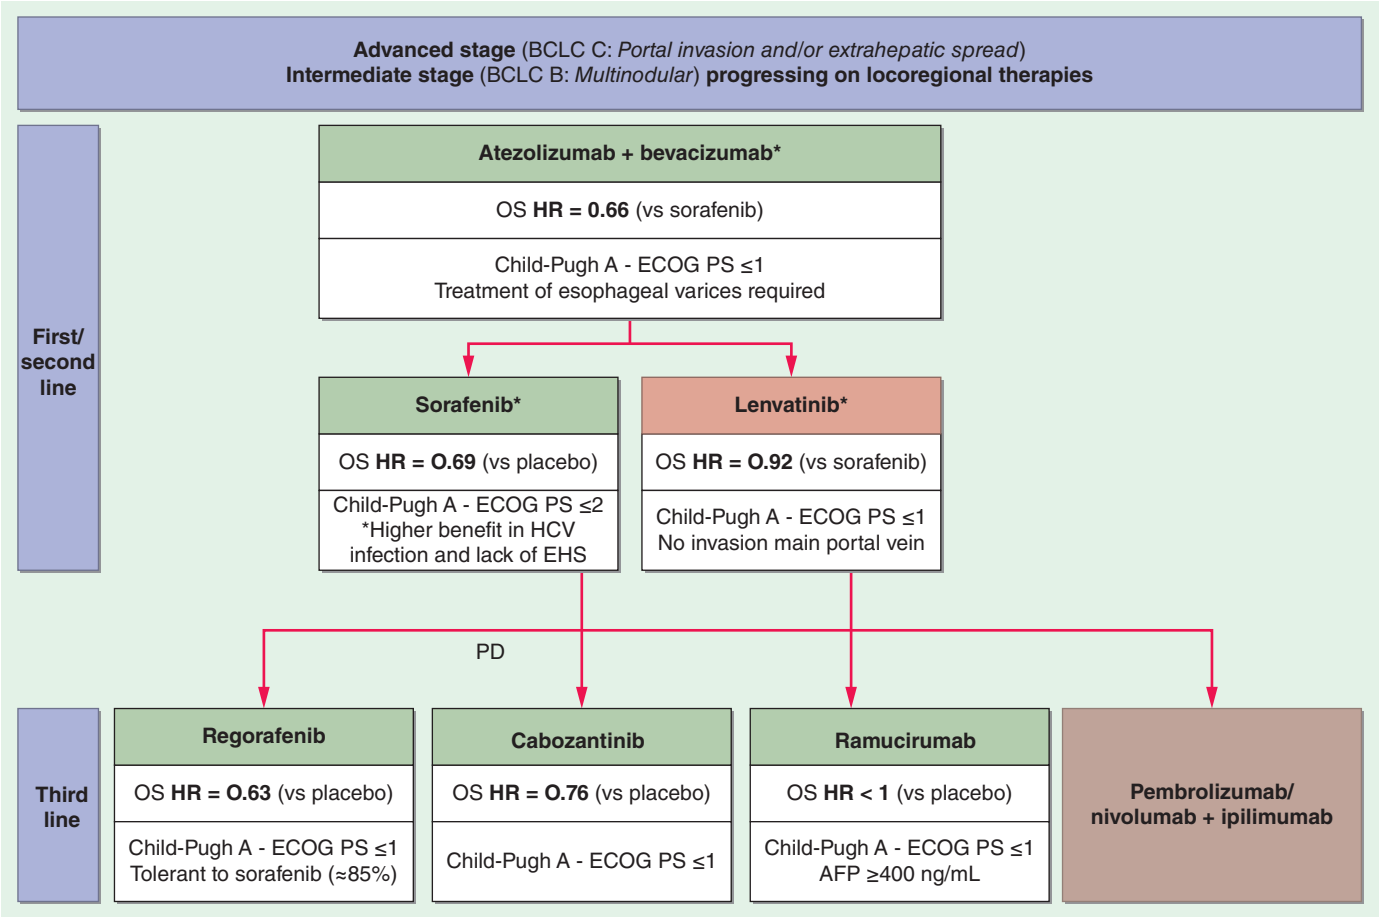

FIGURE 82-5 Treatment strategy for advanced hepatocellular carcinoma with systemic therapies. Drugs in green have positive results from phase 3 trials with a superiority design (atezolizumab plus bevacizumab, sorafenib, regorafenib, cabozantinib, and ramucirumab). Drugs in orange have positive results from phase 3 trials with a noninferiority design (lenvatinib vs sorafenib). Drugs in red have received accelerated approval from the U.S. Food and Drug Administration (FDA) based on promising efficacy results in phase 2 trials in the second-line setting (nivolumab, pembrolizumab, and nivolumab ipilimumab). Key details of the patient populations are provided. *Around 20% of patients can receive sorafenib or lenvatinib in first line due to contraindications to atezolizumab + bevacizumab. AFP, α fetoprotein; BCLC, Barcelona Clinic Liver Cancer (classification); ECOG PS, Eastern Cooperative Oncology Group performance status; EHS, extrahepatic spread; HCV, hepatitis C virus; HR, hazard ratio; mRECIST, modified Response Evaluation Criteria in Solid Tumors; OS, overall survival. *(Reproduced with permission from JM Llovet: Molecular therapies and precision medicine for hepatocellular carcinoma. Nat Rev Clin Oncol 15:599, 2018.)*

Molecular Targeted Therapies Atezolizumab (anti-PD-L1 checkpoint inhibitor) plus bevacizumab (antibody against VEGFA) has become the standard of care in first-line treatment for advanced HCC as a result of a positive phase 3 trial indicating superiority versus sorafenib in terms of survival (Fig. 82-5). Median survival with the combination was 19.2 months compared with 13.4 months for sorafenib. Combination treatment also improved progression-free survival and patient-reported quality of life outcomes. Objective response to the combination was 35.4% versus 13.9% for sorafenib. Adverse events also favored the combination (grade 3–4 adverse events, 36% vs 50% for sorafenib). The most common side effects associated with the combination were hypertension, proteinuria, and low-grade diarrhea, whereas autoimmune events were infrequent. Treatment-related adverse events leading to discontinuation of these two drugs was 15%. Upper gastrointestinal endoscopies are required before initiating the combination therapy for detection and treatment of varices to mitigate the risk of bleeding associated with bevacizumab. Thus, screening for varices is becoming standard before first-line therapy in HCC management.

Alternatively, sorafenib and lenvatinib are indicated for HCC in patients with well-preserved liver function (Child-Pugh class A) and with advanced tumors either as first-line treatment in patients with contraindications or with progression to the combination therapy (Fig. 82-5). A phase III study comparing sorafenib versus placebo showed increased survival from 7.9 months to 10.7 months (hazard ratio [HR] 0.69; 31% reduction in risk of death). Patients with HCV-related HCC achieve significantly better outcomes with sorafenib, with a median survival of 14 months. No predictive biomarkers of responsiveness to sorafenib have been identified. The recommended daily dose of sorafenib is 800 mg. Median treatment duration is about 6 months. Treatment is associated with adverse events, such as diarrhea, hand-foot skin reactions, fatigue, and hypertension. These toxicities lead to treatment discontinuation in 15% of patients and dose reduction in up to half. This therapy cannot be administered to around one-third of the targeted patients due to primary intolerance, advanced age, or liver failure (ascites or encephalopathy). Active vascular disease, either coronary or peripheral, is considered a formal contraindication.

The efficacy of sorafenib probably results from a balance between targeting cancer cells and the microenvironment by blocking up to 40 kinases, including antiangiogenic (VEGF receptor [VEGFR], platelet-derived growth factor receptor [PDGFR]) and antiproliferative drivers (serine/threonine-protein kinase B-raf [BRAF] and mast/stem cell growth factor receptor [c-Kit]) **(Fig. 82-6)**. Median time to progression on sorafenib is 4–5 months in phase III trials.

Another alternative to sorafenib is the multikinase inhibitor lenvatinib; it was noninferior in a phase 3 investigation (13.6 months vs

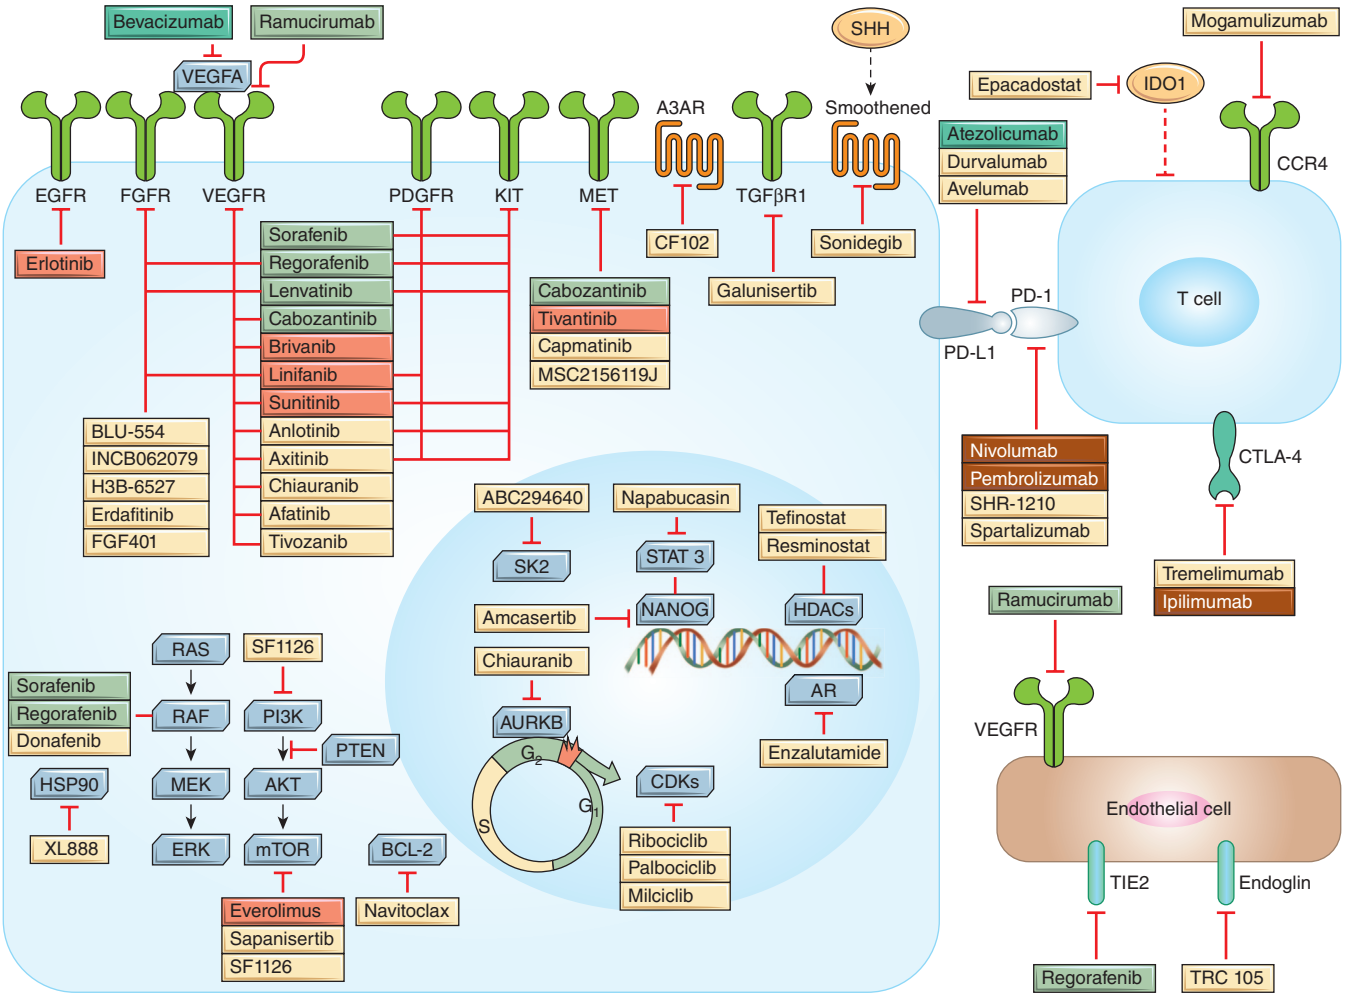

FIGURE 82-6 Molecularly targeted therapies for hepatocellular carcinoma and their target signaling pathways. Green boxes indicate drugs with positive results from phase 3 trials (atezolizumab plus bevacizumab, sorafenib, lenvatinib, regorafenib, lenvatinib, cabozantinib, and ramucirumab). Red boxes indicate drugs with negative results from phase 3 trials (everolimus, sunitinib, linifanib, erlotinib, brivanib, and tivantinib). Drugs in yellow boxes are currently in development for hepatocellular carcinoma in phase 1, 2, or 3 clinical trials. Brown boxes indicate drugs approved based on phase 2 trial data (pembrolizumab, nivolumab + ipilimumab). Dashed arrows and lines indicate indirect activities. A3AR, adenosine receptor A3; AR, androgen receptor; AURKB, aurora kinase B; BCL-2, apoptosis regulator BCL-2; CCR4, CC-chemokine receptor 4; CDKs, cyclin-dependent kinases; CTLA-4, cytotoxic T lymphocyte protein 4; HDAC, histone deacetylase; HSP90, heat shock protein 90; IDO1, indoleamine 2,3-dioxygenase 1; NANOG, homeobox protein NANOG; PD-1, programmed cell death protein 1; PD-L1, programmed cell death ligand 1; SHH, Sonic hedgehog; STAT3, signal transducer and activator of transcription 3; TIE-2, angiopoietin 1 receptor. *(Reproduced with permission from JM Llovet: Molecular therapies and precision medicine for hepatocellular carcinoma. Nat Rev Clin Oncol 15:599, 2018.)*

12.3 months; HR 0.92) (Fig. 82-5). Lenvatinib induces objective responses in 24% of cases. The main side effects are hypertension, proteinuria, asthenia, diarrhea, and weight loss. This treatment induced grade 3–4 drug-related adverse events in 55% of patients, resulting in a withdrawal rate of ~15%.

Three drugs (regorafenib, cabozantinib, and ramucirumab) have shown survival benefits versus placebo in patients progressing on sorafenib, and two additional immune-based treatments have been approved by the U.S. Food and Drug Administration (FDA) based on promising phase 2 data (pembrolizumab and nivolumab plus ipilimumab) (Fig. 82-5). The median survival of patients progressing on first-line treatment is 8 months (obtained from patients allocated to the placebo arm).

A phase III study comparing regorafenib (a more potent multikinase inhibitor than sorafenib targeting similar kinases) versus placebo in patients progressing on sorafenib reported a benefit in survival from 7.8 to 10.6 months (HR 0.62; 38% reduction in risk of death) (Fig. 82-5). Response rate was 10%. Median time on treatment was 3.5 months. Prevalence of toxicity (hand-foot reaction, fatigue, and hypertension) was higher compared with reported toxicity from sorafenib, but adverse events only led to treatment discontinuation in 10% of cases. Cabozantinib, a multikinase VEGFR inhibitor with activity against both AXL and c-MET (Fig. 82-6), improves survival compared to placebo after progression on sorafenib (10.2 months for cabozantinib vs 8.0 months in the placebo arm; HR 0.76). The most common grade 3–4 adverse events were palmar-plantar erythrodysesthesia, hypertension, increased aspartate aminotransferase level, fatigue, and diarrhea. Ramucirumab, an anti-VEGFR-2 monoclonal antibody, is the only biomarker-guided therapy in HCC based on AFP levels. The randomized, placebo-controlled, phase 3 REACH-2 study selected patients with advanced HCC in second line with baseline AFP ≥400 ng/dL. Median survival for patients treated with ramucirumab was 8.1 months, compared to 5 months for patients receiving placebo. The most common grade 3–4 adverse events were hypertension, hyponatremia, and increased aspartate aminotransferase. Patients progressing after second-line therapy and patients with BCLC D stage should receive best supportive palliative care, including management of pain, nutrition, and psychological support.

Immunotherapy and Combinations The combination of the anti-PD-L1 antibody atezolizumab with the VEGFA inhibitor bevacizumab is the first regimen to improve survival in the first-line setting compared to sorafenib. In addition, two additional treatment regimens involving immunotherapies have been approved by the FDA as second-line therapies based on phase 2 data. Single-agent checkpoint inhibitor treatments, such as nivolumab and pembrolizumab, are associated with objective responses of 15–20%, which are durable in time, generally beyond 12 months. Less than 30% of patients experience grade 3–4 treatment-related adverse events. Neither regimen hit the primary endpoint of improved survival in phase 3 investigations compared with sorafenib (nivolumab) or placebo (pembrolizumab). The median survival for nivolumab of 16.4 months in first-line treatment was not superior to the survival time of 14.7 months for sorafenib. Similarly, in the second-line setting, the median survival for pembrolizumab of 13.9 months was not superior to the median survival of 10.6 months for placebo. Emerging regimens have shown signals of efficacy, such as lenvatinib plus pembrolizumab in first-line patients with advanced HCC and the combination of an anti-CTLA-4 (ipilimumab) and anti-PD-1 (nivolumab) in second-line patients.

CHOLANGIOCARCINOMA

Cholangiocarcinoma (CCA) is classified according to its anatomic location as intrahepatic (iCCA; ~20–30%), perihilar (pCCA; ~50–60%), and distal (dCCA; ~20–30%). The latter two are also known as extrahepatic cholangiocarcinomas (eCCAs), with the second-order bile ducts acting as the separation point **(Fig. 82-7)**. This classification is endorsed by the eighth edition of the *American Joint Committee on Cancer (AJCC) Staging Manual*. In addition, iCCA has been recognized as a distinct entity with specific ad hoc clinical practice guidelines. Treatment options beyond surgery are limited, and few molecular targeted therapies have been approved for its treatment. The three subtypes of CCA differ in their anatomic location, epidemiology and risk factors, cell of origin, pathogenesis, and treatment. iCCA originates from adult cholangiocytes, trans-differentiation of adult hepatocytes, and hepatic progenitor cells (cholangiocyte precursors) **(Fig. 82-8)**, as opposed to HCC, which originates only from hepatic progenitor cells or adult hepatocytes. Mixed HCC-iCCA originates from hepatic progenitor cells, whereas eCCA arises from the biliary epithelium and peribiliary glands. Moreover, their mutational profiles also differ. *FGFR2* fusions and *IDH1/2* mutations mostly occur in iCCA, whereas *ERBB2/3* amplifications and *SMAD4* aberrations are characteristic of eCCA. Thus, clinical management and trials testing molecular therapies should be tailored according to each biological/anatomical subtype of CCA, as opposed to a common approach for all biliary tract cancers.

EPIDEMIOLOGY, RISK FACTORS, AND MOLECULAR TRAITS

CCA is the second most common liver cancer after HCC, with a 5-year survival of 10%. iCCA has globally increasing incidence and mortality rates. The incidence of iCCA varies according to exposure to risk factors, ranging from 1–2 cases per 100,000 inhabitants in Europe and North America to the highest incidence in some areas of Southeast Asia, particularly in Thailand (>80 cases per 100,000 inhabitants). The male-to-female ratio is 1.2. Overall, most cases occur with unknown risk factors. The classical risk factors for CCA development include primary sclerosing cholangitis (PSC), biliary duct cysts, hepatolithiasis, and Caroli's disease (congenital cystic dilation of the intrahepatic biliary tree). Parasitic biliary infestation with flukes (i.e., most common is *Opisthorchis viverrini* and *Clonorchis sinensis*) is a prevalent etiology in Asia that can be prevented with the antihelminth therapy praziquantel. PSC is a clear risk factor for iCCA and pCCA development, with a

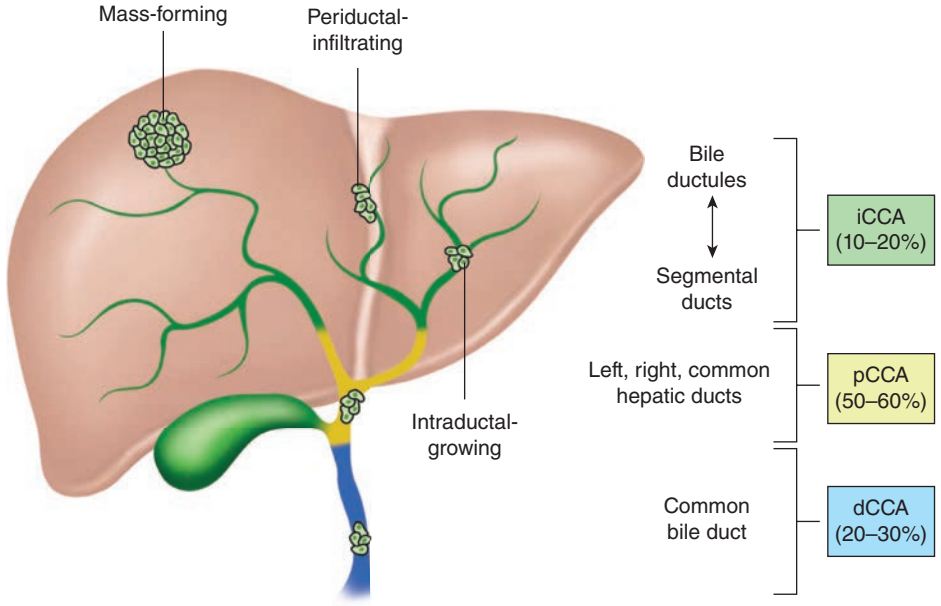

FIGURE 82-7 Anatomical classification of cholangiocarcinoma. Cholangiocarcinoma (CCA) is classified as intrahepatic (iCCA) and extrahepatic (eCCA). eCCA can be subclassified as perihilar (pCCA) and distal (dCCA). *(Reprinted with permission from JM Banales et al: Cholangiocarcinoma 2020: The next horizon in mechanisms and management. Nat Rev Gastroenterol Hepatol 17:557, 2020.)*

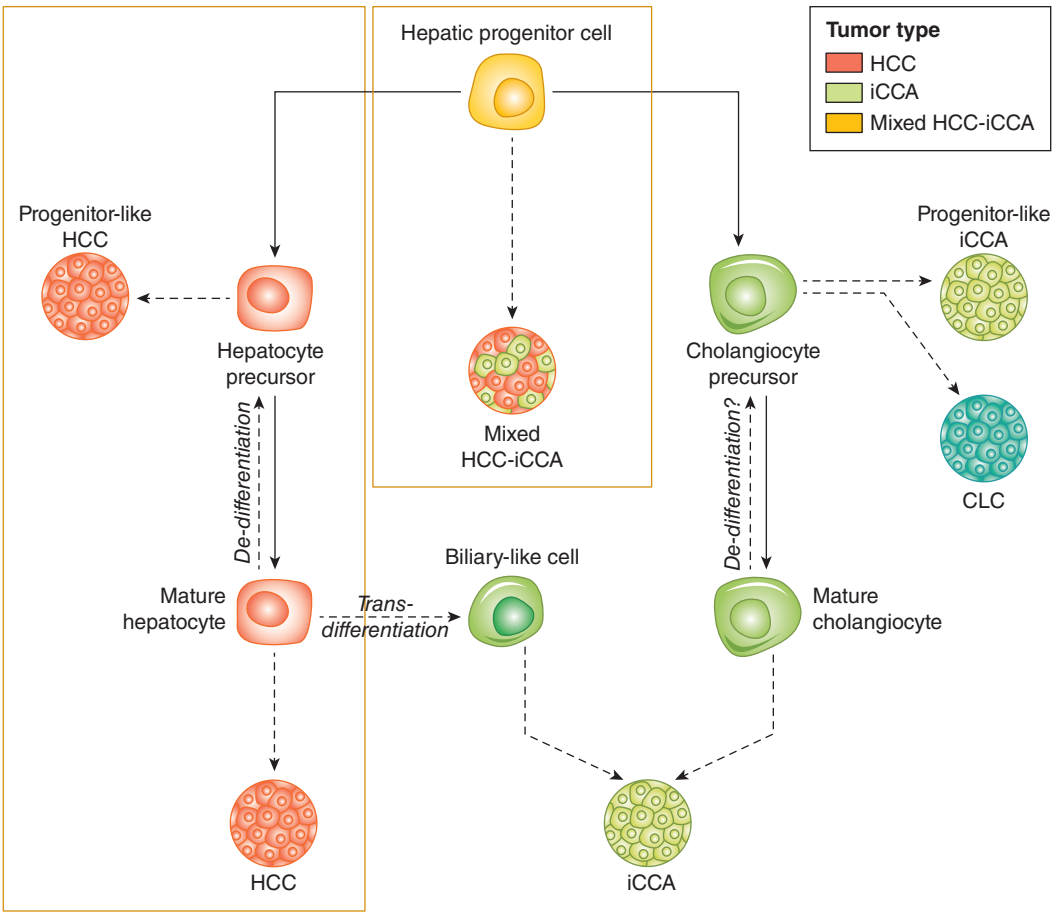

FIGURE 82-8 Cell of origin of liver cancer. Hepatocellular carcinoma (HCC) and intrahepatic cholangiocarcinoma (iCCA) can develop from the neoplastic transformation of mature hepatocytes and cholangiocytes, respectively. There is evidence showing that hepatic progenitor cells (HPCs), their intermediate states, or de-differentiated hepatocytes can originate liver cancers with progenitor-like features, including mixed HCC-iCCA (e.g., cholangiocellular carcinoma [CLC]). Mature hepatocytes can be also reprogrammed into cells that closely resemble biliary epithelial cells and induce the onset of iCCA. *(Printed with permission from ©Mount Sinai Health System.)*

lifetime incidence ranging from 5 to 10%. Surveillance in PSC patients is recommended with annual imaging techniques and CA 19-9 serum determination. Common risk factors for HCC, such as HBV and HCV infection and cirrhosis, have been associated with iCCA development. Sweetened beverages were reported to constitute an additional risk factor in the development of eCCA and gallbladder carcinoma in a population cohort study.

Molecular Classification and Drivers No molecular classification of CCA has been established. Genomic studies have provided insight on two subclasses of iCCA, a proliferation subclass—characterized by activation of oncogenic signaling pathways (including RAS and MET)—and an inflammation subclass, characterized by activation of inflammatory pathways, overexpression of cytokines, and STAT3 activation. Similarly, a molecular classification of eCCA has been proposed, dividing tumors into four categories (metabolic, proliferation, mesenchymal, and immune) based on molecular traits. The hypothesis that the proliferation class with enrichment of *ERBB2/3* mutations might respond to monoclonal antibodies against this receptor and the immune class might respond to checkpoint inhibitors has not been tested or confirmed. The iCCA mutation portrait is characterized by ~50–60% of tumors having at least one targetable driver including *FGFR2* fusion events (~25%); mutations in *IDH1/2* (15%), *KRAS* (15%), *BRAF* (5%), and *EGFR* (3%); and amplifications in *FGF19/CCDN1* (4%). Although mutations in *TP53* (~30%) and *KRAS* (~25%) are more common in eCCA than in iCCA, some molecular drivers are specific for subtypes, such as fusion of *PRKACA* or *PRKACB* for eCCA or *ERBB2* amplifications (~20%) for gallbladder cancer. Liver fluke–associated CCAs have a higher incidence of *TP53* and *SMAD4* mutations. Host genetic polymorphisms predisposing to CCA have not been established.

INTRAHEPATIC CHOLANGIOCARCINOMA

Diagnosis Diagnosis of iCCA requires pathologic confirmation. Guidelines currently do not recommend surveillance for early diagnosis because at-risk populations are ill-defined. Cirrhotic patients at risk of HCC development are enrolled in surveillance programs and can benefit from early detection of iCCA. Otherwise, incidental diagnosis occurs due to cross-sectional imaging performed for other reasons. In most cases, iCCA is diagnosed at advanced stages where symptoms such as weight loss, malaise, abdominal discomfort, or jaundice are present. Pathologic diagnosis of iCCA is based on the World Health Organization (WHO) criteria. Differential diagnosis should be established with metastatic adenocarcinoma and mixed iCCA-HCC tumors, which may require evaluation of markers such as Hep-Par-1, GPC3, HSP70, and glutamine synthetase markers. Imaging studies with CT/MRI are not accurate enough to establish iCCA noninvasive diagnosis. Dynamic CT scanning characterizes 80% of iCCAs as liver mass-forming tumors with progressive contrast uptake from the arterial to the venous/delayed phase. MRI dynamic images also show peripheral enhancement in the arterial phase followed by progressive filling in of the tumor. Atypical radiologic behavior with arterial enhancement recapitulating HCC occurs in 10% of cases. MRI with cholangiopancreatography is useful to visualize the ductal system and vascular structures. Guidelines do not recommend PET scan for diagnosis. Tumor biomarker CA 19-9 at a cutoff level of 100 U/mL has prognostic significance but lacks accuracy (sensitivity and specificity of ~60%) for early diagnosis.

Radiologic criteria are inadequate for iCCA diagnosis in cirrhotic patients. However, in noncirrhotic patients, guidelines endorse a presumed diagnosis of iCCA (i.e., venous phase contrast enhancement on dynamic CT/MRI) if resection is considered. Assessment of disease

extent (venous or arterial invasion and extrahepatic disease) and resectability is best accomplished with CT and/or MRI studies. Doppler ultrasound is accurate in defining vascular invasion. Before surgery, PET scanning may be considered to rule out an occult primary or metastatic site.

Staging System The staging system for iCCA resected cases is based on the TNM staging as per the eighth edition of the AJCC/International Union Against Cancer (UICC) staging. T1 tumors are solitary without vascular invasion and can be divided into T1a or T1b if tumor size is ≤5 cm or >5 cm, respectively; T2 disease includes multiple tumors (e.g., multifocal disease, satellitosis, intrahepatic metastasis) or presence of vascular invasion (microvascular or major vascular invasion); T3 tumors perforate the visceral peritoneum; and T4 disease includes tumors involving local extrahepatic structures by direct invasion. Regional lymph node metastasis in the hilar, periduodenal, and peripancreatic nodes is considered N1 disease, while distant spread is considered M1 disease. TNM stages IA, IB, II, and IIIA overlap with T status, whereas stage IIIB includes T4N0 or N1M0 disease and stage IV includes M1 disease.

TREATMENT

After adopting the TNM staging system, the International Liver Cancer Association (ILCA) guidelines for management of iCCA proposed a treatment algorithm **(Fig. 82-9)**, adapted and updated with the new treatment modalities accepted. Overall, most of the treatments endorsed have a modest level of evidence. Surgical resection represents the sole curative treatment option in 30–40% of patients, with a median survival of 51 months in properly selected candidates. In noncirrhotic individuals, the best candidates for resection are patients at TNM stage I–II, whereas in patients with cirrhosis, liver function should be assessed as previously described for HCC. Preoperative disease assessment should discard vascular invasion, N1, and M1. Lymphadenectomy of regional nodes is recommended given its prognostic value. The main predictors of recurrence (~50–60% at 3 years) and survival are identified at the pathologic examination, including presence of vascular invasion, lymph node metastases, and poor differentiation. A phase 3 trial (BILCAP trial) including all types of CCA in a prespecified per-protocol analysis reported improved survival with adjuvant therapy (53 months vs 36 months; adjusted HR 0.75). Based on this trial, American Society of Clinical Oncology guidelines recommend adjuvant capecitabine for a period of 6 months. Other adjuvant regimens, such as gemcitabine monotherapy or a combination of gemcitabine and oxaliplatin, did not improve OS. Liver transplantation remains controversial, and few studies have reported good outcomes for single tumors ≤2 cm.

Nonsurgical candidates have a dismal life expectancy. Overall, patients at stage III might be considered for locoregional therapies, such as chemoembolization or radioembolization, but the level of evidence is low and is mostly based on cohort studies. A meta-analysis of 14 trials testing locoregional therapies reported median survival times of 15 months. External-beam radiation therapy is not recommended as standard therapy. At more advanced stages (stage IV) in patients with an ECOG of 0–1, systemic chemotherapy with the combination of gemcitabine and cisplatin is considered the standard of practice, yielding median survival times of 11.7 months compared to 8 months

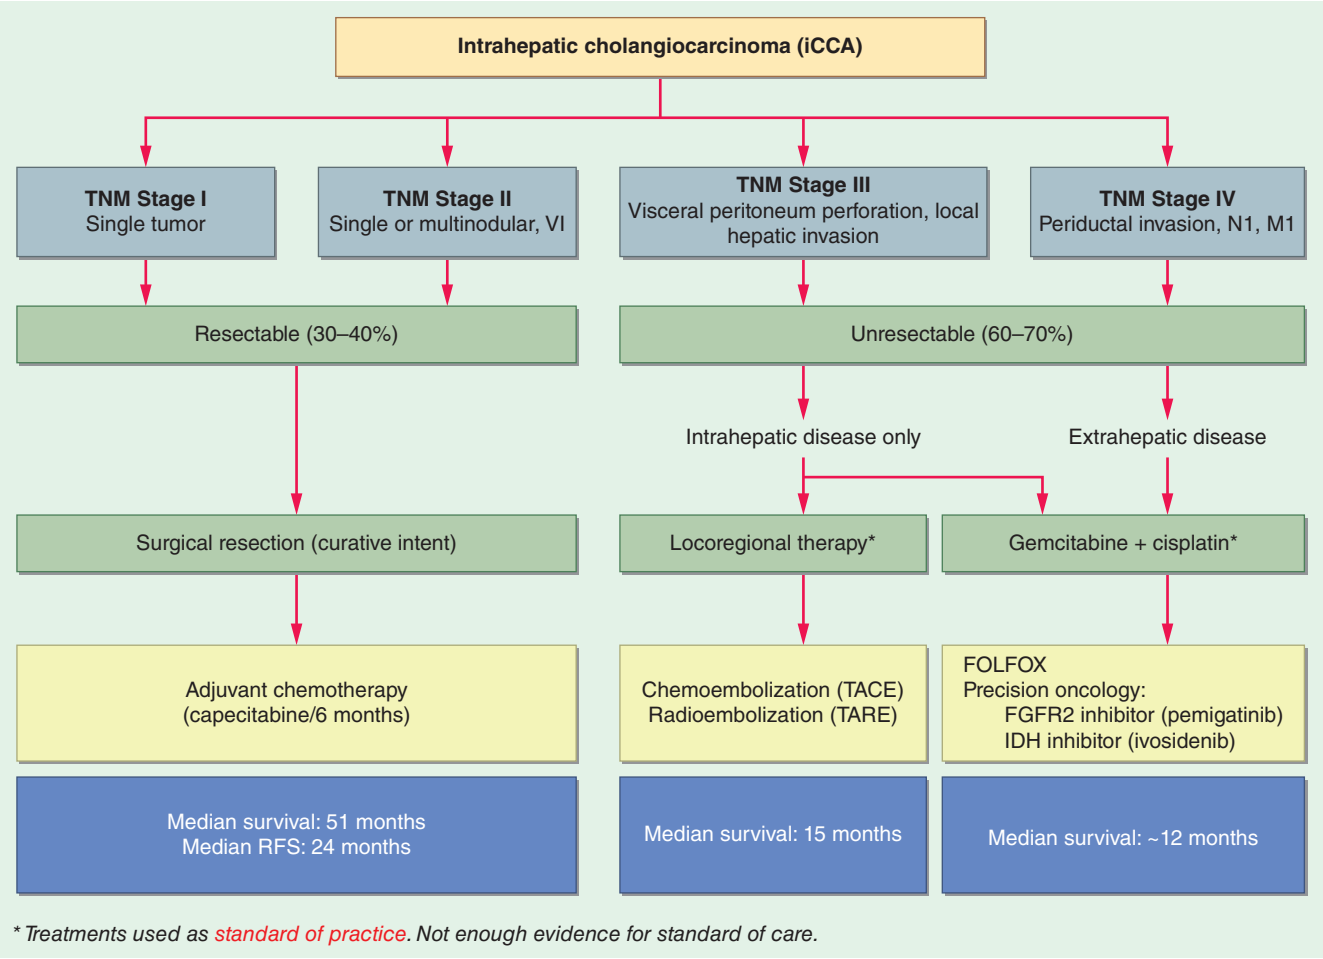

FIGURE 82-9 Staging and treatment schedule for intrahepatic cholangiocarcinoma (iCCA) proposed by the International Liver Cancer Association. FOLFOX, leucovorin, fluorouracil, and oxaliplatin; RFS, recurrence-free survival; TACE, transcatheter arterial chemoembolization; TARE, transarterial radioembolization; TNM, tumor-node-metastasis. *(Reproduced with permission from J Bridgewater et al: Guidelines for the diagnosis and management of intrahepatic cholangiocarcinoma. J Hepatol 60:1268, 2014.)*

for gemcitabine alone. This recommendation for first-line treatment of advanced tumors is based on a subgroup analysis of 80 iCCA patients included in a large randomized phase III trial (n = 410, ABC-02 Trial) of patients with advanced biliary tract tumors. In the second-line setting, a phase 3 study randomized patients who had progressed on cisplatin and gemcitabine to mFOLFOX (leucovorin, fluorouracil, and oxaliplatin) versus best supportive care. The chemotherapy regimen showed an improvement in median OS to 6.2 months (adjusted HR 0.69).

Two molecular targeted therapies have been approved in the second-line setting in iCCA patients with *IDH1/2* mutations or *FGFR2* aberrations. A phase 3 trial compared ivosidenib, an IDH-1 inhibitor, versus placebo; ivosidenib improved progression-free survival (2.7 vs 1.4 months; HR 0.37) and OS. A single-arm phase 2 study assessing pemigatinib (FGFR2 inhibitor) in iCCA patients with *FGFR2* fusions showed a median survival of 21 months and an objective response rate of 35%.

Mixed HCC-iCCA is a rare neoplasm accounting for <0.5% of all primary liver cancers. Diagnosis is based on pathology. The 2010 WHO classification defined two subtypes: the classical and the stem cell feature type. Molecular data have defined a third unique entity, cholangiocellular carcinoma, with distinct molecular traits and better outcome. Due to its low incidence, the demographic features and clinical behavior of these tumors remain ill-defined. Survival and management are similar to iCCA.

EXTRAHEPATIC CHOLANGIOCARCINOMA

Perihilar and Distal Cholangiocarcinoma The eighth edition AJCC/UICC TNM staging classification has established pCCAs as tumors that arise between the second-order bile ducts up to the insertion of the cystic duct, whereas dCCAs arise from this point to the ampulla of Vater (Fig. 82-7). Thus, dCCA can be difficult to distinguish from early pancreatic cancer. Both entities have a similar diagnostic approach. Acute onset of painless jaundice occurs in 90% of patients with pCCA, and 10% present with cholangitis. Primary biliary cholangitis with a cutoff for CA 19-9 >129 U/mL is suspicious for CCA. Imaging assessment starts with CT and MRI; they have a good sensitivity and specificity (>85%) for detecting the degree of bile duct involvement and hepatic and portal vein invasion. MRI cholangiography is optimal for defining the extent of the bile duct lesion. Ruling out IgG4 cholangiopathy by assessing serum IgG4 is mandatory. As a second step, endoscopic retrograde cholangiography with brushing to explore cytology and fluorescence in situ hybridization (FISH) for exploring polysomy are recommended. FISH enhances the sensitivity of cytology from 20 to ~40%.

Diagnosis is based on pathology. The treatment algorithm for pCCA indicates that in cases of a dominant stricture with positive cytology/biopsy or polysomy, a lymph node biopsy via endoscopic ultrasound should be obtained. pCCA with negative lymph node involvement is best treated by surgery, resection, or transplantation, the sole curative options. Staging laparoscopy is recommended to exclude metastatic disease before surgery; metastases occur in 15% of cases. Resection entails hepatic and bile duct removal and Roux-en-Y-hepaticojejunostomy with regional lymphadenectomy. Bilobular involvement is considered a surgical contraindication. Perioperative mortality is as high as 10%, mostly as a result of liver failure. In a few referral centers, unresectable single pCCA <3 cm without dissemination can be considered for liver transplantation with neoadjuvant chemoradiation. This procedure is associated with 5-year survival rates of ~70%. If lymph node involvement is present, systemic chemotherapy can be considered along with biliary tract stenting. Surgical resection (Whipple procedure) is the primary option for management of dCCA, a procedure that achieves a median survival of 2 years and 5-year survival rates of ~25%. Main contraindications for resection are presence of distant lymph node involvement, metastases, or major vascular invasion. At the pathologic examination, perineural invasion, lymph node metastasis, R0 resection (absence of residual tumor at pathologic examination), and tumor differentiation are predictors of survival. Adjuvant therapy with capecitabine for 6 months is accepted based on the BILCAP study. Consensus statements endorse first- and second-line chemotherapy strategies for unresectable eCCA similar as for iCCA. No molecular targeted therapies are available for these entities.

GALLBLADDER CANCER

Gallbladder cancer is the most common cancer of the biliary tract worldwide. The estimated cases of gallbladder cancer in the United States in 2020 were 11,980, more than CCA. The female-to-male ratio is 3:1. Cholelithiasis is the major risk factor, but <1% of patients with cholelithiasis develop this cancer. Gallbladder polyps at risk of transformation are those ≥10 mm in diameter. Early cases are discovered incidentally at routine cholecystectomy. Clinical symptoms, such as jaundice, pain, and weight loss, are associated with advanced stages. Staging of gallbladder cancer follows the TNM classification. The most accurate technique to define staging and vascular and biliary tract invasion is magnetic resonance cholangiopancreatography. CT and PET scans can be also useful for preoperative staging.

The mainstay of treatment is surgical, either simple or radical cholecystectomy (partial hepatectomy and regional lymph node dissection) for stage I or II disease, respectively. Only ~20% of patients are candidates for surgery with curative intent. Survival rates are near 80–90% at 5 years for stage I disease and range from 60 to 90% at 5 years for stage II disease. Regional nodal status and the depth of tumor invasion (T status) are the two most important prognostic factors. Adjuvant therapy with capecitabine is recommended in R0 cases. Gallbladder cancers at stage III and IV are considered unresectable. For patients with ECOG of 0–1, chemotherapy with gemcitabine and cisplatin is the standard of practice based on data from the subgroup analysis including 181 patients with gallbladder cancer in the setting of two clinical trials. Overall, median survival is 10–12 months in advanced cases. Percutaneous transhepatic drainage is indicated in case of biliary obstruction. Radiotherapy is not effective.

OTHER MALIGNANT LIVER TUMORS

FIBROLAMELLAR HEPATOCELLULAR CARCINOMA

Fibrolamellar hepatocellular carcinoma (FLC) is a rare form of primary liver cancer that typically affects children and young adults (10–30 years of age) without background liver disease. FLC accounts for 0.85% of all primary hepatic malignancies in the United States, and its incidence rate is 0.02 cases per 100,000 inhabitants. FLC is considered a unique entity with a specific fusion oncogene *PRKACA-DNAJB1* present in 80–100% of cases. A few mutations have been described, all at a level of <10%. FLC has a better prognosis than HCC, probably due to the absence of cirrhosis and the earlier age of presentation. Surgical resection is the mainstay of treatment, and indications are less restrictive than for HCC. A retrospective series of 575 FLC cases reported a median survival of 70 months after resection. At advanced stages, the expected outcome is <20 months. Chemotherapy is not effective, and there is no standard of care.

HEPATOBLASTOMA

Hepatoblastoma (HB) is the most frequent primary liver tumor in children. The incidence of the disease is 1.5 cases per 1,000,000. Background liver disease is rare in these patients. WNT signaling plays a major role, with *CTNNB1* mutations (70%) as the most frequently reported molecular event. Overexpression of IGF2 and genes in the 14q32 *DLK1/DIO3* locus are also prevalent. Resection followed by chemotherapy with doxorubicin is the mainstay treatment strategy. A study including 1605 patients randomized in eight clinical trials reported better outcome for patients with stage I–II of the PRETEXT (Pretreatment Extent of Tumor) classification (out of four stages), age <3 years, AFP >1000 ng/mL, and absence of metastases. As opposed to HCC, low AFP indicates poor prognosis. The best candidates (stage I or II with small tumors, age <3 years, and AFP >100 ng/mL) achieve 5-year disease-free survival after resection of 90%, compared with 5-year disease-free survival of 20–30% in the worst candidates (metastatic disease and AFP <100 ng/mL).

BENIGN LIVER TUMORS

The most common benign liver tumors are hemangiomas, focal nodular hyperplasia (FNH), and hepatocellular adenomas (HCA). Most benign tumors are identified incidentally by abdominal ultrasound or other imaging techniques. *Hemangiomas* are present in ~5% of the general population and are diagnosed by ultrasound, except in cirrhotic patients or oncology patients in whom contrast-enhanced imaging (contrast-enhanced ultrasound, CT, or MRI) is required. Conservative management is appropriate and follow-up is not recommended. Exceptionally, growing lesions causing symptoms by compression can be considered for resection. FNH is a benign tumor present in <2% of the population and occurs mostly in females aged 40–50 years. FNH is a polyclonal hepatocellular proliferation due to an arterial malformation. MRI has the highest diagnostic accuracy with a specificity of 100% when typical imaging features are present (homogeneous enhancement in the arterial phase with a central scar). Atypical FNH requires biopsy for diagnosis. Treatment is not recommended since these tumors do not degenerate or cause complications. In exceptional cases of expanding symptomatic lesions, surgery is the treatment of choice.

Hepatic adenomas are clonal benign proliferations resulting from single-gene driver mutations. HCAs have a low prevalence of 0.001% of the population and are frequently diagnosed in women aged 35–40 years. The female-to-male ratio is 10:1, and the main risk factors are oral contraceptives in females and use of anabolic androgenic steroids in male body builders. HCAs have the potential for hemorrhage and HCC development, particularly when >5 cm. Molecular classification of HCA is defined as follows: (1) HCA with *CTNNB1* mutations (10–20%) are at risk of HCC development and are present in men treated with androgens; (2) inflammatory adenomas (50–60%) are associated with single mutations (*Gp130*: 65%) and are more prevalent in females with obesity or diabetes; and (3) adenomas with inactivated *HNF1A*. Diagnosis is based on MRI, which correlates with molecular subtypes in 80% of cases (inflammatory and HNF-1A type). For defining HCA with *CTNNB1* mutations, biopsy is required. Upon diagnosis, discontinuation of oral contraceptives and weight loss are recommended. Resection is indicated in all cases of >5 cm, in men, or in those with *CTNNB1* mutation. For HCA <5 cm, 1-year follow-up is recommended. In case of active HCA bleeding, embolization followed by resection is the treatment of choice. The presence of multiple HCAs is common, and guidelines endorse treating them based on the size of the main nodule.

83 Pancreatic Cancer

Daniel D. Von Hoff

Pancreatic cancer is the third leading cause of death from cancer in the United States, with >57,000 Americans diagnosed and >47,000 dying from the disease each year. Unfortunately, pancreatic cancer is projected to be the second leading cause of death from cancer in the United States by 2030. Worldwide, pancreatic cancer is the eleventh most common cancer with 458,000 new patients diagnosed and >432,000 deaths (seventh cause of cancer deaths). Pancreatic cancer currently has the worst survival rate of any cancer with an overall 5-year survival (regardless of stage) of ~8.2%. However, that situation is changing. In particular, (1) knowledge about specific molecular subsets of the disease has become crucial to provide the best possible care for patients, and (2) the application of treatment that improves survival for patients with advanced disease used either after surgery or even earlier in the disease has improved survival.

EPIDEMIOLOGY

Pancreatic cancer accounts for 3.2% of all new cancer cases in the United States and for 7.8% of all deaths from cancer in the United States. The lifetime risk of developing pancreatic cancer is ~1.7%. The incidence of pancreatic cancer has been increasing about 1.03% per year. Pancreatic cancer is more common with increasing age and more common in men than in women. The 5-year survival rate for all stages has only increased from 3% in 1975 to 9% in 2015. The latest information from the U.S. Surveillance, Epidemiology, and End Results (SEER) database predicts that the 5-year survival for patients with localized pancreatic cancer is about 37%, 12% for those with regional disease, and 3.1% for patients with advanced metastatic disease. Pancreatic cancer is more common in developed countries (although generally it tracks with the prevalence of smoking). The incidence is highest in Western Europe and North America followed by other areas in Europe, Australia, New Zealand, and South-Central Asia. The population at greatest risk are women living in Scandinavian countries, while the lowest risk is seen for women living in middle Africa.

RISK FACTORS

Age is one of the greatest risk factors for pancreatic cancer with median age at diagnosis of 70 years (the disease is most frequently diagnosed in the 65–79 age group; for men, 65–69; for women, 75–79). The number of new cases per 100,000 persons and the number of deaths per 100,000 persons are higher for males and for blacks of both sexes. Both the number of cases and the number of deaths per 100,000 people are lower for American Indian/Alaskan natives and Asian Pacific Islanders. Both the number of cases and deaths are intermediate for the Hispanic population. People who have a non-O blood type are at higher risk of developing pancreatic cancer.

Environment The greatest risk factor for pancreatic cancer is cigarette smoking. The risk correlates with the increased number of cigarettes smoked and persists for at least 10 years after smoking cessation. About 30% of pancreatic cancer is caused by smoking. Exposure to cadmium as part of cigarette smoking or via exposure to welding,

soldering, or dietary exposure has been weakly associated with an increased risk of pancreatic cancer.

Although dietary factors are often difficult to interpret, high intakes of fat or meat (particularly well-done barbequed meat) are risk factors. High intakes of citrus fruits and vegetables are associated with a decreased risk. Coffee and low-to-moderate alcohol consumption are not associated with an increased risk for pancreatic cancers, while consumption of sugary carbonated drinks has been associated with an increased risk.

Microbiome To date, no solid evidence links *Helicobacter pylori* infection and pancreatic cancer. Some data link the oral microbiome associated with poor dentition to pancreatic cancer, but the evidence is very thin.

Hereditary/Genetics Hereditary factors may account for 10–16% of all pancreatic cancers. Family members of patients with pancreatic cancer should seek participation in an early detection program with genetic counseling, definition of risk, and if appropriate, periodic MRI screening of the abdomen, although this recommendation is not yet based on research data. In addition, the identification of any pancreatic cancer–associated germline mutations could lead to specific and effective new therapeutics for patients with these abnormalities in their tumors. Table 83-1 identifies the various germline mutations along with their familial cancer syndromes where an increased risk for pancreatic cancer is known.

Knowing the patient has a *BRCA2* or *PALB2* germline mutation or any of the above mutations should lead one to not only refer the patient's relatives to an early detection or high-risk individual clinic but also realize that for patients with a *BRCA2/PALB2* germline mutation consideration for treatment with a poly (ADP-ribose) polymerase (PARP) inhibitor should be considered (see below). Other germline mutations are under study to determine their increased risk of pancreatic cancer, including *CFTR, PRSS2, CDK4, FANCC, PALLD, APC, ATM, BMPR1A, BRCA1, EPCAM, MEN1, MLH1, MSH2, MSH6, NF1, PMS2, SMAD4, TP53, TSC1, TSC2,* and *VHL*. Some of these mutations are associated with pancreatic neuroendocrine tumors (Chap. 84).

In addition to the recognized genetic syndromes, other possible familial pancreatic cancer genes have not yet been discovered. For example, a family history of pancreatic cancer is associated with a 13-fold increase in the disease. If you have one first-degree relative, the risk is increased 4.6-fold, having two first-degree relatives increases the risk 6.4-fold, and three or more first-degree relatives confers a 32-fold increased risk. The risk is also increased if a relative developed pancreatic cancer at <55 years old.

TABLE 83-1 Germline Mutations, Their Familial Cancer Syndrome, and Fold Risk of Pancreatic Cancer

GERMLINE MUTATION	FAMILIAL CANCER SYNDROME	ESTIMATED INCREASED RISK (FOLD) OF PANCREATIC CANCER
BRCA2[a]	Familial breast/ovarian cancer	2–6
PALB2 (partner and localizer of *BRCA2*)	Familial breast cancer and others	~sixfold
p16/CDKN2A	Familial atypical multiple mole melanoma (FAMMM)	15–18
STKII (*LKB1*)	Peutz-Jeghers syndrome	76–140
PRSS1 or *SPIN11*[b]	Hereditary (familial) pancreatitis	53
ATM	Ataxia-telangiectasia	Not yet established
MLH1, MSH2, MSH6, PMS2	Heredity nonpolyposis colorectal syndrome or Lynch syndrome[c]	9–30

[a]Particularly common in individuals with Ashkenazi Jewish heritage. [b]Forty percent chance of pancreatic cancer by the age of 70. [c]Very important because this is associated with microsatellite instability, which is a marker for response to an anti-PD-1/PD-L1 agent.

Other Considerations Most patients with pancreatic cancer relate that they have had developing symptoms over the past few years. Thus, early detection of the disease is possible when the index of suspicion is high.

Medical Conditions Chronic pancreatitis that is nonfamilial is also associated with an increased risk of pancreatic cancer (2.3–16.5-fold increase). Risk is also increased in people with chronic pancreatitis associated with cystic fibrosis or tropical pancreatitis.

A clear association exists between diabetes mellitus (both type 1 and type 2) and pancreatic cancer. Whether this is a causal association or whether the diabetes is the result of the cancer is not exactly clear. What is clear is that when a person presents with new-onset type 2 diabetes, they should be considered at risk for having pancreatic cancer. The excessive insulin or insulin-like growth factors associated with adult-onset diabetes and metabolic syndrome may promote pancreatic carcinogenesis.

Obesity is considered a possible risk factor for pancreatic cancer. A high body mass index (BMI) ≥30 is associated with a doubling of the risk of pancreatic cancer. Since obesity is a risk factor for diabetes, the contribution of obesity alone is unclear. Interestingly, patients with severe obesity who undergo a gastric bypass experience a reduction in the incidence of gastrointestinal (GI) cancer, including pancreatic cancer, by >30% in the first 3 years (along with a dramatic decrease in their hemoglobin A_{1c} and blood glucose). Physical inactivity also has been associated with an increased risk in pancreatic cancer.

PATHOLOGY AND MOLECULAR CONSIDERATION

Location The posterior location of the pancreas in the abdomen is likely one of the issues that leads to a late diagnosis (Fig. 83-1*A*).

Pathology Cancers of the pancreas can be divided into neoplasms of the endocrine pancreas (Chap. 84) and tumors of the exocrine pancreas. The most common neoplasm of the exocrine pancreas and most deadly is pancreatic infiltrating ductal adenocarcinoma. These tumors arise in the head, body, or tail of the pancreas and are characterized by infiltrating desmoplastic stromal reactions (Fig. 83-1*B*).

Other subtypes of nonneuroendocrine pancreatic cancers include acinar cell carcinoma (tumors of the exocrine enzyme producing cell), medullary carcinoma, adenosquamous carcinoma, and other rare subtypes. Each of these is different in behavior and in their molecular characteristics and often requires other specific types of treatment.

Molecular Characteristics The molecular characteristics of pancreatic ductal adenocarcinoma reveal four genes that are commonly mutated or inactivated (sometimes referred to as the "four horsemen"). The most common is *KRAS* (usually in codon 12). It is critical to determine the specific mutation in *KRAS* because specific mutations may indicate specific therapies that should be considered. *KRAS* mutations are seen in virtually 100% of pancreatic adenocarcinomas. In fact, with the deep sequencing now available, if a *KRAS* mutation is not detected in the patient's tumor, one should consider that the tumor is likely of a different origin (e.g., small bowel, gallbladder, or cholangiocarcinoma—all of which could require different treatments). *p16/CDKN2A* is also noted in >90% of invasive pancreatic adenocarcinomas. *TP53* and *DPC4/MADH4* are mutated in about half of these tumors. As a reference point, the *BRCA2* gene noted in Table 83-1 is mutated in 7–10% of pancreatic adenocarcinomas.

Precursor Lesions Many pancreatic adenocarcinomas seem to arise from noninvasive epithelial precursor lesions. Detection of these could allow for early diagnosis of pancreatic cancer. These pancreatic intraepithelial neoplasias (PanINs) have varying degrees of dysplasia designated as PanINs 1–3 (and constitute a progression model for pancreatic cancer). Genetic alterations become more frequent as the PanIN grade increases (e.g., grade 3). Not all PanIN lesions progress to invasive malignancy. PanINs that are ≥1 cm are called *intraductal papillary neoplasms* and are usually noninvasive. If the intraductal tumor is in a branch duct, it is usually noninvasive; however, if the intraductal tumor is in a main duct and is large and nodular, it is more likely to have malignant behavior.

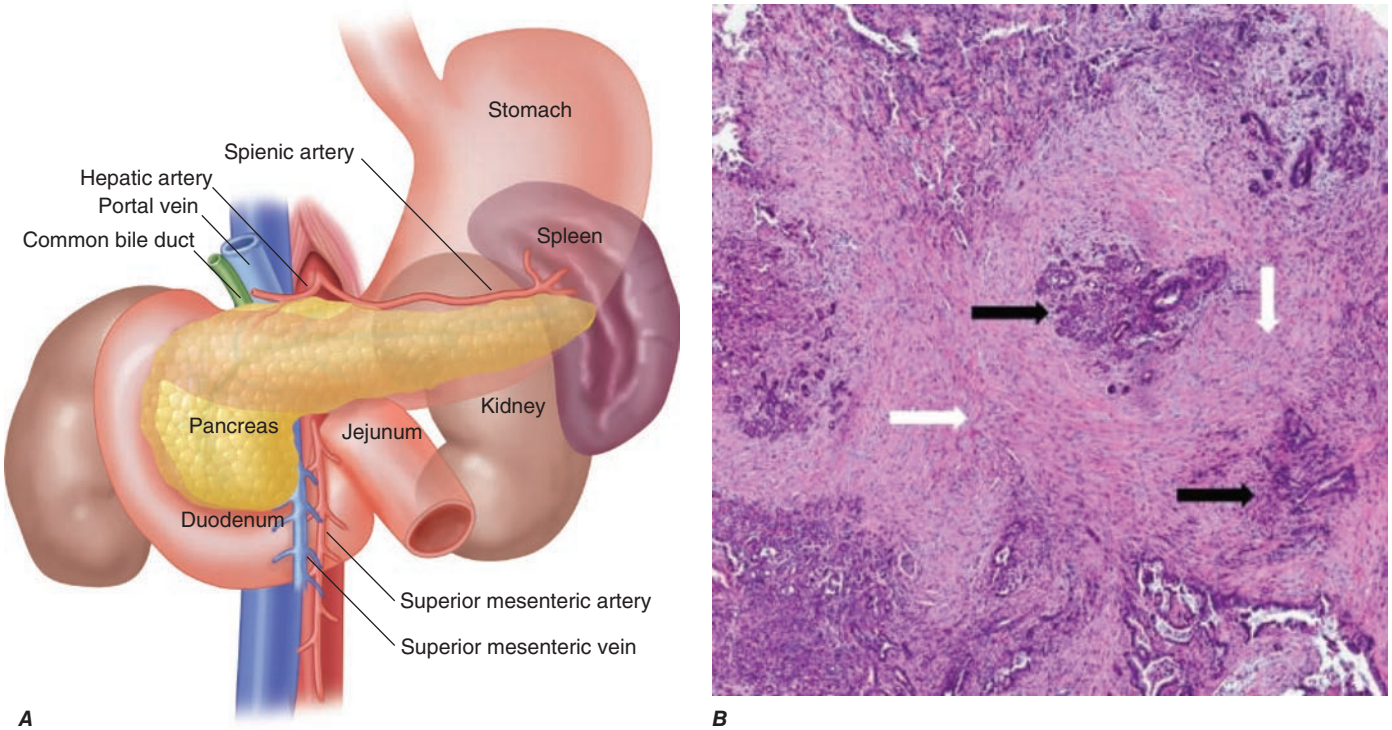

FIGURE 83-1 ***A.*** Note the relationship of the pancreas to the major vessels of the retroperitoneum. ***B.*** Ductal adenocarcinoma of the pancreas (*black arrows*), with intense stromal component (*white arrows*). *(Part A is courtesy of Mary Kay Washington, MD, PhD, Vanderbilt University. Part B is courtesy of Haiyong Han, PhD, Translational Genomics Research Institute [TGen].)*

One other pancreatic tumor is the mucinous cystic neoplasm; they may be seen as incidental findings on scans. These lesions are less likely invasive (20%) unless they are large and have nodules in them.

CLINICAL FEATURES

History and Physical The classic presentation for a patient with pancreatic cancer has been abdominal pain and weight loss with or without jaundice. The pain is midepigastric (sometimes described as a "boring-like" pain). Often the pain is in the back (due to retroperitoneal invasion of the splanchnic nerve plexus). The pain may be exacerbated by eating or lying flat. Other items of note in a history are light stool color from the absence of bile (steatorrhea also causes malodorous stools) and the onset of diabetes in the prior year. Jaundice, first detectable with a bilirubin of 2.5–3.0 mg/dL, is usually associated with tumor in the head of the pancreas. In some instances, depression is noted (with a higher subsequent number of suicides). Pruritis may be seen when the bilirubin reaches 6–8 mg/dL.

Physical signs include jaundice, signs of weight loss, a palpable gallbladder (Courvoisier's sign), hepatomegaly, an abdominal mass, and even an enlarged spleen (usually indicating a portal vein thrombosis). Migratory superficial thrombophlebitis can also be seen (Trousseau's syndrome). Signs of late disease include a lymph node palpable in the supraclavicular fossa (usually on the left where the thoracic duct enters the subclavian vein). This is clinically referred to as Virchow's node. Occasionally, one can palpate subcutaneous metastases in the periumbilical area referred to as a Sister Mary Joseph's node—named after one of the scrub nurses on the Mayo Clinic Operative Team who noted that when she prepped that area and felt those nodules, the patient often had peritoneal metastases.

The history and symptoms noted above may lead a person to see a physician; often CT and MRI scanning detects the disease before advanced disease symptoms appear.

DIAGNOSTIC WORKUP

Imaging Diagnostic imaging plays a major role in diagnosing pancreatic cancer and other intraabdominal diseases. The best technique is the use of a dual-phase contrast-enhanced spiral CT using the pancreatic cancer protocol, which allows arterial phase enhancement and portal venous phase enhancement. This special protocol can provide helpful prospective staging and assessment of resectability. **Figure 83-2** demonstrates such a CT scan (with vascular involvement). **Figure 83-3** demonstrates the use of an 18F glucose positron emission tomography (PET) scan.

Histologic Diagnosis A histologic (tissue) diagnosis is essential and should be obtained with a cutting biopsy needle (not a skinny needle with cytology). Misdiagnosis is more common based on only fine-needle aspirates. Obtaining a tissue diagnosis allows not only for accuracy but also for molecular testing for *KRAS* mutations, microsatellite instability, and other important molecular abnormalities. Those molecular abnormalities and others will be increasingly important as more targeted therapies are developed for patients with pancreatic cancer.

The core needle (16–18 gauge) biopsy can be obtained via endoscopic ultrasound-guided techniques for a tumor localized to the pancreas or, if there are liver lesions or Virchow's node, via percutaneous biopsy by interventional radiologists.

Serum Markers Before treatment, a serum sample should be obtained for levels of CA19-9, carcinoembryonic antigen (CEA), or if both are negative, for CA125 (can be positive when the CA19-9 is negative due to the patient not being a Lewis antigen secretor). These markers are not useful for staging but can be useful in following the course of pancreatic cancer.

IMPORTANT IMMEDIATE CONSIDERATIONS IN PATIENT CARE

While the patient is being evaluated and staged, one must be alert for biliary tract obstruction (and the attendant risk for sepsis from the biliary tree). A stent can be placed (plastic if temporary or metal if needed longer) to relieve the jaundice and pruritus. If surgery is being contemplated, an early surgical consultation is in order as some surgeons may want to proceed to surgery without placement of a stent. This immediate surgical approach is becoming less common as many multidisciplinary teams want consideration of use of chemotherapy

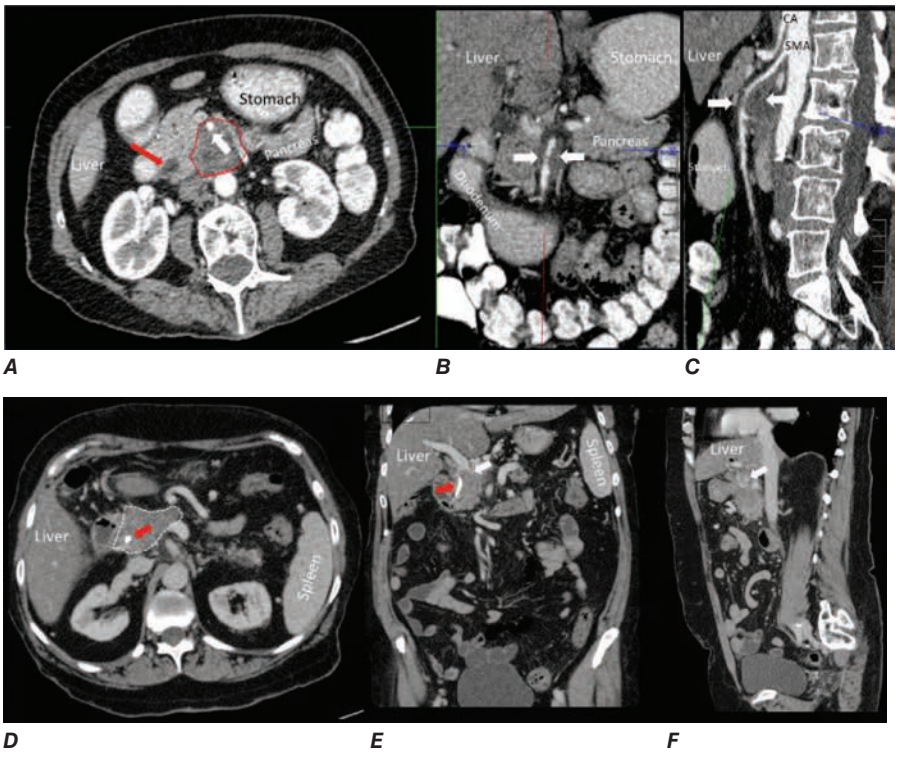

FIGURE 83-2 Selected images from contrast-enhanced CT in patients with locally advanced adenocarcinoma of the pancreas. A high-quality contrast-enhanced CT scan (arterial phase in panels ***A–C*** and portal venous phase in panels ***D–F***) is required for optimal staging of pancreas cancer. Panel ***A*** demonstrates the typical features of adenocarcinoma of the pancreas on arterial phase axial CT scans (*dotted outline*) with tumor encasement of the superior mesenteric artery (*white arrow*). Note the dilatation of the common bile duct (*red arrow*). Panels ***B*** (magnified coronal) and ***C*** (sagittal) show reconstruction of CT images into additional orthogonal planes with exquisite details to confirm the unresectable nature of the tumor due to vascular encasement. Panel ***D*** demonstrates the typical features of adenocarcinoma of the pancreas on portal venous phase axial CT scans in a different subject. The dotted line outlines a pancreas cancer lesion in the pancreatic head, which is encasing the portal splenic confluence (*dotted outline*). Panels ***E*** (*white arrow*) and ***F*** show the pinched appearance of the portal splenic confluence by tumor abutment and invasion of the superior mesenteric vein (*white arrow*) on coronal and sagittal views. Note the presence of a stent in the common bile duct (*red arrow*) to help relieve biliary obstruction caused by the tumor. CA, celiac axis; SMA, superior mesenteric artery.

with or without radiation therapy (called neoadjuvant therapy) before a patient is taken to surgery.

Patients with pancreatic cancer are often hypercoagulable and frequently have migratory thrombophlebitis (Trousseau's sign) as well as deep vein thrombosis with pulmonary emboli (a frequent cause of death). Appropriate examinations plus being alert to thromboses on the routine workup are mandatory so appropriate management can be put in place.

Control of pain or of any symptoms should be pursued to help patients be as comfortable as possible for their decision-making. Sometimes simple approaches like the use of a replacement pancreatic enzyme (at good therapeutic doses) can relieve the bloating, cramping, and diarrhea. Early involvement of a palliative care team can improve a patient's quality of life and sometimes even its length.

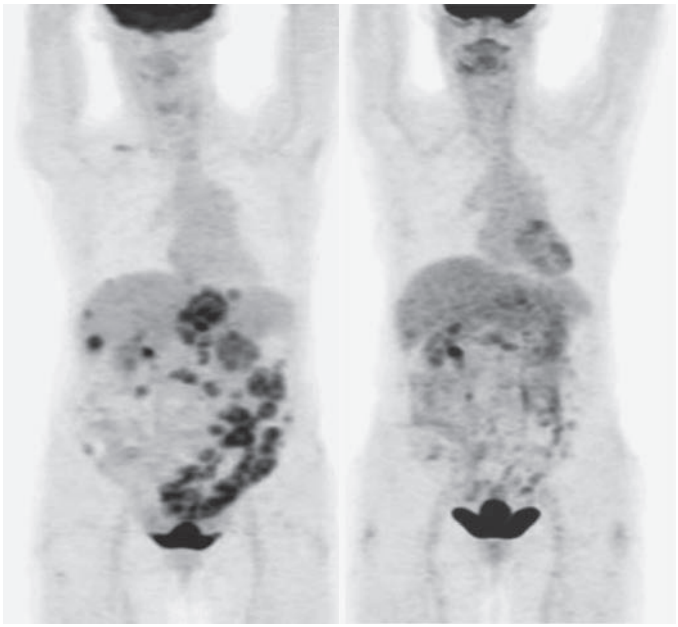

FIGURE 83-3 PET scan demonstrating metastatic disease—baseline and after 6 weeks of chemotherapy with some resolution of liver metastases.

CLINICAL STAGING

The clinical staging of pancreatic cancer according to the American Joint Commission on cancer staging is presented in Table 83-2.

Table 83-3 presents another clinical way to express extent of disease as well as therapeutic approaches (to be discussed later).

For proper staging, some physicians believe that a laparoscopy either before or at the time of surgery is important. If metastatic disease is found at laparoscopy, one can avoid surgery that would not be helpful because disease is already advanced.

TREATMENT

Resectable Disease

Even for patients with resectable disease, the patient should be presented to a combined-modality conference. Some clinicians feel the best approach for patients with resectable disease (as defined in Table 83-3) is surgery. Only a small percentage of patients are in this category (10–20%). Some clinicians feel neoadjuvant therapy (chemotherapy before surgery) should be given before surgery (for controlling potential micrometastatic disease and shrinking the primary tumor). The surgery for patients with tumors in the head or

TABLE 83-2 Definition of Primary Tumor (T)

T CATEGORY	T CRITERIA
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ This includes high-grade pancreatic intraepithelial neoplasia (PanIn-3), intraductal papillary mucinous neoplasm with high-grade dysplasia, intraductal tubulopapillary neoplasm with high-grade dysplasia, and mucinous cystic neoplasm with high-grade dysplasia
T1	Tumor ≤2 cm in greatest dimension
T1a	Tumor ≤0.5 cm in greatest dimension
T1b	Tumor >0.5 cm and <1 cm in greatest dimension
T1c	Tumor 1–2 cm in greatest dimension
T2	Tumor >2 cm and ≤4 cm in greatest dimension
T3	Tumor >4 cm in greatest dimension
T4	Tumor involves celiac axis, superior mesenteric artery, and/or common hepatic artery, regardless of size

uncinate body of the pancreas is usually a pylorus-sparing pancreaticoduodenectomy (a modified Whipple procedure). For tumors in the body or tail, a distal pancreatectomy is usually performed. Clinical and pathologic findings of the resection are defined as either an R0 resection (no macroscopic or microscopic disease left after surgery) or an R1 resection, which refers to residual disease likely left behind. Patients with smaller tumors and lymph node–negative disease have a better survival (median of about 18–23 months with 5-year survival of about 20%).

Two approaches are being explored to try to improve on this.

1. Postoperative adjuvant therapy. The standard of care is to use 24 weeks of adjuvant treatment with a modified folinic acid, 5-fluorouracil, irinotecan, and oxaliplatin (FOLFIRINOX) regimen. In the definitive clinical trial, the median survival was 54 months for the combination of modified FOLFIRINOX versus 35 months for gemcitabine alone (hazard ratio [HR] 0.64; 95% confidence interval [CI] 0.48–0.86; $p = .003$). Toxicities were manageable.
2. A newer approach is the use of neoadjuvant chemotherapy (chemotherapy given before surgery) to try to shrink the tumor and normalize the patient's serum CA19-9 level. Data suggest that patients who have borderline resectable/locally advanced disease can benefit from neoadjuvant therapy. Studies of neoadjuvant chemotherapy with or without radiation therapy are ongoing.

TABLE 83-3 Extent of Disease and Therapeutic Approach

DESIGNATION (MEDIAN SURVIVAL)	THERAPEUTIC APPROACHES
1. Resectable (localized): (18–23 mo) • No encasement of celiac axis or superior mesenteric artery (SMA) • Patent superior mesenteric—portal veins • No extrapancreatic disease	Surgical option (or preoperative-neoadjuvant therapy first) Surgery is followed by postsurgery adjuvant therapy • Currently mFOLFIRINOX
2. Locally advanced: (6–10 mo) • Encasement of arteries • Venous occlusion (superior mesenteric vein [SMV] or portal) • No extrapancreatic disease	Either chemotherapy or chemotherapy + radiation therapy
3. Metastatic: (8.3–12.8 mo)	Systemic chemotherapy

Abbreviation: mFOLFIRINOX, modified FOLFIRINOX (folinic acid, 5-fluorouracil, irinotecan, and oxaliplatin (T Conroy et al: N Engl J Med 379:2395, 2018).

LOCALLY ADVANCED DISEASE (30% OF PATIENTS)

For patients with locally advanced disease, the median survival is also quite poor (6–10 months) because many of the patients die with local problems (e.g., portal vein thrombosis with bleeding

varices, obstruction, sepsis). The approach has been to try to reduce the bulk of the disease with use of radiation therapy plus chemotherapy or chemotherapy alone, with the goal that the disease could become resectable. No standard therapy has been agreed upon, but experimental approaches are applying some of the treatments that show promise in advanced metastatic disease.

ADVANCED METASTATIC DISEASE (60% OF PATIENTS)

Only a few of the many phase 3 randomized trials in patients with advanced pancreatic cancer have led to meaningful increases in survival. We have learned that a regimen needs to have at least a 50% improvement in overall survival or 90% improvement in 1-year survival in a pilot phase 2 trial to predict for any degree of success in large randomized phase 3 trials.

Patients with the best chance of receiving a benefit from treatment have a good performance status (functioning up and around at least 70% of the day), have a reasonable albumin level (≥3.0 g/dL), and a neutrophil/lymphocyte ratio of ≤5.0.

Single-agent gemcitabine achieves a median survival of 6 months and a 1-year survival rate of 18%. **Table 83-4** details three combination regimens that have further improved survival modestly. Median overall survival still ranges from 6 to 11 months. However, 1-year survival is now approaching 35% for these combination regimens with some long-term 4+ year survivors.

Also of note in Table 83-4, liposomal irinotecan has U.S. Food and Drug Administration (FDA) approval in combination with 5-fluorouracil and leucovorin for patients whose tumors have progressed on gemcitabine (e.g., second-line therapy for stage IV disease) based on improved overall survival.

FOR PATIENTS WITH A SPECIFIC MOLECULAR PROFILE IN THEIR TUMOR/GERMLINE

PARP inhibitors have clinical activity against pancreatic cancers having mutations in *BRCA2, BRCA1*, or *PALB2* (i.e., defective DNA repair proteins). In addition, their tumors might be more sensitive to specific combinations of chemotherapy like gemcitabine plus cisplatin. In addition, tumors with microsatellite instability often have more mutations, and such tumors appear to have a higher response rate to immunotherapy with checkpoint inhibitors and anti-PD-1 (pembrolizumab, nivolumab) and anti-PD-L1 antibodies.

TABLE 83-4 Combination Chemotherapy Regimens That Have an Impact on Survival

STUDY DESIGN (AUTHOR/REF)	NO. OF PATIENTS	MEDIAN SURVIVAL (MONTHS)
Gemcitabine + erlotinib vs gemcitabine (Moore et al: J Clin Oncol 26:1960, 2007)	569	6.24 vs 5.91 (HR 0.82; 95% CI 0.69–0.99; $p = .038$)
FOLFIRINOX (folinic acid + 5-fluorouracil + irinotecan + oxaliplatin) vs gemcitabine (Conroy et al: N Engl J Med 364:1817, 2011)	342	11.1 vs 6.8 (HR 0.57; 95% CI 0.45–0.70; $p < .001$)
Nap-paclitaxel + gemcitabine vs gemcitabine, (Von Hoff et al: N Eng J Med 369:1691, 2013.)	861	8.5 vs 6.7 (HR 0.72; 95% CI 0.62–0.83; $p < .001$[a]
Nanoliposomal irinotecan + fluorouracil + folinic acid vs nanoliposomal irinotecan monotherapy vs fluorouracil + folinic acid (Wang-Gillam et al: Lancet 387:545, 2015)	417	6.1 vs 4.2 (HR 0.67; 95% CI 0.49-0.92; $p = .012$[b])

[a]The 2-year survival rate with this regimen is 9% and the 3+ year rate is 4%. Other studies have not reported on these parameters. [b]HR is for nanoliposomal irinotecan + 5-fluorouracil + folinic acid vs 5-fluorouracil + folinic acid.

Abbreviations: CI, confidence interval; HR, hazard ratio.

MAINTENANCE THERAPY FOR PATIENTS RESPONDING TO TREATMENT

For patients with germline *BRCA1* or *BRCA2* mutations whose disease has not progressed during a first-line platinum-based regimen, the PARP inhibitor olaparib has been shown to improve progression-free survival (7.4 vs 3.8 months; HR 0.53; 95% CI 0.35–0.82; $p = .004$) with no change in quality of life.

OTHER POTENTIAL FACTORS INFLUENCING SURVIVAL

Preclinical studies have suggested that vitamin D can inhibit the development and growth of cancer. In models of pancreatic cancer, synthetic analogues of vitamin D had an effect on both tumor cells and on the tumor microenvironment. Clinical studies are conflicting as to whether circulating levels of plasma 25-hydroxyvitamin D (25[OH]D) affect the incidence of pancreatic cancer. However, patients with prediagnostic levels of 25(OH)D that are in the normal range have a longer survival than those who have reduced levels (35% lower hazard for death).

FUTURE DIRECTIONS

Death from pancreatic cancer is often due to progressive inanition. The metabolic consequences of this cancer are being examined. The tumor can be fatal at a modest level of tumor burden based on the profound metabolic effects. Other promising areas of investigation include addressing the florid stromal reaction around the tumor cells (believed to act as a physical barrier to drug delivery and as an immune sanctuary for the tumor cells). Improvements in outcomes for pancreatic cancer would accompany earlier detection. A small decrease in the percentage of patients being diagnosed with stage IV pancreatic cancer has been noted. The reason for this encouraging sign is unknown. The 5-year survival for earlier stage patients has increased from 44.7% in 2004 to 83.7% in 2012. There is emerging evidence that the surveillance to detect *CDKN2A* mutation carriers can detect pancreatic ductal cancer at a resectable stage.

Acknowledgment

Thank you to Nicole Harkey, for assistance in the preparation of this chapter, and Drs. Elizabeth Washington, Ron Korn, and Haiyong Han and the American Joint Committee on Cancer for providing the figures and tables.

84 Gastrointestinal Neuroendocrine Tumors

Matthew H. Kulke

Gastrointestinal (GI) neuroendocrine tumors (NETs) can be broadly grouped according to their site of origin, as either extrapancreatic NETs, historically called carcinoid tumors, or pancreatic NETs. While NETs can pursue a broad range of clinical behaviors, they classically follow a course that is more indolent than many other malignancies. NETs also have the ability to synthesize peptides, growth factors, and bioactive amines that may be ectopically secreted, giving rise to a range of unique clinical syndromes.

INCIDENCE AND PREVALENCE

The diagnosed incidence of NETs has been steadily increasing over the past several decades **(Fig. 84-1)**. An analysis of data from the Surveillance, Epidemiology, and End Results (SEER) program, comprising population-based data in the United States from 1973 to 2012, showed that the incidence had increased 6.4-fold over this time period and that the estimated prevalence of patients who had been diagnosed with a NET was >170,000. This analysis also found that overall survival durations for patients with NETs had improved significantly. The increasing incidence and improved survival durations for patients with NETs likely reflect, at least in part, advances in both diagnosis and treatment. While environmental or other factors leading to an increased incidence of NETs cannot be excluded; common cancer risk factors such as tobacco or alcohol use and dietary patterns have not been clearly linked to NET development.

A minority of NETs develop in the context of autosomal inherited genetic syndromes associated with mutations in specific tumor-suppressor genes. The most common of these is multiple endocrine neoplasia type 1 (MEN 1), due to mutation and loss of function of the *menin* gene, located on chromosome 11q13 **(Chap. 388)**. Patients with MEN 1 are at risk for developing pancreatic NETs as well as hyperparathyroidism and pituitary adenomas; less commonly, they may develop bronchial and thymic NETs. Other inherited syndromes associated with NETs include von Hippel–Lindau disease (VHL), von Recklinghausen's disease (neurofibromatosis type 1), and tuberous sclerosis (Bourneville's disease). Inherited mutations in the VHL gene, located on chromosome 3p25, are associated with the development of cerebellar hemangioblastomas, renal cancer, and pheochromocytomas and, less commonly, pancreatic NETs. Mutations in neurofibromin (*NF1*) are associated with neurofibromatosis (von Recklinghausen's disease); patients with neurofibromatosis are at risk of developing both pancreatic and extrapancreatic NETs. Tuberous sclerosis is caused by mutations that alter either hamartin (*TSC1*) or tuberin (*TSC2*). Both hamartin and tuberin function as inhibitors of the phosphatidylinositol 3-kinase and the mechanistic target of rapamycin (mTOR) signaling cascades, and pancreatic NETs have been reported in these patients. Rare cases of familial small intestine NETs have also been reported; in these cases, multiple synchronous tumors generally arise within the small intestine. A characteristic inherited mutation, however, has not been identified to date in the majority of these cases.

HISTOLOGIC CLASSIFICATION AND MOLECULAR FEATURES

The histologic features of NETs vary widely and are one of the most important determinants of both clinical behavior and treatment. NETs are classified based on the degree tumor differentiation (well or poorly differentiated), as assessed by a pathologist, and tumor grade (grades 1–3) **(Table 84-1)**. Tumor grade closely correlates with mitotic count and Ki-67 proliferative index. Classic, well-differentiated NETs are composed of monotonous sheets of small round cells with uniform nuclei and only rare mitoses. Immunocytochemical staining for chromogranins and synaptophysin is typical. Ultrastructurally, these tumors contain electron-dense neurosecretory granules containing peptides and bioactive amines that may be ectopically secreted, giving rise to a range of clinical syndromes. These classic well-differentiated NETs have low-grade features and generally have a mitotic index of <2 mitoses per 10 high-power field (HPF) and a Ki-67 proliferative index of <3%. Less commonly, well-differentiated NETs have an intermediate histologic grade and pursue a somewhat more aggressive clinical course. These intermediate-grade tumors typically have a mitotic count of 2–20 per 10 HPF and a mitotic index of 3–20%. Well-differentiated high-grade tumors are rare and have mitotic counts that exceed 20 per 10 HPF and a Ki-67 proliferative index of >20%. Poorly

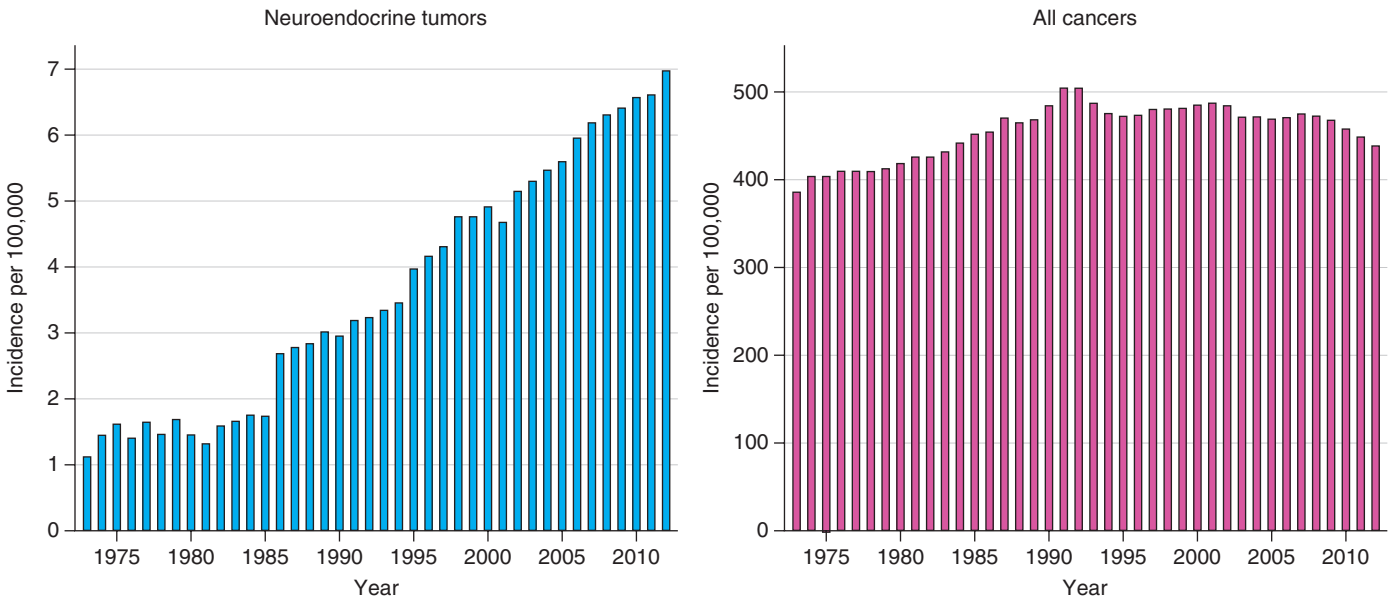

FIGURE 84-1 Incidence of neuroendocrine tumors (NETs). The incidence of neuroendocrine tumors has been increasing over the past several decades, an observation that has been attributed in part to improved diagnosis and classification. *(Adapted from A Dasari et al: Trends in the incidence, prevalence, and survival outcomes in patients with neuroendocrine tumors in the United States. JAMA Oncol 3:1335, 2017.)*

TABLE 84-1 Histologic Classification of Neuroendocrine Tumors

CLASSIFICATION	DIFFERENTIATION	GRADE	MITOTIC COUNT	KI-67
Neuroendocrine tumor	Well differentiated	Low grade (grade 1)	<2 per 10 HPF	<3%
Neuroendocrine tumor	Well differentiated	Intermediate grade (grade 2)	2–20 per 10 HPF	3–20%
Neuroendocrine tumor	Well differentiated	High grade (grade 3)	>20 per 10 HPF	>20%
Neuroendocrine carcinoma	Poorly differentiated	High grade (grade 3)	>20 per 10 HPF	>20%

Abbreviation: HPF, high-power field.

differentiated high-grade tumors form the most clinically aggressive category; prognosis and treatment for these tumors differ markedly from their well-differentiated counterparts.

Whole exome sequencing of sporadic pancreatic NETs found that the most frequently altered gene was *MEN1*, occurring in 44% of tumors. In addition, 43% of tumors had mutations in genes encoding two subunits of a transcription/chromatin remodeling complex consisting of DAXX (death-domain-associated protein) and ATRX (α-thalassemia/mental retardation syndrome X-linked). Mutations in genes associated with the mTOR pathway were identified in 15% of tumors. In contrast, recurrent mutations in extrapancreatic NETs appear to be rare. In one study that evaluated 180 small intestinal NETs using a combination of whole exome and more targeted genome-sequencing analysis, recurrent mutations were only observed in the *CDKN1B* gene (cyclin-dependent kinase inhibitor 1B [$p27^{Kip1}$]) in 8% of cases. Loss of chromosome 18 is a common finding in small-bowel NETs. Small-intestinal GI carcinoids commonly have epigenetic changes; however, the clinical significance of these alterations remains uncertain. Initial studies have suggested that well-differentiated pancreatic and extrapancreatic NETs express only low levels of the immune checkpoint markers PD-1 and PD-L1.

CLINICAL PRESENTATION AND MANAGEMENT OF LOCALIZED PANCREATIC NEUROENDOCRINE TUMORS

Pancreatic NETs have been subcategorized as either "functional," meaning associated with symptoms of hormone secretion, or nonfunctional, in which case they may be clinically silent until they cause anatomic symptoms. The clinical presentation of functional pancreatic NETs depends on the type of hormone secreted and can sometimes lead to dramatic clinical presentations (Table 84-2). The most common functional pancreatic NETs are insulinomas, followed in incidence by glucagonomas and gastrinomas. Pancreatic NETs secreting other hormones, including somatostatin, vasoactive intestinal peptide (VIP), adrenocorticotropic hormone (ACTH), and parathyroid hormone (PTH) have also been described but are uncommon. Only ~20% of pancreatic NETs are associated with symptoms of hormone hypersecretion; the majority of pancreatic NETs are "nonfunctional" and are diagnosed either incidentally or after patients present with abdominal pain, weight loss, or other anatomic symptoms related to tumor bulk.

GASTRINOMA

Patients with gastrinoma typically present with Zollinger-Ellison syndrome (ZES) (Chap. 324). The most common symptoms associated with this syndrome are abdominal pain, diarrhea, gastroesophageal reflux disease (GERD), and peptic ulcer disease. Peptic ulcer disease manifesting as multiple ulcers with associated diarrhea is a classic presentation. Up to 25% of patients with ZES have MEN 1, and a diagnosis of gastrinoma should prompt a family history as well as an assessment for concurrent hyperparathyroidism. Fasting hypergastrinemia is a nearly universal finding in patients with gastrinoma. Importantly, however, proton pump inhibitors (PPIs) can suppress acid secretion sufficiently to cause hypergastrinemia and can confound the diagnosis. Achlorhydria, usually in the context of chronic atrophic gastritis, will also elevate serum gastrin levels but can usually be easily distinguished from gastrinoma given the absence of other evidence of acid hypersecretion.

While often classified as pancreatic NETs, the majority of gastrinomas in fact arise in the "gastrinoma triangle," an anatomic region bounded by the duodenum, pancreas, and confluence of the cystic and common bile ducts. Most gastrinomas (50–90%) in sporadic ZES arise in the duodenum. They are frequently small and may be difficult to localize. Imaging studies generally include either CT or MRI; endoscopic ultrasound or somatostatin scintigraphy may also be helpful.

PPIs are generally highly effective in the treatment of symptoms related to gastrinoma and are considered the initial treatment of choice. Rapid resolution of both abdominal pain and diarrhea related to acid hypersecretion is common. Somatostatin analogues may also be helpful in controlling symptoms in refractory cases. Once symptoms are controlled, surgical resection is generally recommended for patients with sporadic gastrinomas, both to eliminate the cause of gastrin secretion and to decrease the risk of developing metastatic disease. The technique used for resection depends in large part on the precise location of the tumor. In some cases where preoperative imaging is not successful but a diagnosis is strongly suspected, exploratory laparotomy with intraoperative ultrasound may be undertaken. In gastrinoma patients who have underlying MEN 1, tumors are generally small and multiple; the role of routine surgery in this setting remains more controversial but generally is still recommended in patients with larger tumors measuring ≥1.5–2 cm in diameter.

INSULINOMA

Patients with insulinoma generally present with symptoms of hypoglycemia, which may include confusion, headache, disorientation, visual difficulties, irrational behavior, and even coma. In some cases, the diagnosis of insulinoma may not be immediately evident, and patients with

TABLE 84-2 Clinical Presentation and Management of Secretory Syndromes Associated with Neuroendocrine Tumors

	CLINICAL SYMPTOMS AND MANIFESTATIONS	TREATMENT OPTIONS TO CONTROL SECRETORY SYMPTOMS
Pancreatic Neuroendocrine Tumors		
Gastrinoma (generally located in "gastrinoma triangle")	Zollinger-Ellison syndrome: gastroesophageal reflux, peptic ulcer disease, diarrhea	Proton pump inhibitors, somatostatin analogues
Insulinoma	Hypoglycemia leading to confusion, lethargy, coma; weight gain	Diazoxide, everolimus
Glucagonoma	Skin rash (necrolytic migratory erythema), glucose intolerance, weight loss	Somatostatin analogues
VIPoma	Verner-Morrison syndrome: watery diarrhea, hypokalemia, achlorhydria	Somatostatin analogues
ACTHoma	Cushing's syndrome: hyperglycemia, weight gain, hypokalemia	Ketoconazole, consider adrenalectomy
Extrapancreatic gastrointestinal neuroendocrine tumors		
Typically in setting of advanced disease from small intestine or appendiceal primary tumors	Carcinoid syndrome: flushing, diarrhea, right-sided valvular heart disease, mesenteric fibrosis	Somatostatin analogues, telotristat ethyl

insulinoma may initially be diagnosed with psychiatric illnesses that in retrospect were hypoglycemic symptoms. The diagnosis of insulinoma is generally confirmed with elevated fasting insulin levels in conjunction with elevated proinsulin and C-peptide. Fasting hypoglycemia can also be caused by severe liver disease, alcoholism, and poor nutrition. Postprandial hypoglycemia may also occur after gastric bypass surgery. Surreptitious use of insulin or hypoglycemic agents may be difficult to distinguish from an insulinoma. Evaluation of proinsulin and C-peptide levels, both of which should be normal in patients using exogenous insulin, and measurement of sulfonylurea levels in serum or plasma are helpful in such cases.

The hypoglycemia associated with insulinomas can be severe and challenging to manage. Diazoxide has historically been used in the initial management of patients with insulinoma and results in inhibition of insulin release, though it can also be associated with side effects including sodium retention and nausea. Everolimus, in addition to its antitumor effect (see below), is highly effective in improving glycemic control in patients with insulinoma. The benefits of everolimus in this setting may be related both to induction of insulin resistance and a direct antitumor effect. While somatostatin analogues are usually effective in treating symptoms of hormone hypersecretion associated with other types of NETs, they should be used with caution in patients with insulinoma. Somatostatin analogues may suppress counterregulatory hormones, such as growth hormone (GH), glucagon, and catecholamines, and precipitously worsen hypoglycemia.

Insulinomas may be difficult to localize, as they are less consistently avid on somatostatin scintigraphy than other pancreatic NETs. Insulinomas are also generally small, with the majority measuring <2 cm in diameter. Because of their generally small size, insulinomas are best localized with endoscopic ultrasound (EUS). In the absence of metastatic disease, surgical resection is usually recommended. The primary treatment for exophytic or peripheral insulinomas is enucleation. If enucleation is not possible because of invasion or the location of the tumor within the pancreas, then pancreatoduodenectomy for tumors in the head of the pancreas or distal pancreatectomy with preservation of the spleen for smaller tumors not involving splenic vessels may be considered.

GLUCAGONOMA

Patients with glucagonoma most commonly present with a characteristic dermatitis, called necrolytic migratory erythema **(Fig. 84-2)**. The rash usually involves intertriginous sites, especially in the groin or buttock, and can wax and wane. Other common presenting symptoms of glucagonoma include glucose intolerance and weight loss. The diagnosis of glucagonoma can be confirmed by demonstrating an increased plasma glucagon level, generally in excess of 1000 pg/mL. Somatostatin analogues are usually highly effective as an initial treatment to alleviate the symptoms and rash associated with glucagon hypersecretion. The majority of glucagonomas are large in size at presentation and arise in the tail of the pancreas. For patients with localized disease, distal pancreatectomy and splenectomy are recommended. A hypercoagulable state has been reported in up to 33% of patients with glucagonoma, and perioperative anticoagulation should generally be employed.

SOMATOSTATINOMA

Patients with somatostatinoma typically present with diabetes mellitus, gallbladder disease, diarrhea, and steatorrhea. Somatostatinomas occur primarily in the pancreas or duodenum, are usually large, and are commonly metastatic at presentation. They are only rarely associated with MEN 1. The diagnosis of somatostatinoma is based on the demonstration of elevated plasma somatostatin levels, and as such, the potential benefits of using somatostatin analogs as a treatment for patients with somatostatinoma is questionable. Surgery is recommended for patients with localized disease.

VIPOMA

VIPomas are associated with a distinct syndrome that has been variously called Verner-Morrison syndrome, pancreatic cholera, and WDHA syndrome (*w*atery *d*iarrhea, *h*ypokalemia, and *a*chlorhydria).

FIGURE 84-2 Glucagonoma syndrome. Patients with glucagonoma may present with a classic skin rash, necrolytic migratory erythema (shown). Other presenting symptoms include glucose intolerance and weight loss.

VIP is a 28-amino-acid peptide that mimics the effects of the cholera toxin by stimulating chloride secretion in the small intestine and increasing smooth-muscle contractility, resulting in profound diarrhea. Treatment of dehydration, hypokalemia, and electrolyte losses with fluid and electrolyte replacement is the most critical initial treatment for patients with VIPoma. VIPomas are usually solitary and arise in the pancreatic tail. Elevated plasma levels of VIP are typical but should not be the only basis of the diagnosis of VIPomas because they can occur with some diarrheal states including inflammatory bowel disease, in the setting of small bowel resection, and radiation enteritis. Chronic surreptitious use of laxatives/diuretics can be particularly difficult to detect clinically. Somatostatin analogues are usually highly effective in controlling the diarrhea; surgical resection is recommended for patients with localized disease.

OTHER SECRETORY PANCREATIC NETS

Pancreatic NETs secreting GH-releasing factor (GRF), calcitonin, ACTH, and PTH-related protein have also been described; it is also possible for pancreatic NETs to secrete more than one hormone or for the secretory profiles to evolve over time. Gastrinomas, in particular, may evolve and may be associated with secretion of ACTH, resulting in ectopic Cushing's syndrome. Tumors secreting these hormones may not be as responsive to treatment with somatostatin analogues as the more common pancreatic NETs and the associated hormonal symptoms may cause significant morbidity. As with other pancreatic NETs, patients with localized disease are generally treated with surgical resection. In patients with ACTH-secreting tumors, the associated symptoms of Cushing's syndrome can be alleviated with adrenalectomy if resection of the primary tumor is not possible or in the setting of metastatic disease.

PANCREATIC NETS ARISING IN THE SETTING OF MEN 1

Pancreatic NETs occurring in patients with MEN 1 are typically multiple and often pursue a relatively indolent course. Because of the high probability of multiple tumors, surgical resection of confirmed pancreatic NETs in patients with MEN 1 is usually undertaken with caution given the likelihood of tumors arising in the remaining pancreas if

partial pancreatectomy is undertaken as well as the significant morbidities associated with total pancreatectomy. However, for symptomatic tumors or for growing tumors >2 cm in size, surgical resection may still be considered.

NONFUNCTIONING PANCREATIC NETS

As noted above, the majority of pancreatic NETs are not associated with symptoms of hormone hypersecretion and are considered "nonfunctional." As a result, they often remain clinically silent and either are diagnosed incidentally or are not diagnosed until widespread, metastatic disease is present resulting in anatomic symptoms. If they are localized at diagnosis, the general treatment recommendation is surgical resection; however, the management of small, asymptomatic pancreatic NETs is debated. Assuming tumors are low grade, patients with incidentally discovered, low-grade tumors measuring <1 cm in size can be safely followed; other retrospective studies have suggested nonoperative management for nonfunctioning pancreatic NETs measuring up to 3 cm. In contrast, however, an analysis of the SEER database suggested that at least some tumors measuring <2 cm in size can pursue a more aggressive course. Management of small, incidentally discovered, asymptomatic, low-grade pancreatic NETs is therefore based on clinical judgement, taking into account surgical risk and patient comorbidities.

CLINICAL PRESENTATION AND MANAGEMENT OF LOCALIZED EXTRAPANCREATIC GASTROINTESTINAL NEUROENDOCRINE TUMORS

Extrapancreatic GI NETs, historically called carcinoid tumors, may arise virtually anywhere in the GI tract and differ significantly in their clinical characteristics depending on their location. The most common locations for extrapancreatic NETs are the stomach, distal small intestine, appendix, and rectum.

GASTRIC NETS

Gastric NETs can be categorized into three groups: type 1 (associated with chronic atrophic gastritis); type 2 (associated with gastrinomas and ZES), and type 3 (sporadic, gastric NETs). Type 1 gastric NETs are the most common of the three types. In type 1 gastric NETs, chronic atrophic gastritis results in loss of acid secretion with consequent loss of the negative feedback loop on gastrin-producing cells in the antrum of the stomach. Pernicious anemia is also commonly associated with this condition; classic laboratory findings are a markedly elevated gastrin level and low levels of vitamin B_{12}. Unchecked gastrin secretion in these patients results in hyperplasia of the endocrine cells in the gastric fundus. A typical finding on endoscopy is diffuse endocrine cell hyperplasia with multiple gastric carcinoid tumors **(Fig. 84-3)**. These tumors generally pursue a benign course and can be monitored with serial endoscopy. In cases where tumors continue to grow or become symptomatic, antrectomy to remove the source of gastrin production can result in tumor regression. Type 2 tumors are rare and usually occur in the setting of gastrinoma; as with type 1 gastric NETs, elevated gastrin levels result in diffuse gastric neuroendocrine hyperplasia and multifocal gastric NETs. Resection of the gastrinoma, removing the source of gastrin production, is the treatment of choice.

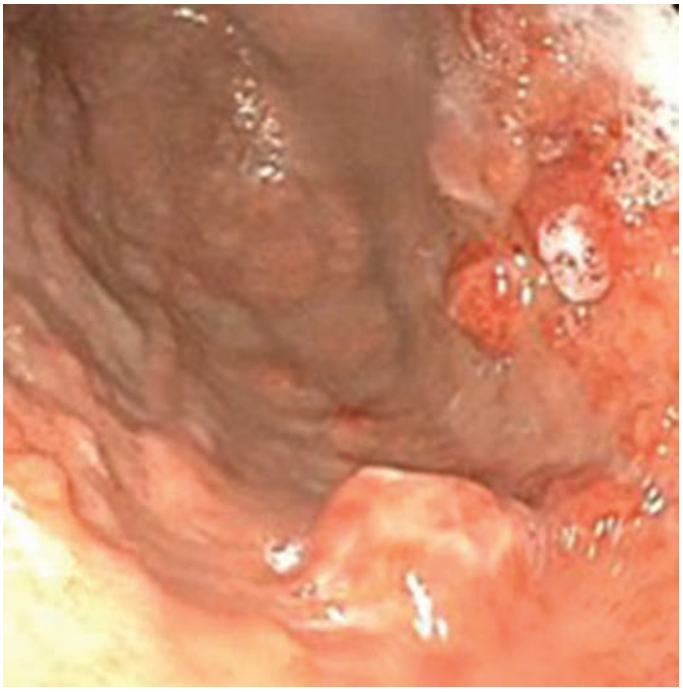

FIGURE 84-3 Multifocal gastric neuroendocrine tumor. *(Courtesy of Christopher Huang MD, Boston Medical Center.)*

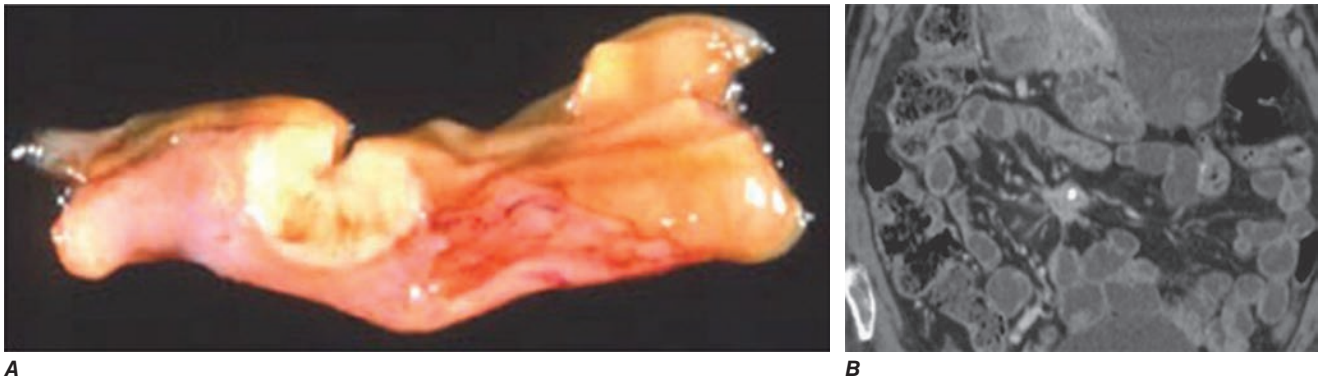
In contrast to type 1 and type 2 gastric NETs, type 3 gastric NETs are generally solitary, arise in the setting of normal gastrin levels, and may pursue a far more aggressive course. For early-stage, smaller tumors, endoscopic or wedge resection may be performed. For larger tumors, partial gastrectomy with lymphadenectomy is recommended.

NETS OF THE SMALL INTESTINE

Small-bowel NETs occur most commonly in the terminal ileum and are notoriously difficult to diagnose at an early stage. One reason for this is that they arise within the muscularis, and their submucosal location makes them difficult to see during routine colonoscopy **(Fig. 84-4*A*)**. Small-bowel NETs are also often multifocal; multifocal tumors appear to arise independently throughout the small intestine, although the mechanisms underlying this phenomenon remain uncertain.

Small-bowel NETs are often associated with desmoplasia and mesenteric fibrosis, likely as a result of fibroblast proliferation stimulated by tumor serotonin secretion. Mesenteric fibrosis frequently



A ***B***

FIGURE 84-4 Small intestine neuroendocrine tumor. ***A.*** Small intestine neuroendocrine tumors arising in submucosal location. The submucosal location of small intestine neuroendocrine tumors, together with their location beyond the ileocecal valve in the terminal ileum, can make endoscopic detection challenging. ***B.*** Classic "spoke and wheel" appearance of calcified mesenteric mass associated with small intestine primary neuroendocrine tumor. Mesenteric fibrosis commonly leads to intermittent obstructive symptoms and can also lead to ischemia when the mesenteric vasculature is involved. *(Fig. B: Courtesy of Christina LeBedis MD, Boston Medical Center.)*

results in intermittent small-bowel obstruction and, in some cases, bowel ischemia due to involvement of the mesenteric vessels. Patients may experience symptoms of intermittent abdominal pain and associated diarrhea, sometimes for months or years before diagnosis, that because of the difficulty in diagnosis are often attributed to irritable bowel syndrome. One classic finding that can aid in diagnosis is that the lymph node metastases associated with small intestine NETs are usually larger than the primary tumor and may be calcified, which, together with the tethering of the small intestine caused by the associated fibrosis, results in a classic "spoke and wheel" appearance on computed tomography **(Fig. 84-4*B*)**.

Surgical resection of the primary tumor and associated metastases is recommended when feasible and is performed with curative intent when distant metastatic disease is not already present. Resection should also be considered in patients with metastatic disease experiencing intermittent obstruction or abdominal discomfort thought to be related to the primary tumor or associated mesenteric disease. Some have also advocated the routine resection of asymptomatic small-bowel primary tumors in patients with distant metastatic disease, with the rationale that this may be a way to prevent the future development of fibrosis and obstruction and preempt the development of unresectable disease due to tumor involvement of the mesenteric vessels. However, the available data on the benefits of resecting an asymptomatic primary tumor in this context are conflicting. Some studies have suggested that this practice results in an overall survival benefit, but the retrospective nature of these studies makes the data difficult to interpret given the high potential for selection bias in patients taken to surgery compared with those who were not. Other studies have suggested that prophylactic primary tumor resection confers no survival benefit and that surgery can be safely delayed until it is indicated based on the development of symptoms.

NETS OF THE APPENDIX

NETs are one of the most common tumors arising in the appendix. They are typically discovered incidentally in younger individuals undergoing appendectomy for acute appendicitis and not uncommonly are identified only at the time of pathology review. While the unexpected diagnosis of an appendiceal NET in such situations can cause considerable anxiety, in the majority of cases, the prognosis is excellent. Indeed, the clinical behavior of appendiceal NETs has been inferred from multiple large retrospective surgical series that suggest that the risk of lymph node or distant metastases from appendiceal NETs with well-differentiated histology and a tumor diameter measuring <2 cm is extremely low. In such cases, appendectomy alone is felt to be a sufficient surgical procedure.

In contrast, the risk of metastases for tumors measuring 2–3 cm is ~20–30% and is even greater for tumors measuring >3 cm. For patients with larger tumors, more formal staging studies with either cross-sectional imaging or somatostatin scintigraphy are generally recommended to assess for distant metastases, and a subsequent right colectomy to remove regional lymph nodes is performed if no distant metastases are observed. Whether right colectomy should be performed for tumors measuring <2 cm with features such as mesoappendiceal invasion or tumor origin at the appendiceal base, which in some series have suggested a poorer prognosis, remains uncertain. Additionally, tumors may arise in which neuroendocrine cells are admixed with mucin-producing cells or cells exhibiting features of frank adenocarcinoma. In such mixed neuroendocrine-adenocarcinoma tumors, sometimes termed "adenocarcinoids," treatment recommendations are generally dictated by the more aggressive component of the tumor and align with typical recommendations for colorectal adenocarcinoma.

RECTAL NETS

With the increased use of screening colonoscopy, the diagnosis of rectal NET has also become more common. For unclear reasons, the incidence of rectal carcinoid tumors shows geographic variation. In European studies, they compose up to 14% of all NETs, while in some Asian series (Japan, China, Korea), they compose up to 90% of all NETs. The majority of rectal NETs are small, measuring <1 cm in diameter, and have well-differentiated histology. These tumors rarely metastasize and can usually be safely removed endoscopically with subsequent endoscopic monitoring. In contrast, up to one-third of rectal NETs between 1 and 2 cm are associated with metastases, and those >2 cm, though uncommon, metastasize in >70% of patients. When identified early, these tumors generally require a surgical resection. In contrast to NETs of the appendix and small intestine, hormone secretion from rectal NETs, even when metastatic, is exceedingly rare.

CLINICAL PRESENTATION, DIAGNOSIS, AND EVALUATION OF PATIENTS WITH METASTATIC NEUROENDOCRINE TUMORS

While patients who undergo resection of localized NETs may be at risk of developing tumor recurrence or metastatic disease, postoperative treatment has not yet been shown to alter the risk of recurrence, and systemic adjuvant therapy is not recommended following resection of well-differentiated NETs, as it is for some other cancers. Whether adjuvant systemic therapy may be of benefit following resection of high-grade NETs is uncertain, and an approach utilizing platinum-based chemotherapy with or without external-beam radiation, analogous to that used in small-cell carcinoma, is sometimes considered.

The evaluation of patients with known or suspected metastatic disease generally includes both standard cross-sectional imaging such as CT or MRI and somatostatin scintigraphy. Somatostatin scintigraphy in this setting is based on the fact that >90% of NETs express somatostatin receptors. Gallium-68 (^{68}GA) dotatate, a radioligand bound to a somatostatin analogue, can be used as a nuclear medicine tracer to perform PET scanning and is highly sensitive in detecting both primary NETs and metastases **(Fig. 84-5)**. Because of the sensitivity of this approach, false-positive results can occur due to somatostatin receptor expression in other tissues. Physiologic uptake in the pancreatic uncinated process is common; uptake can also occur in the setting of sarcoidosis, in meningiomas, and in thyroid goiter or thyroiditis. Standard fluorodeoxyglucose (FDG) positron emission tomography (PET) scans are often negative in well-differentiated NET due to their low metabolic activity but can show uptake in higher-grade tumors; conversely, rates of somatostatin expression tend to be lower in higher-grade tumors, and ^{68}GA dotatate scans may be negative in this setting.

The utility of blood-based tumor markers in NETs is controversial. The circulating tumor marker chromogranin A is commonly used as a screen for the presence of NETs and also to monitor for both

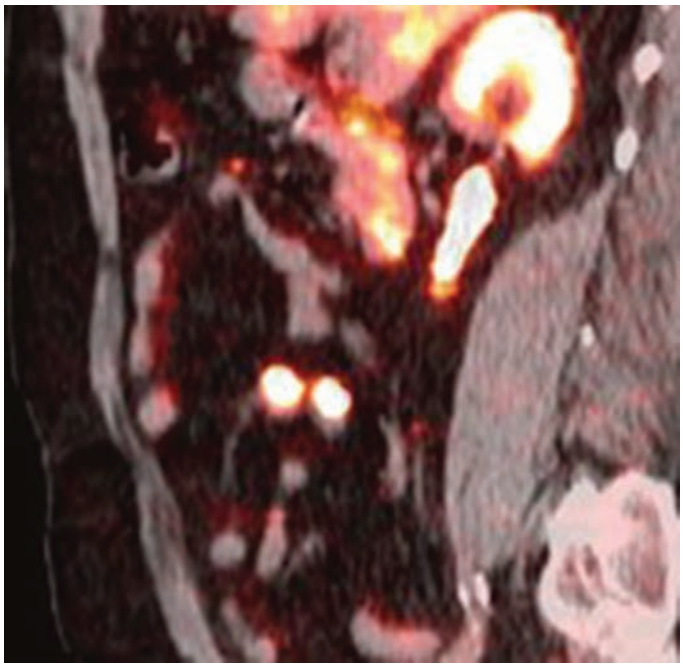


FIGURE 84-5 Gallium-68 Dotatate PET scan demonstrating a small bowel neuroendocrine tumor and associated mesenteric mass. *(Courtesy of Sara Meibom, MD, Boston Medical Center.)*

recurrence and progression of disease in patients with known metastases. While chromogranin A is elevated in patients with metastatic NETs, it is neither particularly sensitive nor specific. A broad range of different assays for chromogranin A have also posed challenges in interpreting results in a standardized fashion. Chromogranin A is often elevated in a number of nonmalignant conditions, including in patients with impaired renal function and in patients who are taking PPIs. Elevated values of chromogranin A should be interpreted with caution in patients in whom a NET is being considered but in whom a diagnosis has not been established.

The overall survival durations for patients with metastatic NETs vary significantly, depending on both the primary location of the tumor and the histologic grade. Median survival durations for patients with well-differentiated NETs have markedly increased in recent years, likely reflecting both earlier diagnoses and improved treatments. For example, in early analyses of the SEER database, the median survival for patients with advanced pancreatic NETs was ~2 years; this had increased to 4 years in a more recent analysis. Similar increases were observed in patients with advanced small intestine NETs, where the median survival for patients with well-differentiated small intestine NETs exceeds 5 years. The sometimes prolonged survival of patients with NETs can sometimes make it challenging to determine at what point to initiate treatment. In patients with symptoms of hormone secretion, decisions to initiate therapy are straightforward. In asymptomatic patients, on the other hand, observation off treatment can sometimes be appropriate. Nevertheless, the natural course of NETs is ultimately to progress, and if treatment is not initiated, close monitoring is essential to ensure patients maximize access to available treatment options over the course of their disease.

MANAGEMENT OF SYMPTOMS OF HORMONE HYPERSECRETION AND THE CARCINOID SYNDROME

Patients with advanced NETs may in some cases experience more symptoms from hormone hypersecretion than from tumor bulk. The management of hormonal symptoms associated with pancreatic NETs depends on the hormone being secreted (see above). Patients with GI NETs, particularly those with small intestine or appendiceal primaries, may develop the carcinoid syndrome. Flushing and diarrhea are the two most common symptoms associated with carcinoid syndrome. The characteristic flush is of sudden onset; it is a deep red or violaceous erythema of the upper body, especially the neck and face, often associated with a feeling of warmth. Flushes may be precipitated by stress, alcohol, exercise, and certain foods such as cheese. Flushing episodes initially are brief, lasting 2–5 min, though later in the disease course, they may last hours. The diarrhea associated with carcinoid syndrome may or may not be associated with flushing and is described as watery in nature. Diarrhea can be profound, sometimes occurring in excess of 10 times daily and is one of the symptoms that most significantly interferes with activities of daily living. Less common manifestations of the carcinoid syndrome include wheezing or asthma-like symptoms. Impaired cognitive function has also been described in particularly advanced cases.

The main secretory product implicated in the carcinoid syndrome is serotonin (5-HT). Serotonin is synthesized from tryptophan by the enzyme tryptophan hydroxylase **(Fig. 84-6)**. Up to 50% of dietary tryptophan can be used in this synthetic pathway by tumor cells, resulting in inadequate supplies for conversion to niacin; hence, some patients develop symptoms of niacin deficiency and pellagra-like lesions. Serotonin has numerous biologic effects, including the stimulation of intestinal secretion, increasing intestinal motility, and the stimulation of fibroblast growth. Other secreted products contributing to carcinoid syndrome symptoms are thought to include histamines and tachykinins, including substance P.

DIAGNOSIS AND TREATMENT OF THE CARCINOID SYNDROME

While the carcinoid syndrome can develop in patients with NETs from almost any site, it is most commonly associated with appendiceal or small intestine NETs. In these patients, the syndrome usually develops only after the development of hepatic metastases or retroperitoneal lesions, allowing entry of serotonin and other vasoactive substances into the systemic circulation. While serotonin levels can be measured in plasma, such measurements are frequently highly variable. Evidence of excess serotonin secretion can be more reliably confirmed by measuring levels of the serotonin metabolite 5-hydroxyindole acetic acid (5-HIAA), commonly using a 24-h urine collection. Urine collections can be challenging, and false-positive elevations may occur if the patient is eating serotonin-rich foods (e.g., salmon, eggs). As a result, elevated levels of 5-HIAA are suggestive but not diagnostic of the carcinoid syndrome. Patients with NETs may also experience symptoms of carcinoid syndrome related to other secreted products, including histamine, absent evidence of serotonin secretion. Conversely, patients without NETs may also describe symptoms analogous to carcinoid syndrome but due to other causes. The symptoms associated with systemic mastocytosis, in particular, can be easily confused with carcinoid syndrome.

The symptoms of carcinoid syndrome, including diarrhea, are generally refractory to standard antidiarrheals or other traditional medications but can often be well controlled with somatostatin analogues **(Fig. 84-7)**. Approximately 90% of NETs express somatostatin receptors. The presence of somatostatin receptors on NETs can be easily confirmed with uptake on somatostatin scintigraphy such as ^{68}GA dotatate PET scan; uptake on somatostatin scintigraphy is predictive of response to treatment with somatostatin analogues. Somatostatin is a 14-amino-acid peptide that inhibits the secretion of a broad range of hormones. Due to its short half-life, administration of somatostatin

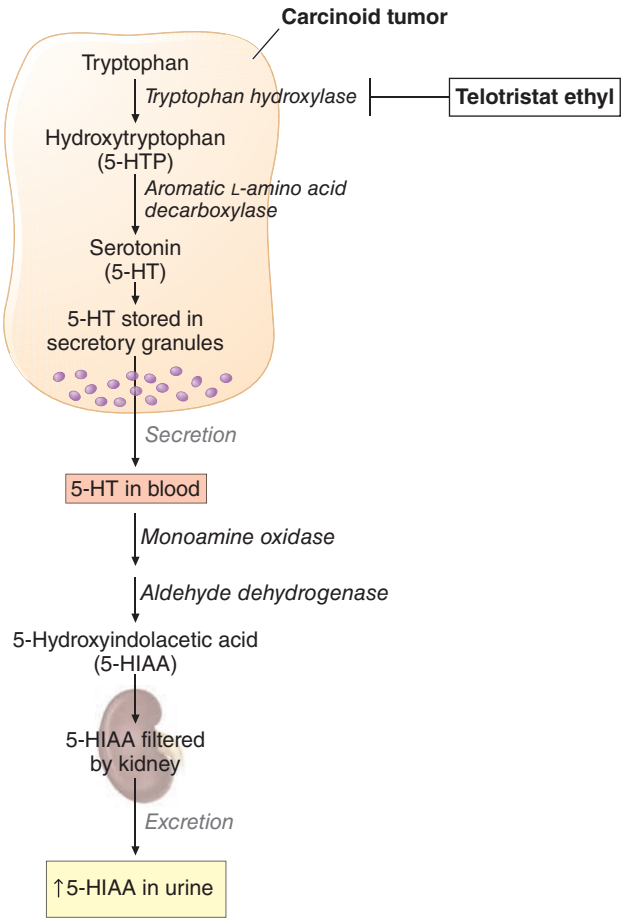

FIGURE 84-6 Serotonin synthesis and secretion in neuroendocrine tumors. Tryptophan is converted to hydroxytryptophan by tryptophan hydroxylase within the tumor cell and, subsequently, to serotonin (5-HT). Serotonin is subsequently converted to 5-hydroxyindole acetic acid (5-HIAA), which can be measured in a 24-h urine collection and can facilitate the diagnosis of carcinoid syndrome. Telotristat ethyl inhibits tryptophan hydroxylase and can be used as a treatment for carcinoid syndrome.

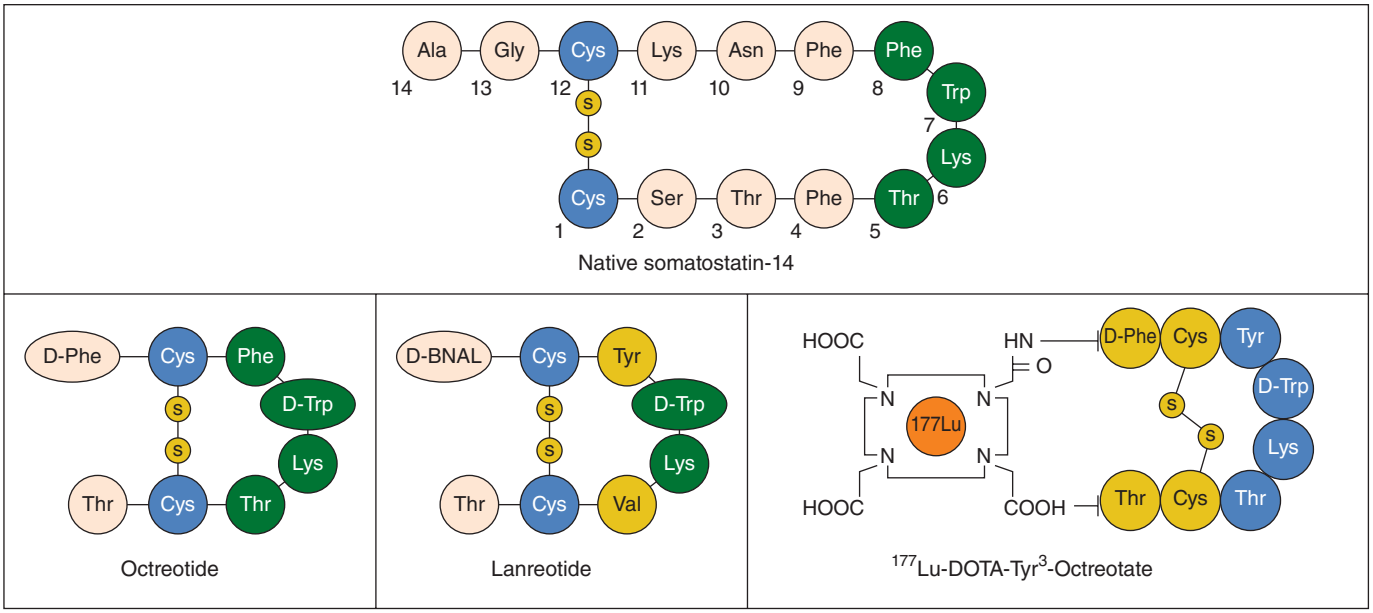

FIGURE 84-7 Somatostatin analogues. Commonly used somatostatin analogues include octreotide and lanreotide, which mirror the molecular structure of human somatostatin and bind to somatostatin receptors on neuroendocrine tumors. Somatostatin analogues inhibit tumoral hormone secretion and also have an antiproliferative effect. Radiolabeled somatostatin analogues such as ^{177}Lu-DOTA-octreotate, shown in the figure, share a similar molecular structure and are used therapeutically.

itself is not therapeutically practical. Longer-acting somatostatin analogues, including octreotide and lanreotide, share an 8-amino-acid binding domain with naturally occurring somatostatin and bind primarily to somatostatin receptor subtypes 2 and 5. Both have been shown to be effective in the treatment of carcinoid syndrome.

In an initial study, treatment of patients with octreotide 150 μg subcutaneously three times daily controlled symptoms of flushing and diarrhea in 88% of patients. A depot preparation (octreotide long-acting release [LAR]) that can be administered monthly has largely eliminated the need for daily octreotide injections and is now considered a standard approach for symptomatic treatment of advanced NETs. Lanreotide, another long-acting somatostatin analogue that is also administered monthly, appears to have similar clinical efficacy to octreotide in the treatment of metastatic NETs and the carcinoid syndrome. As described further below, both octreotide and lanreotide also share the ability to slow tumor growth, providing an additional benefit to patients.

Somatostatin analogue side effects are generally mild. Mild nausea, abdominal discomfort, bloating, and loose stools occur in up to one-third of patients during the first month or two of treatment but usually subsequently subside. Patients with persistent symptoms of bloating or loose stools may be experiencing pancreatic insufficiency associated with use of somatostatin analogues; use of pancreatic enzyme supplements can ameliorate these symptoms. Mild glucose intolerance may also occur due to inhibition of insulin secretion. One of the more significant side effects associated with somatostatin analogues is impaired gallbladder contractility, resulting in delayed gallbladder emptying, and long-term administration of somatostatin analogues has been associated with an increased risk of cholelithiasis. For this reason, patients with advanced NETs in whom surgery is planned and for whom somatostatin analogue therapy is being considered should generally also undergo prophylactic cholecystectomy.

Over time, for reasons that remain uncertain, patients receiving somatostatin analogues for symptoms of hormone secretion may become refractory to treatment. Not uncommonly, such patients experience symptom exacerbation toward the final week of each treatment cycle. Such patients may benefit from an increased frequency of administration (i.e., every 3 weeks) or use of additional short-acting octreotide for breakthrough symptoms.

The association between high levels of circulating serotonin and symptoms of the carcinoid syndrome has also led to a strategy aiming to directly inhibit serotonin synthesis (Fig. 84-6). This approach was first undertaken in the late 1960s with the drug para-chlorophenylalanine, which was reported to reduce symptoms of carcinoid syndrome but also caused significant central nervous system (CNS) side effects. Telotristat ethyl, a tryptophan hydroxylase inhibitor with minimal CNS penetration, was evaluated in a randomized trial that enrolled 135 patients with persistent carcinoid syndrome–related diarrhea while receiving somatostatin analogues. Treatment with telotristat ethyl was associated with a reduction in bowel movement frequency as well as significant decreases in urinary 5-HIAA compared to placebo. Thus, telotristat is a treatment option for patients with carcinoid syndrome who have persistent diarrhea despite treatment with somatostatin analogues.

CARCINOID CRISIS

Carcinoid crisis has been described in the setting of tumor manipulation during surgery and, less commonly, after other interventions such as hepatic artery embolization or radionuclide therapy. It may also occur as a result of exogenous administration of epinephrine or during induction of anesthesia. It is most common in patients who already have significant symptoms of carcinoid syndrome and is thought to be caused by a sudden release of biologically active compounds from the tumor. Carcinoid crisis can be life-threatening and can manifest as either profound hypotension or hypertension. Prospective studies on the prevention and management of carcinoid crisis are limited; however, somatostatin analogues should be readily available during surgical procedures, and in some cases, continuous prophylactic intravenous administration of somatostatin analogues has been utilized as a way to mitigate risk.

CARCINOID HEART DISEASE

Carcinoid heart disease occurs in approximately two-thirds of patients with the carcinoid syndrome. Carcinoid heart lesions are characterized by plaque-like, fibrous endocardial thickening that classically involves the right side of the heart and often causes retraction and fixation of the leaflets of the tricuspid and pulmonary valves (Fig. 84-8). The fibrosis in carcinoid heart disease is thought to be directly related to exposure of heart valve fibroblasts to high circulating levels of serotonin. Lesions similar to those observed in carcinoid heart disease were observed in patients receiving fenfluramine, a drug also known to increase serotonin signaling, as well as in patients receiving ergot-containing dopamine receptor agonists for Parkinson's disease. Metabolites of fenfluramine, as well as the dopamine receptor agonists, have high

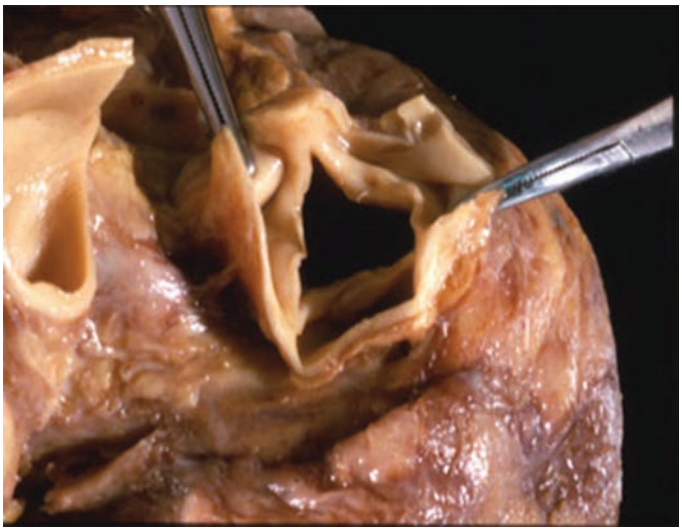

FIGURE 84-8 Carcinoid heart disease. Fibrosis secondary to elevated levels of circulating serotonin classically involves the tricuspid valve, resulting in valve retraction and tricuspid regurgitation.

affinity for serotonin receptor subtype 5-HT_{2B} receptors, whose activation is known to cause fibroblast mitogenesis and which are normally expressed in heart valve fibroblasts. These observations support the hypothesis that serotonin overproduction in patients with carcinoid syndrome mediates the valvular changes by activating 5-HT_{2B} receptors in the endocardium.

Tricuspid regurgitation is a nearly universal feature of carcinoid heart disease; tricuspid stenosis, pulmonary regurgitation, and pulmonary stenosis may also occur. Left-sided heart disease occurs in <10% of patients and has been associated with the presence of a patent foramen ovale. The preponderance of lesions in the right heart is related directly to the fact that serotonin is secreted by liver metastases or retroperitoneal tumor deposits into the venous circulation and subsequently into the right atrium and right ventricle. The lower incidence of heart disease in the left heart is postulated to be due to the fact that serotonin is metabolized in the pulmonary vasculature before entering the left atrium and ventricle. Among patients with carcinoid syndrome, patients with heart disease exhibit higher levels of serum serotonin and urinary 5-HIAA excretion than patients without heart disease. Treatment with somatostatin analogues resulting in decreased serotonin secretion does not result in regression of cardiac lesions. Reduction of serotonin levels as a result of treatment with somatostatin analogues or with the tryptophan hydroxylase inhibitor telotristat ethyl seems likely to slow progression of carcinoid heart disease but has not been formally evaluated in clinical trials.

Right-sided heart failure in patients with carcinoid heart disease may lead to significant morbidity and mortality. The development of multiple new treatments to improve overall disease control in patients with advanced NETs has led to increased interest in valvular replacement, which may result in significant clinical benefit in appropriately selected patients with carcinoid heart disease. The appropriate timing of valve replacement in such patients can be challenging given the competing desires to perform surgery before the onset of severe right-sided heart failure, which can increase surgical morbidity, and the need to achieve adequate overall tumor control. However, advanced and less invasive techniques, including catheter-based valve replacement, have made valve replacement an increasingly attractive option for patients with this condition.

HEPATIC-DIRECTED THERAPY FOR METASTATIC NETS

The liver is one of the most common sites for metastases in patients with NETs and, in some cases, is the only site of metastatic disease. Hepatic-directed therapies can often be effective as a means of controlling, if not eliminating, metastases, particularly in patients who have more indolent tumors with well-differentiated histology. Common approaches for such patients include surgical resection, ablation or embolization, and orthotopic liver transplantation.

For patients with limited hepatic disease whose tumors have well-differentiated histology, surgical resection is generally considered the preferable option. While data are limited to retrospective series with the consequent risk of selection bias, long-term survival durations and symptomatic improvements reported in select populations of patients undergoing hepatic resection of neuroendocrine liver metastases compare favorably with outcomes associated with other management approaches, and 5-year survival rates approach 90% in some series. In patients in whom anatomy precludes resection or in whom a greater number of lesions are present, radiofrequency ablation or cryoablation can also be used, either as a primary treatment modality or as an adjunct to surgical resection. While ablation is considered to be less morbid than hepatic resection, it is generally utilized only in smaller tumors so that zones of ablation are limited.

In most cases, however, liver metastases are large, multiple, and involve both lobes of the liver. In such cases, the benefit of surgical resection and ablation is limited. Hepatic arterial embolization can be considered in these cases, assuming that extrahepatic disease remains relatively limited and that clinical benefit can be achieved by reducing hepatic tumor bulk. Hepatic artery embolization is based on the principle that tumors in the liver derive most of their blood supply from the hepatic artery, whereas healthy hepatocytes derive most of their blood supply from the portal vein. Multiple different embolization techniques have been explored, ranging from the simple infusion of gel foam powder into the hepatic artery (bland embolization) to the administration of chemotherapy or chemotherapy-eluting beads into the hepatic artery (chemoembolization) or the intra-arterial administration of radioisotope-tagged microspheres (radioembolization). Limited data suggest an optimal approach to embolization, and few studies have compared these approaches directly. Tumor response rates with all of these approaches generally exceed 50%. Specific approaches are therefore often tailored to the patient, taking into account tumor location, overall tumor burden, and comorbidities. Bland embolization, for example, may be associated with less morbidity, whereas chemoembolization or radioembolization may result in longer durations of response.

The role of orthotopic liver transplantation for the treatment of NETs remains uncertain. Data from available institutional series suggest that a small number of highly selected patients may achieve long-term survival. However, 5-year overall median survival durations in most series are ~50%, and the majority of patients undergoing hepatic transplantation develop tumor recurrence. Additionally, the widespread utility of hepatic transplantation is limited by organ availability. Decisions regarding proceeding with transplantation in patients with advanced NETs are therefore highly individualized.

SYSTEMIC TREATMENT TO CONTROL TUMOR GROWTH

While hepatic-directed therapies can be effective in the management of patients with liver-predominant disease, a majority of patients will either present with or ultimately develop more widespread metastases. A number of systemic treatment options have been developed and can be effective in treating such patients. These options include treatment with traditional somatostatin analogues, peptide receptor radioligand therapy, traditional cytotoxic chemotherapy, and an increasing array of molecularly targeted therapies targeting the mTOR or vascular endothelial growth factor (VEGF) pathways **(Table 84-3)**. The choice and sequence of therapy depend in part on the type of tumor, the extent of disease, and patient symptoms and comorbidities.

SOMATOSTATIN ANALOGUES

While somatostatin analogues were originally developed as a treatment to reduce hormone secretion in NETs, they are also effective in slowing tumor growth. The biologic mechanisms underlying this effect remain uncertain, but clinical studies have been definitive. The first of these studies, the PROMID study, randomized patients with metastatic small-intestinal NET to receive either octreotide LAR at a

TABLE 84-3 Selected Randomized Trials of Therapeutic Agents for the Treatment of Advanced Neuroendocrine Tumors (NETs)

TUMOR TYPE	NUMBER OF PATIENTS	PROGRESSION-FREE SURVIVAL
Pancreatic and extrapancreatic NET		
Lanreotide vs placebo (CLARINET)	204	65 vs 33% at 2 years ($p < .001$)
Pancreatic NET		
Everolimus vs placebo (RADIANT 3)	410	11 months vs 4.6 months ($p < .001$)
Sunitinib vs placebo	171	11.4 months vs 5.5 months ($p < .001$)
Surufatinib vs placebo	264	10.9 months vs 3.7 months ($p = .001$)
Temozolomide/capecitabine vs temozolomide	144	22.7 months vs 14.4 months ($p = .021$)
Extrapancreatic NET		
Octreotide vs placebo (PROMID)	85	14.3 months vs 6 months[a]
Everolimus + octreotide vs octreotide (RADIANT 2)	429	16.4 months vs 11.3 months
Everolimus vs placebo (RADIANT 4)	302	11 months vs 3.9 months
Surufatinib vs placebo	198	9.2 months vs 3.8 months ($p < .0001$)
Pazopanib vs placebo	171	11.6 months vs 8.5 months ($p < .0005$)
177-Lutetium dotatate vs octreotide (NETTER 1)	230	65.2 vs 10.8% at 20 months ($p < .001$)

[a]Time to tumor progression.

dose of 30 mg monthly or placebo. The median time to tumor progression in patients receiving octreotide was 14 months compared to only 6 months for patients receiving placebo. Because the study was limited to patients with small-intestinal NET, the generalizability of these results to patients with NETs of other origins, including pancreatic NET, was initially uncertain. This question was ultimately addressed by the phase 3 CLARINET trial, which compared lanreotide, a somatostatin analogue that is similar to octreotide in its somatostatin receptor–binding affinities, to placebo in 204 patients with a range of advanced well- or moderately differentiated gastroenteropancreatic NETs. Progression-free survival duration at 2 years was 65% in patients receiving lanreotide and 33% in patients receiving placebo, a difference that was statistically significant. One unusual aspect of the PROMID and CLARINET studies is the difference in progression-free survival durations in the placebo arms of the studies, which has been attributed to differences in patient selection. Either octreotide or lanreotide is currently considered an acceptable option for control of tumor growth in patients with advanced NETs.

Whether treatment with somatostatin analogues also increases overall survival in patients with advanced NETs has not been demonstrated, although a correlation between progression-free survival and overall survival in patients with advanced NETs treated with single-agent somatostatin analogue therapy has been shown. The timing of initiation of somatostatin analogues in patients with advanced NETs remains uncertain. The variable clinical course of NETs means that tumors can remain indolent for years even without treatment. For patients with asymptomatic, small-volume disease, observation alone may be an appropriate initial option. However, for patients with a larger disease burden, evidence of disease progression, or symptomatic disease, somatostatin analogues are generally used as an initial systemic treatment due to their ease of use and tolerability.

PEPTIDE RECEPTOR RADIOLIGAND THERAPY

Peptide receptor radioligand therapy employs the systemic administration of radiolabeled somatostatin analogues and is a treatment option for patients who require more aggressive treatment due to progression on traditional somatostatin analogues or other therapies (Fig. 84-7). Peptide receptor radioligand therapy may also be considered as an initial treatment in patients with significant symptoms or tumor burden. With this approach, a radioligand is coupled to a somatostatin analogue, using the somatostatin analogue to target the tumor. When bound to the tumor cell, the radioligand is then internalized, resulting in cell death. Due to its mechanism of action, peptide receptor radioligand therapy is only considered in patients whose tumors demonstrate uptake on somatostatin scintigraphy.

Several different radioligands have been evaluated, the most successful of which have been yttrium (^{90}Y) and lutetium (^{177}Lu). These two ligands differ from one another in terms of their particle energy and tissue penetration; of the two, ^{90}Y-DOTA-TOC emits higher-energy β particles and has deeper tissue penetration. ^{90}Y-DOTA-TOC (^{90}Y-dotatoc) has been evaluated in numerous series with overall tumor responses reported in approximately one-third of patients. Enthusiasm for this approach, however, has been tempered due to concerns about side effects including both renal and hematologic toxicity.

^{177}Lu-DOTA-octreotate emits both β particles and lower-energy γ particles and, in most studies, has been associated with less toxicity than ^{90}Y-DOTA-TOC. Initial single-center studies with ^{177}Lu-DOTA-octreotate showed promising antitumor activity, and based on these studies, a randomized trial of ^{177}Lu-dotatate in midgut GI NETs was undertaken. In this study (NETTER-1), 229 patients with inoperable, somatostatin receptor–positive midgut NETs were randomly assigned to receive either four doses of ^{177}Lu-dotatate administered intravenously every 8 weeks or treatment with high-dose octreotide LAR (60 mg) every 4 weeks. Treatment with ^{177}Lu-dotatate was associated with objective tumor responses in 18% of patients and also was associated with a significant improvement in progression-free survival: progression-free survival at month 20 was 10.8% for octreotide LAR alone and 65.2% in the ^{177}Lu-dotatate group. Subsequent analyses have also suggested improved overall survival associated with ^{177}Lu-dotatate treatment, as well as improvements in quality of life across a number of parameters, including global health status, overall physical functioning, fatigue, pain, and diarrhea.

The renal clearance of radiopeptides, including ^{177}Lu-DOTA-octreotate, poses a risk of renal toxicity. The renal toxicity can be mitigated with the coadministration of intravenous amino acids during treatment. The most common adverse event among patients receiving ^{177}Lu-dotatate in the NETTER-1 study was nausea, most likely related to the amino acid infusions rather than to the radioisotope itself. Mild thrombocytopenia and leukopenia were also reported.

One limitation of the NETTER-1 study was its restriction to patients with advanced small intestine NETs. However, longer-term safety data as well as data supporting the efficacy of ^{177}Lu-dotatate in a broader range of gastroenteropancreatic NETs are available from large institutional series that include >1000 patients. Long-term toxicities from these series have included rare cases of acute leukemia and myelodysplastic syndrome, presumably associated with radiation exposure. Nevertheless, these studies generally support both the efficacy and safety of ^{177}Lu-dotatate as a treatment for patients with a range of somatostatin receptor–positive NETs.

ALKYLATING AGENTS

While the efficacy of traditional cytotoxic chemotherapy appears to be minimal in most extrapancreatic GI NETs, alkylating agents have a clear role in the treatment of advanced pancreatic NETs. Streptozocin-based combination therapy was historically used as treatment standard in such patients but has largely fallen out of favor due to both toxicity concerns and a cumbersome administration schedule. Temozolomide is an orally administered alkylating agent that has largely replaced streptozocin as a backbone in combination regimens used for the treatment of pancreatic NETs.

Initial studies evaluating temozolomide in combination with a range of different agents showed that temozolomide-based combination therapy was associated with tumor responses in 24–70% of patients. One of the most active combination regimens appeared to be temozolomide and capecitabine. This combination was subsequently compared to

temozolomide alone in a prospective randomized study undertaken by the Eastern Cooperative Oncology Group that enrolled 144 patients with advanced pancreatic NETs. The overall response rates in the two arms were relatively similar; 33% of patients who received the combination of temozolomide and capecitabine experienced objective tumor responses as compared to 28% of the patients who received temozolomide as a single agent. However, progression-free survival was significantly longer in the combination arm (22.7 vs 14.4 months). Based on these results, the combination of temozolomide and capecitabine is now the preferred chemotherapy combination for advanced pancreatic NETs.

The reason that some pancreatic NETs respond to alkylating agents while others do not is uncertain. In patients with glioblastoma, methylation of the promoter region for methylguanine DNA methyltransferase (MGMT) is associated with decreased MGMT protein expression and is highly associated with temozolomide responsiveness. MGMT is an enzyme that is responsible for repairing DNA damage induced by alkylating agents. Reduced levels of MGMT presumably impair the ability of tumor cells to repair their DNA in response to treatment and enhance the cytotoxicity of temozolomide. Several retrospective studies have suggested that lack of MGMT expression in pancreatic NET may be associated with responsiveness to temozolomide-based therapy; however, this finding has not yet been prospectively validated.

SMALL-MOLECULE TYROSINE KINASE INHIBITORS

The highly vascular nature of NETs combined with observations in preclinical models that disruption of signaling pathways associated with VEGF inhibits neuroendocrine cell growth prompted a number of clinical trials evaluating therapeutic agents that inhibit the VEGF pathway in both pancreatic and extrapancreatic NETs. The VEGF pathway is activated through the binding of VEGF to its cell surface receptor, which initiates an intracellular signaling cascade that promotes angiogenesis as well as cell growth, proliferation, and survival. Clinical trials of VEGF pathway inhibitors in NETs have included a number of small-molecule tyrosine kinase inhibitors that, while they differ to some extent in specificity, all have in common the property targeting VEGFR2, the receptor isoform most strongly implicated in promoting angiogenesis.

Sunitinib, a multitargeted tyrosine kinase inhibitor that inhibits a range of growth factor receptors including VEGFR2, was one of the first agents in this class found to have activity in pancreatic NETs. In an initial phase 2 trial, sunitinib was administered to 109 patients with either pancreatic or extrapancreatic NET. Of 61 patients with pancreatic NET enrolled in the study, 11 had evidence of an objective tumor response. Based on these observations, sunitinib was evaluated in an international, randomized trial in which continuous administration of sunitinib (37.5 mg daily) was compared with placebo in 171 patients with advanced, progressive pancreatic NET. The median progression-free survival was significantly longer in patients treated with sunitinib compared with patients treated with placebo (11.4 vs 5.5 months). Common side effects associated with sunitinib included hypertension, proteinuria, and fatigue.

A second VEGFR-targeted tyrosine kinase inhibitor, surufatinib, has been evaluated in a randomized trial in which 264 patients with advanced pancreatic NETs from 21 centers in China were randomized to receive either surufatinib, administered at a dose of 300 mg daily, or placebo. Patients receiving surufatinib experienced a median progression-free survival duration of 10.9 months, as compared to 3.7 months in patients receiving placebo, closely mirroring the results of the earlier sunitinib study. Other small-molecular tyrosine kinase inhibitors have been evaluated in smaller, single-arm studies and have shown activity in pancreatic NETs, including sorafenib, cabozantinib, pazopanib, and axitinib.

Small-molecule tyrosine kinase inhibitors targeting the VEGF pathway have also been evaluated in patients with advanced nonpancreatic GI NET. In most of these studies, objective tumor response rates are lower than those seen in pancreatic NET, though many of these initial studies also revealed low rates of tumor progression and encouraging progression-free survival durations, suggesting that these agents had antitumor activity. Pazopanib was compared to placebo in a randomized study undertaken by the ALLIANCE cooperative group, which enrolled 171 patients with nonpancreatic NETs. Patients treated with pazopanib in this study had a superior progression-free survival compared to those who received placebo (11.6 vs 8.5 months), a difference that was statistically significant. Surufatinib was used in a randomized study of 198 patients with extrapancreatic NETs; the median progression-free survival was 9.2 months in patients receiving surufatinib and 3.8 months in those receiving placebo, a statistically significant difference. These studies suggest that VEGF-targeted tyrosine kinase inhibitors have antitumor activity in extrapancreatic and pancreatic NETs.

mTOR INHIBITORS

mTOR is an intracellular protein kinase that has been implicated in the regulation of a number of processes regulating cell growth in both normal and malignant cells. It functions as a downstream component of the PI3-AKT-mTOR pathway. This pathway is negatively regulated by the tuberous sclerosis complex, comprising TSC1 and TSC2. An association between the development of pancreatic NETs and inherited mutations in *TSC2* in patients with tuberous sclerosis complex was a contributing factor to initial interest in exploring mTOR inhibition as a therapeutic approach in this setting.

Following initial evidence of antitumor activity associated with everolimus (10 mg daily) in an international, multicenter, phase 2 trial of 160 patients, everolimus monotherapy (10 mg daily) was compared with best supportive care alone in the RADIANT-3 trial that enrolled 410 patients with advanced progressing pancreatic NET. While overall objective responses were uncommon, treatment with everolimus was associated with a significant prolongation in median progression-free survival (11.0 vs 4.6 months) compared to placebo, supporting its use as a standard treatment to control tumor growth in patients with advanced pancreatic NET. Common toxicities associated with everolimus are generally mild and can include stomatitis and rash; a more severe but less common side effect is pneumonitis.

Everolimus was also associated with promising activity in early phase 2 studies enrolling patients extrapancreatic NET. The first large randomized study evaluating everolimus was the RADIANT 2 trial; 429 patients with advanced GI NETs were randomly assigned to receive octreotide LAR (30 mg intramuscularly every 28 days) with or without everolimus (10 mg daily). Treatment with everolimus in this study was associated with an improvement in median progression-free survival (16.4 vs 11.3 months), but the difference in this study was of only borderline statistical significance. A second study, the RADIANT 4 study, enrolled 302 patients with advanced NETs of either GI (excluding pancreatic) or lung origin, randomizing them to receive either everolimus or placebo. In this study, treatment with octreotide was not required. As in the RADIANT 3 study, objective tumor responses were uncommon; however, median progression-free survival in patients who received everolimus was significantly longer than in those who received placebo (11 vs 3.9 months). Based on the results of this study, everolimus is considered a standard treatment for control of tumor growth in extrapancreatic NETs.

OTHER SYSTEMIC TREATMENTS FOR CONTROL OF TUMOR GROWTH

Interferon α has been used as a treatment for advanced NETs for several decades. With the development of newer approaches, its routine use has diminished. The use of interferon α was based primarily on observations in large, retrospective series where low-dose interferon α was reported to both reduce symptoms of hormonal hypersecretion and slow tumor progression. Interferon can be myelosuppressive, requiring dose titration, and in some patients can induce both fatigue and depression. Antitumor activity has also been reported with oxaliplatin-based chemotherapy regimens. A combined analysis of two phase 2 trials examining oxaliplatin-fluoropyrimidine chemotherapy plus bevacizumab in advanced NET suggested antitumor activity for these regimens; the benefit appeared to be greatest in patients with intermediate-grade rather than low-grade tumors.

SYSTEMIC THERAPY FOR HIGH-GRADE NEUROENDOCRINE CARCINOMA

High-grade NETs are relatively uncommon; their clinical behavior is fundamentally different from well-differentiated NETs in that these tumors pursue an aggressive clinical course. Systemic chemotherapy for advanced high-grade neuroendocrine carcinoma has historically followed a paradigm analogous to that used for small-cell carcinoma of the lung, with combinations of either cisplatin or carboplatin administered together with etoposide generally considered the preferred first-line approach. One of the most important elements in determining the optimal chemotherapeutic approach is assessing the Ki-67 proliferative index. A large retrospective series that evaluated 252 patients with high-grade neuroendocrine carcinoma found that the activity of platinum-based therapy was greatest in patients who had a Ki-67 proliferative index of 55% or higher; in these patients, the overall tumor response rate was 42%. In contrast, the overall response rate in patients in whom the Ki-67 proliferative index was <55% was only 15%. As in small-cell carcinoma of the lung, immune checkpoint inhibitors also appear to have some activity in high-grade neuroendocrine carcinoma. While minimal activity has been noted in well-differentiated NETs, a combination of ipilimumab and nivolumab was associated with an overall tumor response rate of 42% in an initial phase 2 trial enrolling 19 patients with high-grade neuroendocrine carcinoma.

85 Renal Cell Carcinoma

Robert J. Motzer, Martin H. Voss

Renal cell carcinomas account for 90–95% of malignant neoplasms arising from the kidney. Notable features include frequent diagnosis without symptoms, resistance to cytotoxic agents, robust activity of angiogenesis-targeted agents, immune infiltration commonly rendering tumors susceptible to checkpoint-directed immunotherapy, and a variable clinical course for patients with metastatic disease, including anecdotal reports of spontaneous regression. Most of the remaining 5–10% of malignant neoplasms arising from the kidney are transitional cell carcinomas (urothelial carcinomas) originating in the lining of the renal pelvis. See **Chap. 86** for transitional cell carcinomas.

EPIDEMIOLOGY

The incidence of cancers of the kidney and renal pelvis rose for three decades, reached a plateau of approximately 64,000 cases annually in the United States between 2012 and 2018, but has since increased to approximately 76,000 cases annually, resulting in close to 14,000 deaths per year. It is the eighth most common cancer overall in the United States, the sixth most common in males, and the eighth most common in females; the male-to-female ratio is 2:1. Although this malignancy may be diagnosed at any age, it is uncommon in those under 45 years, and incidence peaks between the ages of 55 and 75 years. Many factors have been investigated as possible contributing causes; associations include cigarette smoking, obesity, and hypertension. Risk is also increased for patients with polycystic kidney disease that has been complicated by chronic renal failure.

Most cases of renal cell carcinoma (RCC) are sporadic, although familial forms have been reported **(Table 85-1)**. One well established example includes clear cell RCC arising in the context of von Hippel-Lindau (VHL) syndrome, an autosomal dominant disorder. Genetic studies identified the *VHL* gene on the short arm of chromosome 3. Individuals with VHL syndrome have an estimated lifetime risk of developing clear cell RCC of around 70%. Other *VHL*-associated neoplasms include retinal hemangioma, hemangioblastoma of the spinal cord and cerebellum, pheochromocytoma, and neuroendocrine tumors and cysts. Birt-Hogg-Dubé syndrome is a rare human autosomal dominant genetic disorder characterized by fibrofolliculomas (benign tumors arising in hair follicles), pulmonary cysts, and renal cell carcinomas of varying histologies, most commonly the chromophobe type, occurring in about a third of patients. This disorder is associated with mutations in the *FLCN* gene, which codes for folliculin. Other hereditary syndromes are summarized in Table 85-1.

PATHOLOGY AND GENETICS

Renal cell malignancies represent a heterogeneous group of tumors with distinct histopathologic, genetic, and clinical features **(Table 85-2)**. Categories include clear cell carcinoma (70% of cases), papillary tumors (10–15%), chromophobe tumors (≤5%), renal medullary carcinoma (<1%), translocation carcinoma (<5%), and other less common variants. Papillary tumors can be bilateral and multifocal. Chromophobe tumors tend to have a more indolent clinical course. Translocation-associated RCC, rare in adult patients, is the predominant histology in children. Renal medullary carcinoma is rare, very aggressive, and associated with sickle cell trait. Tumors that do not meet criteria for defined variants are generally referred to as "unclassified" with variable clinical courses.

Clear cell tumors, the predominant histology, are found in >80% of patients who develop metastases and arise from the epithelial cells of the proximal tubules. Loss of chromosome 3p is uniformly seen as the earliest event in the development of these cancers. This leads to loss of heterozygosity for a number of relevant 3p genes, including *VHL*, *PBRM1*, *BAP1*, and *SETD2*, which can be functionally lost through secondary events in the remaining allele. *VHL* encodes a tumor suppressor protein that is involved in regulating the transcription of vascular endothelial growth factor (VEGF) and a number of other effectors through ubiquitination of hypoxia-inducible factors (HIF). Inactivation of *VHL*, through upregulation of VEGF signaling, promotes tumor angiogenesis and growth, ultimately rendering clear cell RCC cells susceptible to antiangiogenesis therapy.

Large-scale sequencing efforts have helped elucidate recurrent patterns of genomic evolution that correlate with distinct clinical phenotypes, e.g., varying levels of aggressiveness or specific patterns of metastatic spread. For example, early loss of chromosome 9p appears to confer a high risk for early metastatic dissemination and correlates with poor cancer-specific survival.

A growing number of other RCC variants are well defined (see Table 85-2 for examples). For instance, up to 15% of RCCs are of the papillary subtype, with several subtypes that can be distinguished either by light microscopy or tumor genomics. For example, activating mutations in the *MET* oncogene or gain of chromosome 7 (where *MET* is located) are hallmark events of type 1 papillary RCC and considered

TABLE 85-1 Hereditary Renal Cell Tumors

SYNDROME	CHROMOSOME(S)	GENE	PROTEIN	KIDNEY TUMOR TYPE	ADDITIONAL CLINICAL FINDINGS
von Hippel-Lindau syndrome	3p25	*VHL*	von Hippel-Lindau protein	Clear cell	Hemangioblastoma of the retina and central nervous system; pheochromocytoma; pancreatic and renal cysts; neuroendocrine tumors
Hereditary papillary RCC	7p31	*MET*	MET	Papillary (type I)	Bilateral and multifocal kidney tumors
Hereditary leiomyomatosis and RCC (HLRCC syndrome)	1q42	*FH*	Fumarate hydratase	Papillary (non–type I)	Leiomyoma; uterine leiomyoma/ leiomyosarcoma
Birt-Hogg-Dubé syndrome	17p11	*FLCN*	Folliculin	Chromophobe; oncocytoma	Facial fibrofolliculoma; pulmonary cysts
Tuberous sclerosis	9q34 16p13	*TSC1* *TSC2*	Hamartin Tuberin	Angiomyolipomas; lymphangioleiomyomatosis; rare RCC with variety of histologic appearances	Angiofibroma, subungual fibroma; cardiac rhabdomyoma; adenomatous small intestine polyps; pulmonary and renal cysts; cortical tuber; subependymal giant cell astrocytomas

Abbreviation: RCC, renal cell carcinoma.

actionable via targeted MET inhibitors. Tumors of the less common chromophobe subtype originate from the distal nephron. They are in part driven by changes in mitochondrial gene function and typically characterized by aneuploidy with common loss of an entire chromosome copy for chromosomes 1, 2, 6, 10, 13, and 17.

CLINICAL PRESENTATION

Presenting signs and symptoms may include hematuria, flank or abdominal pain, and a palpable mass. Other symptoms are fever, weight loss, anemia, and a varicocele. Tumors are, however, commonly detected as an incidental finding on a radiograph. Widespread use of radiologic cross-sectional imaging (computed tomography [CT], magnetic resonance imaging [MRI]) contributes to earlier detection of renal masses during evaluation for other medical conditions. The increasing number of incidentally discovered low-stage tumors has contributed to an improved 5-year survival for patients with RCC and increased use of nephron-sparing surgery (partial nephrectomy). A spectrum of paraneoplastic syndromes has been associated with these malignancies, including erythrocytosis, hypercalcemia, nonmetastatic hepatic dysfunction (Stauffer's syndrome), and acquired dysfibrinogenemia. Erythrocytosis is noted at presentation in only about 3% of patients. Anemia, commonly a sign of more advanced disease, is more common. Kidney cancer was called the "internist's tumor" since it was often discovered from the initial presentation of a paraneoplastic syndrome. This was more common before the era of modern imaging, as was initial presentation by the classic triad of hematuria, flank pain, and a palpable abdominal mass.

The standard evaluation of patients with suspected renal tumors includes a CT scan of the abdomen and pelvis, chest radiograph, and urine analysis. If metastatic disease is suspected from the chest radiograph, a CT of the chest is warranted. MRI is useful in evaluating the inferior vena cava in cases of suspected tumor involvement or invasion by thrombus, or when intravenous contrast administration given with CT is prohibited by impaired renal function. In clinical practice, any solid renal masses should be considered malignant until proven otherwise; a definitive diagnosis is required. If no metastases are demonstrated, surgery is indicated, even if the renal vein or inferior vena cava is invaded. In small tumors (particularly those of clear cell variant) the risk of impending metastatic spread is lower and surgery can potentially be delayed. In that setting, a needle biopsy should be performed to confirm the underlying histology, and radiographic surveillance is indicated until the time of surgery. The differential diagnosis of a renal mass includes cysts, benign neoplasms (adenoma, angiomyolipoma, oncocytoma), inflammatory lesions (pyelonephritis or abscesses), and other malignancies originating in the kidney such as transitional cell carcinoma of the renal pelvis, sarcoma, lymphoma, and Wilms' tumor or metastases from cancers originating in other organs. All of these are less common causes of renal masses than is RCC. The most common sites of distant metastases are the lungs, lymph nodes, liver, bone, and brain. These tumors may follow an unpredictable and protracted clinical course.

STAGING AND PROGNOSIS

Staging is based on the American Joint Committee on Cancer (AJCC) staging system **(Fig. 85-1)**. Stage I tumors are ≤7 cm in greatest diameter and confined to the kidney, stage II tumors are >7 cm and confined to the kidney, stage III tumors extend through the renal capsule but are confined to Gerota's fascia, grossly infiltrate the renal vein, or involve regional lymph nodes (N1), and stage IV disease includes tumors that have invaded adjacent organs or involve nonregional lymph nodes or distant metastases. Sixty-five percent of patients present with stage I or II disease, 15–20% with stage III, and 15–20% with stage IV. The 5-year survival rate is currently 75% across all RCCs, but varies greatly by stage.

TABLE 85-2 Classification of Malignant Epithelial Neoplasms Arising from the Kidney

CARCINOMA TYPE	CHARACTERISTIC GROWTH PATTERN	CHROMOSOMAL EVENTS	GENES WITH RECURRENT SOMATIC ALTERATIONS
Clear cell	Acinar or sarcomatoid	3p–, 5q+, 14q–, 9p–	*VHL, PBRM1, BAP1, SETD2*
Papillary	Papillary or sarcomatoid	+7, +17, 9p–	*MET, FH, CDKN2A* (focal deletions)
Chromophobe	Solid, tubular, or sarcomatoid	Whole arm losses (1, 2, 6, 10, 13, 17, and 21)	*TP53, PTEN, TERT* promotor
Renal medullary carcinoma	Varying growth patterns, including cribriform, reticular, sarcomatoid, adenoid, and microcystic	+8q, 22q–, 22q translocations	*SMARCB1* (focal deletions, mutations, gene fusions), *SETD2*
MITF translocation[a]	Mimicking clear cell and papillary variants	Xp11.2 translocations; t(6;11) translocations	*TFE3* gene fusions, *TFEB* gene fusions

Prognostic risk models are helpful for counseling patients diagnosed with metastatic disease and for anticipating survival rates when designing a clinical trial. A widely used prognostic model for advanced disease, the International Metastatic RCC Database Consortium (IMDC) risk model, incorporates six factors shown to correlate with worse survival: poor performance status, low hemoglobin concentration, high serum calcium, high neutrophil levels, high platelet levels, and <1-year interval from diagnosis to systemic treatment. Patients with zero risk factors had significantly longer median survival (43 months) than patients with one or two risk factors (22.5 months) and those with three to six risk factors (8 months) when treated with first-line angiogenesis inhibitors (see below).

TREATMENT

Renal Cell Carcinoma

LOCALIZED TUMOR

The standard management for stage I or II tumors and selected cases of stage III disease is radical or partial nephrectomy. A radical nephrectomy involves en bloc removal of Gerota's fascia and its contents, including the kidney, and commonly the ipsilateral adrenal gland and regional lymph nodes that appear abnormal on imaging or intraoperatively. Open, laparoscopic, or robotic surgical techniques may be used. The role of a template lymphadenectomy in patients without apparent lymphadenopathy is controversial. Extension into the renal vein or inferior vena cava (stage III disease) does not preclude resection, which would then include thrombectomy.

Nephron-sparing approaches, i.e., open or laparoscopic partial nephrectomy, may be appropriate depending on the size and location of the tumor. This approach is particularly relevant for patients with solitary kidneys, bilateral tumors, or chronic renal insufficiency but can also be applied electively to resect small masses for patients with normal kidney function. Radical nephrectomy carries a greater risk for chronic kidney disease and cardiovascular morbidity and mortality.

Adjuvant systemic therapies, including cytokines and targeted agents, have been studied in randomized clinical trials, largely with negative results, and the standard of care remains active surveillance after nephrectomy.

METASTATIC DISEASE

Surgery has a limited role for patients with metastatic disease. Long-term survival may occur in patients who relapse with a solitary site that is removed (metastasectomy). Nephrectomy despite presence of metastases (cytoreductive nephrectomy) is considered for carefully selected patients with stage IV disease. One indication for this approach can be to alleviate pain or hemorrhage of a primary tumor.

Radiation therapy is used for palliation of bone or brain metastases. The type of radiotherapy most commonly used is external-beam therapy, including stereotactic radiosurgery and other forms of image-guided radiotherapy.

Systemic therapy is the mainstay of care for metastatic disease. The timing of initiating such treatment should be carefully considered; some patients are asymptomatic at diagnosis, and with indolent behavior, it may be best to document progression before initiating treatment.

Metastatic RCC is refractory to cytotoxic chemotherapy. Patients are treated with molecularly targeted agents, including targeted immunotherapies. Treatments are continued with noncurative intent while tolerated and until disease progression is evident on cross-sectional imaging. Outcomes for patients with metastatic disease improved when increased understanding of underlying biology led to the successful development of several tyrosine kinase inhibitors (TKIs) targeting proangiogenic signaling through the VEGF receptors as well as allosteric inhibitors of mammalian target of rapamycin (mTOR) signaling. Serial large-scale randomized trials demonstrated that such agents, typically orally available, could be administered sequentially and in combination. Pivotal studies, by design, defined a dedicated space for each regimen in treatment-naïve or pretreated patients **(Table 85-3)**.

Targeted immunotherapies were introduced after VEGF- and mTOR-directed agents had established standards of care in the first- and second-line setting. Nivolumab, a checkpoint inhibitor targeting PD-1, was compared to the mTOR inhibitor everolimus in a randomized trial in patients who had progressed on prior TKI therapy, challenging the standard approach in pretreated patients. Nivolumab demonstrated superior overall survival, positioning it as the new second-line agent of choice. Subsequently, immunotherapy combination regimens demonstrated efficacy in randomized trials conducted in treatment-naïve patients. In separate studies, two doublets demonstrated survival benefit over standard sunitinib therapy and changed the standard of care for untreated metastatic clear cell RCC: nivolumab in combination with the CTLA-4-directed checkpoint inhibitor ipilimumab proved superior to sunitinib in patients with high-risk features per the IMDC model, achieving complete radiographic disappearance of cancer in >10% of patients treated with the combination. In a second trial, the combination of the

TABLE 85-3 Commonly Used Systemic Regimens for Metastatic Renal Cell Carcinoma

PD-1 inhibitor + TKI	Pembrolizumab + axitinib	2019	Advanced RCC, first line

Abbreviations: CTLA-4, cytotoxic T-lymphocyte-associated protein; FDA, U.S. Food and Drug Administration; mTOR, mammalian target of rapamycin; PD-1, programmed cell death-1; RCC, renal cell carcinoma; TKI, tyrosine kinase inhibitor.

TKI axitinib together with the PD-1 inhibitor pembrolizumab was superior to sunitinib alone in all-comers with untreated metastatic RCC, again with high response rates across all IMDC risk groups. In both trials, responses were long-lasting, with improved time to disease progression and longer overall survival for combination regimens. Additional trials are ongoing to fortify the new standard of combination therapy in the first line.

With an ever-growing number of approved options directed toward different molecular targets, biomarkers are urgently needed to help individualize therapeutic choices and to gain insight as to whether and why treatments are working. Although a multitude of candidate biomarkers have been investigated for their predictive value in metastatic RCC, none have been validated for clinical use to date.

Projected overall survival in patients starting systemic therapies for newly diagnosed metastatic disease has tripled over the past 15–20 years; this can largely be attributed to the successful drug developments discussed here.

GLOBAL CONSIDERATIONS

Worldwide, over 400,000 patients are diagnosed each year with malignant tumors arising from the kidney, resulting in >175,000 deaths annually. Kidney cancer is the 10th most common cancer in men and the 15th most common cancer in women. Higher incidence is observed in developed countries, including the United States, Canada, Europe, Australia, New Zealand, and Uruguay. Relatively low rates are reported in Southeast Asia and Africa. The incidence of kidney cancer has been steadily increasing over the past four decades. Mortality trends have stabilized in Europe and the United States, but not in less developed countries. This is likely related to differences in access to optimal therapies. Treatment guidelines for both localized and metastatic renal cancer are similar between U.S. and European documents and contingent on the access to adequate health care and availability of targeted drugs to treat metastases.

86 Cancer of the Bladder and Urinary Tract

Noah M. Hahn

GLOBAL CONSIDERATIONS

Within the United States, urothelial carcinomas of the bladder and urinary tract are most closely related to tobacco smoking history. However, within developing countries, water supplies contaminated with arsenic or schistosomiasis parasites also are major carcinogenic contributors.

INTRODUCTION

Cancers of the urinary tract including the bladder, renal pelvis, ureter, and urethra occur frequently, and they represent the second most common class of genitourinary cancers. Bladder cancer alone represents the sixth most common cancer diagnosis annually in the United States with 81,400 new cases and 17,980 deaths every year. Because cancers of the renal pelvis are often lumped in with all kidney cancers, the true incidence and mortality from nonbladder urinary tract cancers are less precise. While less frequent than bladder cancer, an additional 20,000 new cases and 5000 deaths are estimated every year. An accelerated understanding of the molecular underpinnings of bladder and urinary tract cancer biology has led to a significant increase in urothelial cancer clinical trials resulting in U.S. Food and Drug Administration (FDA) approval of multiple new therapeutic agents since 2016 with more expected to follow. This chapter reviews the established, current, and emerging evidence that serves as the basis for the rapidly evolving standards of care for patients with bladder and urinary tract cancers.

CLINICAL EPIDEMIOLOGY AND RISK FACTORS

Bladder cancer typically affects older patients with a median age at diagnosis of 73 years. Males are four times more frequently affected than females. Similarly, bladder cancer is more common in Caucasians than in Asian patients. Inheritable germline genetic risk factors have been identified in up to one-seventh of patients with bladder or urinary tract cancers. However, a singular germline genetic alteration has not

been observed in a majority of these cases, and the impact of germline genetic alterations on family members of urothelial cancer patients is uncertain. Patients with defects in mismatch repair genes leading to microsatellite instability (*MLH1, MSH2, MSH6*, etc.) as part of the familial cancer Lynch syndrome are at particular risk of upper urinary tract cancers of the renal pelvis and ureter. Additionally, patients with Cowden disease (*PTEN* mutations) or retinoblastoma (*RB1* mutations) are at increased risk for developing bladder cancer.

Historically, associations have existed between environmental toxic exposures and higher rates of developing bladder cancer. Carcinogenic agents associated with increased risk of bladder cancer have included the aromatic amines benzidine and beta-naphthylamine that can be present in industrial dyes as well as arsenic that can be found in some drinking water supplies in underdeveloped countries. Other chemicals in the leather, paint, rubber, textiles, and printing industries have been associated with bladder cancer. Associations with exposures to hair dyes and hair sprays in workers in the hairstyling field have been suggested. Additionally, concern has been raised regarding use of the antidiabetic medication, pioglitazone, and bladder cancer risk. Extensive reviews and meta-analyses have produced differing conclusions. The data suggest a small risk of bladder cancer from long-term pioglitazone use, which has led to inclusion of bladder cancer risk within the pioglitazone prescribing information. An association between chronic inflammatory states and the development of squamous bladder cancer clearly exists in underdeveloped countries in patients chronically infected with the parasitic disease schistosomiasis and in paraplegic patients with chronic indwelling catheters. Above and beyond each of these associations, however, smoking of tobacco products (cigarettes, cigars, pipes, etc.) remains the overwhelming leading risk factor for development of bladder cancer. Among new bladder cancer diagnoses, 90% of cases occur in current or former smokers. Toxicologists have estimated that >70 confirmed carcinogenic toxins are present within tobacco smoke. It is estimated that one-third of bladder cancer cases could be prevented through simple modification of lifestyle choices, in particular cessation of smoking.

CLINICAL PRESENTATION AND DIAGNOSTIC WORKUP

Occasionally, patients will present with flank pain in association with an upper tract renal pelvis or ureter cancer or due to hydronephrosis in association with a bladder tumor obstructing the orifice of the ureter within the bladder. Only in rare cases do patients present with significant cachexia and widespread metastatic disease. For most patients, painless hematuria (either gross or microscopic) represents the initial manifestation of an underlying urinary tract cancer. In females, hematuria due to malignancy can often be mistaken for a urinary tract infection or menstrual bleeding. While treatment with antibiotics is warranted if a concurrent urinary tract infection is noted on initial urinalysis, persistent hematuria requires further workup. Painless hematuria in males is almost always abnormal and should be worked up. Initial investigations in patients of either sex should include urine cytology and visual examination of the bladder by cystoscopy. Cytology is successful in identifying cancer in only 50% of individuals with high-grade bladder cancers. In addition to urine cytology, radiographic evaluation of the kidneys and upper urinary tract by CT urogram should be performed. Because of the increased sensitivity and reduced IV contrast loads, CT urograms have largely replaced IV pyelograms as the preferred upper urinary tract imaging modality. A magnetic resonance (MR) urogram may be substituted in patients with poor renal function. Additional diagnostic testing of the urine to assess for cancer-associated chromosomal changes by fluorescent in situ hybridization, increased levels of nuclear mitotic proteins, increased bladder tumor–associated antigens, or higher levels of staining on cells shed by the bladder may identify some cancers missed by traditional cytology testing. However, they may also produce abnormal results in patients who do not have cancer. For now, these adjunct molecular tests are primarily utilized in detecting recurrent cancer in patients with a prior diagnosis of urinary tract cancer. Small tumors, particularly flat noninvasive tumors of the bladder, may be detected at higher rates with the use of blue light cystoscopy or narrow-band imaging cystoscopy. Both blue light and narrow-band imaging cystoscopies are now used routinely in the monitoring of patients with bladder cancer. For patients with no bladder abnormalities in whom upper tract tumors are suspected, visualization of the upper urinary tracts and renal pelvises should be performed by ureteroscopy or retrograde pyelography.

In all patients with abnormalities noted in the bladder or upper urinary tracts, complete endoscopic resection for histologic diagnosis and staging should be performed when possible via either transurethral resection of bladder tumor (TURBT) or endoscopic resection of upper tract tumors.

HISTOLOGY

Urothelial carcinoma, often called transitional cell carcinoma in the past, is the most common urinary tract cancer histology and is observed in ~90% of cases. Squamous, glandular, micropapillary, plasmacytoid, sarcomatoid, and other variant features can often be found in portions of urothelial carcinoma tumors; however, pure variant histologies are rare. The presence of some variant histologies including micropapillary and plasmacytoid has been associated with worse surgical outcomes compared to urothelial carcinoma. Nonurothelial variant histologies including squamous cell carcinoma, adenocarcinoma, small-cell carcinoma, and carcinosarcoma collectively account for ≤10% of urinary tract tumors. Examples of traditional urothelial carcinoma and some of the variant histologies are shown in **Fig. 86-1**.

MOLECULAR BIOLOGY

Clinically, urothelial carcinoma of the bladder displays a biphasic phenotype characterized by (1) low-grade papillary tumors that frequently recur but rarely invade or metastasize and (2) high-grade sometimes flat tumors that invade early leading to lethal metastatic disease. In both of these phenotypes, loss of portions of chromosomes 9q and 9p by loss of heterozygosity is an early molecular event, whose exact significance is not clear. Potential candidate regulatory genes in these genomic regions include *CDNK2A,* a cyclin-dependent kinase inhibitor, and *TSC1,* a gene encoding hamartin mutated in tuberous sclerosis. Early investigations have demonstrated that low-grade tumors are characterized by alterations in the *RAS/RAF* signaling pathway with activating *FGFR3* mutations or gene fusions present in 60–80% of patients. In contrast, the high-grade invasive phenotype is notable for early deleterious mutations in *TP53* and *RB1*, alterations in *CDH1* (E-cadherin), and increased expression of *VEGFR2.* In urothelial carcinoma of the renal pelvis and ureter, 10–20% of cases may be associated with Lynch syndrome hereditary defects in the *MLH1*, *MSH2*, or *MSH6* mismatch repair genes, leading to microsatellite instability and frequent DNA mutations. Testing for germline mutations in these genes is recommended in patients with upper urinary tract urothelial carcinoma under the age of 60 at diagnosis, with a first-degree relative with a Lynch syndrome–associated cancer diagnosed under the age of 50, or with two first-degree relatives with a Lynch syndrome–associated cancer regardless of the age at diagnosis.

As genomic analysis technologies have improved, so has our understanding of the molecular biology unique to urothelial carcinoma. In 2017, the full bladder cancer results of The Cancer Genome Atlas (TCGA) project were published. This effort comprehensively analyzed gene mutations, fusions, expression, copy number variations, methylation, and microRNA across the genome of patients with bladder urothelial carcinoma treated with surgery. Key findings from this effort include (1) genomic alterations in genes (e.g., *FGFR3*, *EGFR*, *ERBB2*, *ERBB3*, *PIK3CA*, *TSC1*, etc.) targetable by currently approved drugs or drugs in development in 71% of patients; (2) genomic alterations in chromatin-modifying genes (*KMT2D, KDM6A, KMT2C, EP300, CREBBP*, etc.) in the majority of patients; (3) hypermethylation with epigenetic silencing of gene expression in one-fourth of patients; and (4) the identification by RNA sequencing of five distinct intrinsic molecular subtypes (luminal papillary, luminal infiltrated, luminal, basal squamous, and neuronal) closely resembling luminal and basal subclassifications of breast cancers. These bladder TCGA findings have led to clinical trial designs enriching for patients with specific

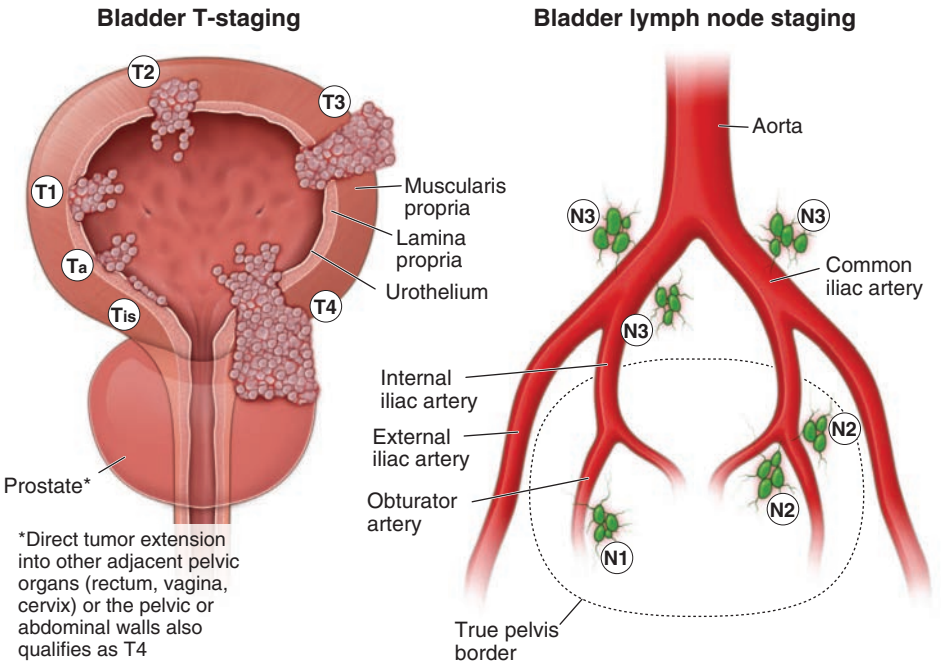
gene mutation profiles as well as interrogation of candidate biomarkers according to intrinsic molecular subtypes.

STAGING AND OUTCOMES BY STAGE

The staging of bladder cancer is dependent on the depth of invasion within the bladder wall, involvement of lymph nodes, and spread to surrounding and distant organs as depicted in Fig. 86-2. Approximately 75% of bladder cancer presents with non–muscle-invasive bladder cancer (NMIBC), 18% with disease invading into or through the muscular wall of the bladder, and only 3% presenting with metastatic spread to distant organs. NMIBC is defined by tumors that involve only the immediate epithelial layer of cells (carcinoma in situ [CIS] and Ta) or that only penetrate into the connective tissue below the urothelium (T1) but not into the muscular layer known as the *muscularis propria*. Muscle-invasive bladder cancer (MIBC) is defined by tumors that invade into the muscularis propria (T2), through the muscularis propria to involve the surrounding serosa (T3), or into immediately adjacent pelvic organs such as the rectum, prostate, vagina, or cervix (T4). Lymph node staging is classified according to involvement of a solitary node within the true pelvis (N1), two nodes involved in the true pelvis (N2), or involvement of the common iliac nodes (N3). Any disease that has spread beyond the common iliac nodes is considered metastatic (M1). The staging of bladder cancer is driven primarily by the T stage of the tumor, with stages 0a–II defined entirely by the T stage in the absence of nodal or metastatic disease. Involvement of regional lymph nodes in the true pelvis or along the common iliac artery qualifies as stage III disease, whereas involvement of any distant metastases qualifies as stage IV disease. Clinical outcomes of patients with bladder cancer correlate closely with staging at diagnosis with 5-year overall survival rates of 70–90% for disease confined to the bladder (stage I–II), 36–50% for disease that penetrates through the bladder or has spread to regional lymph nodes (stage III), and only 5% for disease extending to metastatic sites (stage IV).

TREATMENT APPROACHES

Early-Stage Disease For NMIBC, removal of all visible tumors by TURBT in the operating room is considered the mainstay of surgical treatment. Risk of recurrence can be classified as low, intermediate, or high depending on the presence of features summarized in Table 86-1. For patients with low-risk disease, meta-analyses have demonstrated a 12% reduction in early relapses when a single chemotherapy treatment of mitomycin C, epirubicin, or gemcitabine was instilled directly into the bladder (intravesical therapy) within 24 hours of the TURBT. For patients with intermediate- or high-risk tumors, weekly intravesical instillations for 6 consecutive weeks of the attenuated mycobacterium strain known as *Bacille Calmette-Guérin* (BCG) reduce the risk of recurrence at 12 months from 56 to 29%. In addition, BCG treatment has been shown to decrease the rate of progression to MIBC by 27%. Intravesical



Bladder cancer prognosis according to stage

T	N	M	Stage	5-yr survival
Tis/Ta	N0	M0	0is/0a	96%
T1	N0	M0	1	90%
T2	N0	M0	2	70%
T3	N0	M0	3	50%
T1-T4	N1-N3	M0	3	36%
Any T	Any N	M1	4	5%

N1 - Cancer spread to 1 lymph node in the true pelvis

N2 - Cancer spread to 2 lymph nodes in the true pelvis

N3 - Cancer spread to lymph nodes along the common iliac artery

FIGURE 86-2 Bladder cancer staging and prognosis. TNM, tumor-node-metastasis.

BCG is generally well tolerated. Side effects can include dysuria, urinary frequency, bladder spasms, hematuria, and, in rare cases (<5%), a systemic inflammatory response that can mimic disseminated BCG infection. Following a 6-week induction BCG schedule, additional maintenance BCG treatments given according to the Southwest Oncology Group schedule further reduce the risk of recurrent NMIBC compared to induction BCG alone. In patients with NMIBC that recurs long after initial BCG treatment, a repeat course of BCG can be considered. For patients with recurrence after a second adequate course of BCG or with relapsed NMIBC within 6 months of initial BCG exposure, surgical removal of the entire bladder by cystectomy is recommended due to the high risk of progression to MIBC and potentially metastatic disease. For patients who are not fit enough for or who refuse cystectomy, non-BCG alternative intravesical agents (mitomycin C, gemcitabine, docetaxel, valrubicin) or systemically administered agents that inhibit the PD-1/PD-L1 immune checkpoint pathway (pembrolizumab) can achieve durable tumor responses in a small fraction of patients.

TABLE 86-1 Non–Muscle-Invasive Bladder Cancer Recurrence Risk Groups

RISK GROUP	CHARACTERISTICS
Low risk	Initial tumor, solitary tumor, low grade, <3 cm, no CIS
Intermediate risk	All tumors not defined in the two adjacent categories (between the category of low and high risk)
High risk	Any of the following: • T1 tumor • High-grade • CIS • Multiple and recurrent and large (>3 cm) Ta low-grade tumors (all conditions must be met for this point on Ta low-grade tumors)

Abbreviation: CIS, carcinoma in situ.

Upper Tract Disease In patients with urothelial carcinoma of the renal pelvis or ureter, endoscopic tissue acquisition and staging are more challenging than primary tumors located in the bladder. Tumors possessing all of the following are considered low risk: solitary tumor, low grade, size <1 cm, and no invasive component on imaging. Low-risk tumors can successfully be treated by laser ureteroscopic ablation or surgical resection and reanastomosis of the remaining ureter ends in tumors that cannot be successfully eradicated endoscopically.

Muscle-Invasive Disease In patients with urothelial carcinoma of the bladder that invades into or through the muscularis propria but with no evidence of metastatic spread, more aggressive therapy options summarized in Table 86-2 are required to achieve cure. In carefully selected patients with no evidence of CIS or hydronephrosis, bladder-sparing combined-modality therapy with concurrent chemotherapy and radiation can achieve cure in ~65% of patients. Various chemotherapy regimens have been utilized in combination with radiation including cisplatin, carboplatin, 5-fluorouracil, mitomycin C, paclitaxel, and gemcitabine. It is important to note that a maximal debulking of all visible tumor by TURBT is required prior to initiation of combined-modality therapy. In patients who achieve a complete response to combined-modality therapy, regular cystoscopic monitoring of the bladder is required with salvage cystectomy offered to patients who develop MIBC in follow-up.

In a similar fashion, bladder-sparing partial cystectomy can be performed in a very small subset of MIBC patients. The ideal patient for partial cystectomy is the patient with a solitary, clinical T2 urothelial carcinoma in the dome of the bladder. In such patients, the tumor and immediate surrounding urothelium can be resected with reconstruction of the remaining bladder to maintain near physiologic urinary function.

In the majority of patients, however, resection of the entire bladder is required. In males, a cystoprostatectomy with removal of the bladder, prostate, and pelvic lymph nodes is performed, whereas in females, an anterior exenteration with removal of the bladder, uterus, ovaries, cervix, and pelvic lymph nodes is performed. With the bladder removed, three options exist to reroute the urine outflow. In an ileostomy, the bilateral ureters are connected to a portion of ileum that is brought through an incision in the abdominal wall to create a stoma that drains urine into an affixed bag outside of the body. In a continent urinary reservoir or "Indiana pouch," the ureters are connected to a portion of ileum that has been separated on both ends from the rest of the small-bowel transit to form a urinary reservoir. The remaining small bowel is reanastomosed, and the urinary reservoir is brought up just beneath the abdominal wall muscles with patients catheterizing the urinary reservoir several times per day via a small stoma tract. Last, in a neobladder, the same urinary reservoir described previously is brought down into the pelvis and is anastomosed to the remaining urethra to provide the opportunity to the patient to void urine through the urethra. The choice of which urinary reconstruction to perform is affected not only by patient choice but also by anatomic tumor considerations and

TABLE 86-2 Treatment Approaches to MIBC Patients

TREATMENT	PATIENT SELECTION	CLINICAL OUTCOMES
Bladder-sparing chemoradiation	No CIS, no hydronephrosis, maximal TURBT required	65% cure, 55% bladder intact, highly dependent on patient selection
Bladder-sparing partial cystectomy	Solitary tumors in dome of bladder are ideal	Variable, highly dependent on patient selection
Cystectomy	Any MIBC patient	50% cure with surgery alone, highly dependent on pathologic stage
Neoadjuvant cisplatin-based chemotherapy	Cisplatin-eligible MIBC patients	5–10% improvement in overall survival compared to cystectomy alone
Adjuvant cisplatin-based chemotherapy	Cisplatin-eligible high-risk postcystectomy MIBC patients (pT3-4, N+)	Similar improvement as neoadjuvant treatment, data less robust, many patients not suitable for adjuvant treatment

Abbreviations: CIS, carcinoma in situ; MIBC, muscle-invasive bladder cancer; TURBT, transurethral resection of bladder tumor.

urologist experience with each procedure. Regardless of the type of surgery performed, all patients undergo a significant catabolic change in their metabolism following removal of the bladder. While many MIBC patients are affected by weight loss preoperatively, it is not uncommon for postcystectomy patients to lose an additional 10–15 lb in the first month postoperatively. In addition, patients can experience long-term nutritional changes such as low B_{12} levels due to alterations in small-bowel physiology caused by all of the urinary diversion options.

Despite aggressive surgery, only half of patients undergoing cystectomy are cured by surgery alone. Therefore, many clinical trials have investigated the role of systemic chemotherapy before (neoadjuvant) or after (adjuvant) surgery. Meta-analyses have shown a 5–10% absolute overall survival advantage when combination chemotherapy regimens utilizing cisplatin have been used before surgery. A similar benefit exists with cisplatin-based combination chemotherapy given after surgery. However, the data in the adjuvant setting are based on smaller, older trials. Furthermore, in the postoperative setting, some patients may not recover sufficiently from their surgery within a time frame optimal for chemotherapy administration. Importantly, non–cisplatin-containing chemotherapy regimens have proven inferior to cisplatin-containing regimens. Therefore, if patients are not suitable candidates for cisplatin administration due to poor functional status or comorbidities (e.g., poor renal function), patients should proceed directly to surgery and forego neoadjuvant therapy.

For patients with high-risk urothelial carcinoma of the upper urinary tract, resection of the kidney and ureter (including the ureter bladder cuff) by nephroureterectomy is preferred. Segmental ureterectomy may be appropriate in patients with decreased renal function in which nephron-sparing outcomes are critical to prevent the need for dialysis. Similarly, in CIS patients, administration of BCG therapy via a nephrostomy tube can be considered to preserve intact renal function. The use of cisplatin-based neoadjuvant chemotherapy has been associated with a pathologic complete response at surgery of 14% in upper tract urothelial carcinoma patients. Similarly, in the post-nephroureterectomy setting, adjuvant platinum-based chemotherapy (carboplatin or cisplatin) reduced recurrence rates by 55% compared to surgery alone. The use of perioperative chemotherapy either before or after surgery is now recommended for upper tract urothelial carcinoma patients in national guidelines.

Metastatic Disease For patients with metastatic urothelial carcinoma regardless of primary tumor origin, systemic chemotherapy is the most established standard of care. In a randomized phase 3 clinical trial, the combination of methotrexate, vinblastine, doxorubicin, and cisplatin (MVAC) demonstrated an improvement in median overall survival from 8.2 to 12.5 months compared to single-agent cisplatin. In a head-to-head randomized phase 3 clinical trial, the combination of cisplatin and gemcitabine (CG) demonstrated similar overall survival compared to MVAC with a more favorable side effect profile. Since 2000, treatment with either MVAC or CG has remained a standard first-line treatment of patients with metastatic urothelial carcinoma with adequate renal function and functional status suitable for cisplatin therapy. For patients with lymph node–only metastases and good functional status, cure is achieved in 15–20% of such patients. Unfortunately, only ~5% of metastatic patients fulfill both these criteria. Furthermore, approximately half of patients with urothelial carcinoma have renal insufficiency, comorbidities, or frail functional status, and are not candidates for cisplatin treatment. In cisplatin-ineligible patients, carboplatin-based chemotherapy regimens have historically been used with median overall survival rates decreased to 9.3 months. Agents inhibiting the immune checkpoint programmed cell death protein 1 (PD-1) and programmed death ligand 1 (PD-L1) pathways have become additional standard options for both front-line chemotherapy-naive (atezolizumab, pembrolizumab), front-line maintenance (avelumab), and second-line postplatinum (pembrolizumab, nivolumab, and avelumab) metastatic urothelial carcinoma patients. Although these agents only result in tumor responses in 10–30% of patients, they have been approved due to their improved safety profiles compared to traditional chemotherapy options and the prolonged durability of some tumor responses. These agents aim to reactivate a patient's own immune system to recognize and eliminate their cancer. As such, their unique side effect profile is characterized by immune-related toxicities that are rare but can be severe and may include colitis, pneumonitis, hepatitis, nephritis, myocarditis, rash, hypothyroidism, Guillain-Barré syndrome, idiopathic thrombocytopenia purpura, and adrenal insufficiency.

In patients with activating tumor fibroblast growth factor 2 or 3 (*FGFR2/3*) mutations or fusions with progressive disease following platinum-based therapy, the oral FGFR tyrosine kinase inhibitor erdafitinib is another standard option resulting in tumor responses in 32% of patients with a median duration of response of 5.4 months. Additionally, the nectin-4–targeting antibody-drug conjugate enfortumab vedotin provides an additional standard option for patients with progression after both platinum-based therapy and PD-1/PD-L1 immune checkpoint therapy independent of tumor mutation status. Tumor responses are observed in 44% of patients, including patients with liver metastases, with a median response duration of 7.6 months. Additional novel urothelial carcinoma therapeutics are under ongoing investigation.

87 Benign and Malignant Diseases of the Prostate

Howard I. Scher, James A. Eastham

Benign and malignant changes in the prostate increase with age. Autopsies of men in the eighth decade of life show hyperplastic changes in >90% and malignant changes in >70% of individuals. The high prevalence of these diseases among the elderly, who often have competing causes of morbidity and mortality, mandates a risk-adapted approach to diagnosis and treatment. This can be achieved by considering these diseases as a series of states. Each state represents a distinct clinical milestone for which therapy(ies) may be recommended based on disease extent, current symptoms, the risk of developing symptoms, or the risk of death from disease in relation to death from other causes within a given time frame. For benign proliferative disorders, symptoms of bladder outlet obstruction and potential complications including urinary retention and urinary tract infection are weighed against the side effects and complications of medical or surgical intervention. For prostate malignancies, the likelihood that a clinically significant cancer is present in the gland and the concomitant risk of symptoms or death from cancer are balanced against the morbidities of the recommended treatments and preexisting comorbidities.

ANATOMY AND PATHOLOGY

The prostate is in the pelvis and is adjacent to the rectum, the bladder, the periprostatic and dorsal vein complexes, the neurovascular bundles that are responsible for erectile function, and the urinary sphincter that is responsible for passive urinary control. The prostate is composed of branching tubuloalveolar glands arranged in lobules surrounded by fibromuscular stroma. The acinar unit includes an epithelial compartment made up of epithelial, basal, and neuroendocrine cells separated by a basement membrane and a stromal compartment that includes fibroblasts and smooth-muscle cells. Prostate-specific antigen (PSA) and prostatic acid phosphatase (PAP) are produced in the epithelial cells. Both prostate epithelial cells and stromal cells express androgen receptors (ARs) and depend on androgens for growth. Testosterone, the major circulating androgen, is converted by the enzyme 5α-reductase to dihydrotestosterone in the gland.

The periurethral portion of the gland increases in size during puberty and after the age of 55 years due to the growth of nonmalignant cells in the transition zone of the prostate that surrounds the urethra. Most cancers develop in the peripheral zone, and cancers in this location may be palpated during a digital rectal examination (DRE).

PROSTATE CANCER

The American Cancer Society's estimates for prostate cancer in the United States for 2021 are ~248,530 new prostate cancer cases and ~34,130 deaths from prostate cancer. The absolute number of prostate cancer deaths has decreased in the past 10 years, attributed by some to the widespread use of PSA-based detection strategies. However, the paradox of management is that although 1 in 8 men will eventually be diagnosed with prostate cancer and the disease remains the second leading cause of cancer deaths in men, only 1 man in 41 with prostate cancer will die of his disease.

EPIDEMIOLOGY

Epidemiologic studies show that the risk of being diagnosed with prostate cancer increases 2.5-fold if one first-degree relative is affected and fivefold if two or more are affected. Current estimates are that 40% of early-onset and 5–10% of all prostate cancers are hereditary. Prostate cancer affects ethnic groups differently. Matched for age, African-American males have a higher incidence and present at a more advanced stage with higher-grade, more aggressive cancers. Genome-wide association studies (GWAS) have identified >40 prostate cancer susceptibility loci that are estimated to explain up to 25% of prostate cancer risk. Among the genes implicated in variations in incidence and outcome are single-nucleotide polymorphisms (SNPs) in the vitamin D receptor in African Americans and variants in the AR, CYP3A4, both involved in the deactivation of testosterone, as well as CYP17, which is involved in steroid biosynthesis. One early change is hypermethylation of the GSTP1 gene promoter, which leads to loss of function of a gene that detoxifies carcinogens. The finding that many prostate cancers develop adjacent to a lesion termed *proliferative inflammatory atrophy* (PIA) suggests a role for inflammation.

The prevalence of autopsy-detected cancers is similar around the world, while the incidence of clinical disease varies. Thus, environmental and dietary factors may play a role in prostate cancer growth and progression. High consumption of dietary fats, such as α-linoleic acid or polycyclic aromatic hydrocarbons that form when red meats are cooked, is believed to increase risk. Like breast cancer in Asian women, the risk of prostate cancer in Asian men increases when they move to Western environments. Protective factors include consumption of the isoflavonoid genistein (which inhibits 5α-reductase), cruciferous vegetables with isothiocyanate sulforaphane, lycopene found in tomatoes, and inhibitors of cholesterol biosynthesis (e.g., statin drugs). Not smoking, regular exercise, and maintaining a healthy body weight may reduce the risk of progression.

DIAGNOSIS AND TREATMENT BY CLINICAL STATE

The prostate cancer continuum—from the appearance of a preneoplastic and invasive lesion that is localized to the gland, to a metastatic lesion causing symptoms and, ultimately, mortality—can span decades. To limit overdiagnosis of clinically insignificant cancers and for disease management in general, competing risks are considered in the context of a series of clinical states **(Fig. 87-1)**. The states are defined operationally based on whether or not a cancer diagnosis has been established and, for those with a diagnosis, the state of the primary tumor (treated vs untreated), whether or not metastases are detectable on imaging studies, and the measured level of testosterone in the blood. With this approach, an individual resides in only one state and remains in that state until he has progressed. At each assessment, the decision to offer treatment and the specific form of treatment are based on the presence or absence of cancer-related symptoms, and if absent, the risk posed by the cancer relative to competing causes of morbidity and mortality that may be present in that individual. It follows that the more advanced the disease, the greater is the need for treatment.

For those without a cancer diagnosis, the decision to undergo testing to detect a cancer is based on the individual's estimated life expectancy and, separately, the probability that a clinically significant cancer may be present. For those with a prostate cancer diagnosis, the clinical states model considers the probability of developing symptoms or dying from the disease. Thus, a patient with a localized tumor that has been surgically removed remains in the state of localized disease if the PSA remains undetectable. The time within a state then becomes a measure of the efficacy of an intervention, though the effect may not be assessable for years. Because many men with active cancer are not at risk for developing metastases, symptoms, or death, the clinical states model allows a distinction between *cure*—the elimination of all cancer cells, the primary therapeutic objective of treatment for most cancers—and *cancer control*, by which the tempo of the illness is determined to be so slow or has been altered by treatment to the point where it is unlikely to cause symptoms, to metastasize, or to shorten a patient's life expectancy. Importantly, from a patient standpoint, both outcomes can be considered equivalent therapeutically assuming the patient has not experienced symptoms of the disease or the treatment needed to control it. Even when a recurrence is documented, immediate therapy is not always necessary. Rather, as at the time of diagnosis, the need for intervention is based on the tempo of the illness as it unfolds in the individual, relative to the risk-to-benefit ratio of the intervention being considered.

NO CANCER DIAGNOSIS

Prevention No agent is currently approved for the prevention of prostate cancer. The results from several large double-blind,

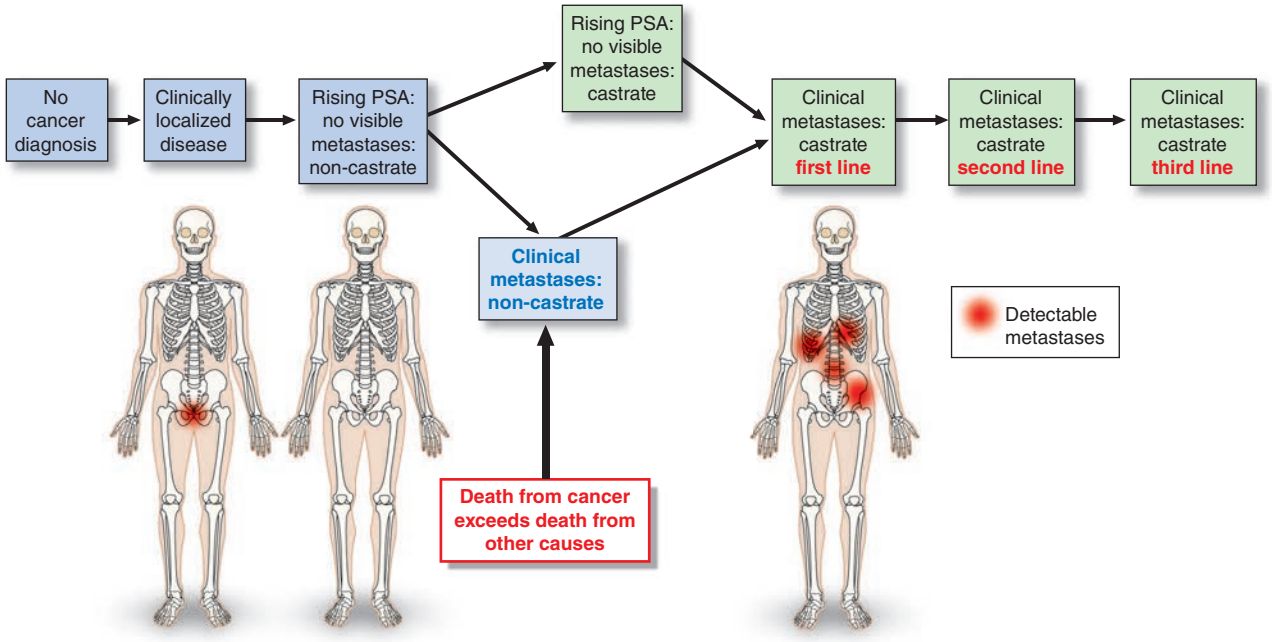

FIGURE 87-1 Clinical states of prostate cancer. PSA, prostate-specific antigen.

randomized chemoprevention trials have established 5α-reductase inhibitors (5ARIs) as the predominant therapy to reduce the future risk of a prostate cancer diagnosis. The Prostate Cancer Prevention Trial (PCPT), in which men aged >55 years received placebo or the 5ARI finasteride, which inhibits the type 1 isoform, showed a 25% (95% confidence interval 19–31%) reduction in prostate cancer incidence from 24% with placebo to 18% with finasteride. In REDUCE (Reduction by Dutasteride of Prostate Cancer Events trial), a reduction in incidence from 25% with placebo to 20% with dutasteride was found (p = .001). Dutasteride inhibits both the type 1 and type 2 5ARI isoforms. While both studies met their endpoint, there was concern that most of the cancers that were "prevented" were low risk. Neither drug is approved for prostate cancer prevention. In comparison, the Selenium and Vitamin E Cancer Prevention Trial (SELECT), which enrolled African-American men aged ≥50 years and others aged ≥55 years, showed no difference in cancer incidence in patients receiving vitamin E (4.6%) or selenium (4.9%) alone or in combination (4.6%) relative to placebo (4.4%). A similar lack of benefit for vitamin E, vitamin C, and selenium was seen in the Physicians Health Study II.

Early Detection and Diagnosis The decision to pursue a diagnosis of prostate cancer must balance the benefit from detecting and treating clinically significant cancers that, left untreated, would adversely affect a patient's quality and duration of life, against the morbidity associated with the overdiagnosis and overtreatment of clinically insignificant cancers that are highly prevalent in the general population. The balance is best approached through shared decision-making between the patient and physician. Considerations for whether to pursue a diagnosis include symptoms, an abnormal DRE, or more typically, a change in or an elevated serum PSA. Genetic risk is also considered.

PHYSICAL EXAMINATION The DRE focuses on prostate size, consistency, and abnormalities within or beyond the gland. Many cancers occur in the peripheral zone and may be palpated on DRE. Carcinomas are characteristically hard, nodular, and irregular, while induration may also be due to benign prostatic hyperplasia (BPH) or calculi. Overall, 20–25% of men with an abnormal DRE have prostate cancer.

PROSTATE-SPECIFIC ANTIGEN PSA (kallikrein-related peptidase 3; *KLK3*) is a kallikrein-related serine protease that causes liquefaction of seminal coagulum. It is produced by both nonmalignant and malignant epithelial cells and, as such, is prostate-specific, not prostate cancer–specific. Serum levels of PSA may increase from prostatitis, BPH, or prostate cancer. Serum levels are not significantly affected by the DRE. PSA circulating in the blood is inactive and mainly occurs as a complex with the protease inhibitor α_1-antichymotrypsin and as free (unbound) PSA forms. The formation of complexes between PSA, α_2-macroglobulin, or other protease inhibitors is less significant. Free PSA is rapidly eliminated from the blood by glomerular filtration with an estimated half-life of 12–18 h. Elimination of PSA bound to α_1-antichymotrypsin is slow (estimated half-life of 1–2 weeks) as it, too, is largely cleared by the kidneys. Levels should be undetectable after about 6 weeks if the prostate has been completely removed (radical prostatectomy).

PSA testing was approved by the U.S. Food and Drug Administration (FDA) in 1994 for early detection of prostate cancer, and the widespread use of the test has played a significant role in the proportion of men diagnosed with early-stage cancers: >70–80% of newly diagnosed cancers are clinically organ confined. The level of PSA in blood is strongly associated with the risk and outcome of prostate cancer. A single PSA measured at age 60 is associated (area under the curve [AUC] of 0.90) with lifetime risk of death from prostate cancer. Most (90%) prostate cancer deaths occur among men with PSA levels in the top quartile (>2 ng/mL), although only a minority of men with PSA >2 ng/mL will develop lethal prostate cancer. Despite this and mortality rate reductions reported from large randomized prostate cancer screening trials, routine use of the test remains controversial.

In 2012, the U.S. Preventive Services Task Force (USPSTF) published a review of the evidence for PSA-based screening for prostate cancer and made a clear recommendation against screening. By giving a grade of "D" in the recommendation statement that was based on this review, the USPSTF concluded that "there is moderate or high certainty that this service has no net benefit or that the harms outweigh the benefits." In 2013, the American Urological Association (AUA) updated their consensus statement regarding prostate cancer screening. They concluded that the quality of evidence for the benefits of screening was moderate for men aged 55–69 years. For men outside this age range, evidence was lacking for benefit, but the harms of screening, including overdiagnosis and overtreatment, remained. The AUA recommends shared decision-making for men aged 55–69 years considering PSA-based screening, a target age group for whom benefits may outweigh harms. Outside this age range, PSA-based screening as a routine was not recommended. The entire guideline is available at *http://www.auanet.org/guidelines/early-detection-of-prostate-cancer-(2013-reviewed-and-validity-confirmed-2015)*. As of 2017, the USPSTF has issued a revised recommendation with a grade of "C" for PSA-based

prostate cancer screening for men aged 55–69. Now they recommend shared decision-making for men between the ages of 55 and 69 and do not recommend screening for men aged 70 or greater, roughly in agreement with the 2013 AUA guideline. The USPSTF also notes that the increased use of active surveillance (observation with selective delayed treatment) for low-risk prostate cancer has reduced the risks of screening.

We believe that implementation of the following three guidelines will further improve PSA screening outcomes in the United States and will have a greater practical impact on men's health than the USPSTF and AUA recommendations that are based almost solely on age. First, avoid PSA tests in men with little to gain. There is no rationale for recommending PSA screening in asymptomatic men with a short life expectancy. Hence, men over the age of 75 should only be tested in special circumstances, such as a higher than median PSA measured before age 70 or excellent overall health. In addition, because a baseline PSA is a strong predictor of the future risk of lethal prostate cancer, men with low PSAs, for example <1 ng/mL, can undergo testing less frequently, perhaps every 5 years, with screening possibly ending at age 60 if the PSA remains at ≤1 ng/mL. Men with PSAs that are above an age median but below biopsy thresholds can be counseled about their elevated risk and actively encouraged to return for regular screening and more comprehensive risk assessment. Second, do not treat those who do not need treatment. High proportions of men with screen-detected prostate cancer do not need immediate treatment and can be managed by active surveillance. Third, refer men who do need treatment to high-volume centers. Although it is clearly not feasible to restrict treatment exclusively to high-volume centers, shifting treatment trends so that more patients are treated at such centers by high-volume providers will improve cancer control and decrease complications. The goal of prostate cancer screening should be to maximize the benefits of PSA testing and minimize its harms. Following the three rules outlined here should continue to improve the ratio of harms to benefits from PSA screening.

The PSA criteria used to recommend a diagnostic prostate biopsy have evolved over time. However, based on the commonly used cut point for prostate biopsy (a total PSA ≥4 ng/mL), most men with a PSA elevation do not have histologic evidence of prostate cancer at biopsy. In addition, many men with PSA levels below this cut point harbor cancer cells in their prostate. Information from the Prostate Cancer Prevention Trial demonstrates that there is no PSA below which the risk of prostate cancer is zero. Thus, the PSA level establishes the likelihood that a man will harbor cancer if he undergoes a prostate biopsy. The goal is to increase the sensitivity of the test for younger men harboring clinically significant cancers that may cause symptoms and shorten survival and to reduce the frequency of detecting cancers of low malignant potential in elderly men more likely to die of other causes. Patients with symptomatic bacterial prostatitis should have a course of antibiotics before biopsy. However, the routine use of antibiotics in an asymptomatic man with an elevated PSA level is strongly discouraged.

SECOND-LINE SCREENING TESTS Several tests have been developed to better stratify men with an elevated PSA test into those more or less likely to have clinically significant prostate cancer. The 4Kscore® Test (OPKO Lab, Nashville, TN) measures four prostate-specific kallikreins (total PSA, free PSA, intact PSA, and human kallikrein 2). The results are combined with clinical information in an algorithm that estimates an individual's percent risk of having an aggressive prostate cancer should that individual opt for a prostate biopsy. The 4Kscore test has also been shown to identify the likelihood that an individual will develop aggressive prostate cancer, defined as high-grade prostate cancer pathology and/or poor prostate cancer clinical outcomes, within 20 years.

The Prostate Health Index (PHI™, Innovative Diagnostic Laboratory, Richmond, VA) is a blood test that estimates the risk of having prostate cancer. The PHI test is a combination of free PSA, total PSA, and the [–2]proPSA isoform of free PSA. These three tests are combined in a formula that calculates the PHI score. The PHI score is a better predictor of prostate cancer than the total PSA test alone or the free PSA test alone. Urine-based testing measuring exosomes (ExoDx Prostate Test) or mRNA levels of prostate cancer–related genes (SelectMDx) is also available.

PROSTATE BIOPSY A diagnosis of cancer is established by an image-guided needle biopsy. Direct visualization by transrectal ultrasound (TRUS), magnetic resonance imaging (MRI), or fusion of the ultrasound and MRI images ensures that all areas of the gland, including suspicious areas, are sampled. Contemporary schemas advise an extended-pattern 12-core biopsy that includes sampling from the peripheral zone as well as a lesion-directed palpable nodule or suspicious image-guided sampling. Because a prostate biopsy is subject to sampling error, men with an abnormal PSA and negative biopsy are frequently advised to undergo additional testing, which may include a 4Kscore test, PHI, prostate MRI, and/or repeat biopsy.

PATHOLOGY Each core of the biopsy is examined for the presence of cancer, and the amount of cancer is quantified based on the length of the cancer within the core and the percentage of the core involved. Of the cancers identified, >95% are adenocarcinomas; the rest are squamous or transitional cell tumors or, rarely, carcinosarcomas or small-cell histologies. Metastases to the prostate are rare, but in some cases, colon cancers or transitional cell tumors of the bladder invade the gland by direct extension.

When prostate cancer is diagnosed, a measure of histologic aggressiveness is assigned using the *Gleason grading system*, in which the dominant and secondary glandular histologic patterns are scored from 1 (well differentiated) to 5 (undifferentiated) and summed to give a total score of 2–10 for each tumor. The most poorly differentiated area of tumor (i.e., the area with the highest histologic grade) often determines biologic behavior. The presence or absence of perineural invasion and extracapsular spread is also recorded.

Over the years, the Gleason grading system has undergone several changes. Currently, Gleason total scores of 2–5 are no longer assigned, and in practice, the lowest total score is now assigned a 6, although the scale continues to range from 2 to 10. This leads to a logical yet incorrect assumption on the part of patients that their Gleason 6 cancer is in the middle of the scale, triggering the fear that their cancer is serious and the assumption that treatment is necessary despite Gleason score 6 being favorable risk. To address these issues, a new five-grade group system has been developed:

Grade group 1 (Gleason score ≤6)
Grade group 2 (Gleason score 3+4 = 7)
Grade group 3 (Gleason score 4+3 = 7)
Grade group 4 (Gleason score 4+4 = 8)
Grade group 5 (Gleason scores 9 and 10)

The new system simplifies the grading of prostate cancer, appropriately classifying the lowest risk as grade group 1 (rather than Gleason score 6), and accurately predicts prognosis.

PROSTATE CANCER STAGING The TNM (tumor, node, metastasis) staging system includes categories for cancers that are identified solely on the basis of an abnormal PSA (T1c), those that are palpable but clinically confined to the gland (T2), and those that have extended outside the gland (T3 and T4) **(Table 87-1, Fig. 87-2)**. DRE alone is inaccurate in determining the extent of disease within the gland, the presence or absence of capsular invasion, involvement of seminal vesicles, and extension of disease to lymph nodes. Because of the inadequacy of DRE for staging, the TNM staging system was modified to include the results of imaging. Unfortunately, no single test has been proven to accurately indicate the stage or the presence of organ-confined disease, seminal vesicle involvement, or lymph node spread.

TRUS is the imaging technique most frequently used to assess the primary tumor, but its chief use is directing prostate biopsies, not staging. No TRUS finding consistently indicates cancer with certainty. Computed tomography (CT) lacks sensitivity and specificity to detect extraprostatic extension and is inferior to MRI in visualization of lymph nodes. In general, MRI is superior to CT to detect cancers in the prostate, to assess local disease extent, and fused with ultrasound imaging, to guide sites to biopsy within the gland. MRI is also useful for the planning of surgery and radiation therapy.

Radionuclide bone scans (bone scintigraphy) are used to evaluate spread to osseous sites. This test is sensitive but relatively nonspecific

TABLE 87-1 TNM Classification

TNM (tumor, node, metastasis) Staging System for Prostate Cancer[a]	
Tx	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Localized Disease	
T1	Clinically inapparent tumor, neither palpable nor visible by imaging
T1a	Tumor incidental histologic finding in ≤5% of resected tissue; not palpable
T1b	Tumor incidental histologic finding in >5% of resected tissue
T1c	Tumor identified by needle biopsy (e.g., because of elevated PSA)
T2	Tumor confined within prostate[b]
T2a	Tumor involves half of one lobe or less
T2b	Tumor involves more than one half of one lobe, not both lobes
T2c	Tumor involves both lobes
Local Extension	
T3	Tumor extends through the prostate capsule[c]
T3a	Extracapsular extension (unilateral or bilateral)
T3b	Tumor invades seminal vesicles
T4	Tumor is fixed or invades adjacent structures other than seminal vesicles such as external sphincter, rectum, bladder, levator muscles, and/or pelvic wall
Metastatic Disease	
N1	Positive regional lymph nodes
M1	Distant metastases

[a]Revised from SB Edge et al (eds): *AJCC Cancer Staging Manual*, 7th ed. New York, Springer, 2010. [b]Tumor found in one or both lobes by needle biopsy, but not palpable or reliably visible by imaging, is classified as T1c. [c]Invasion into the prostatic apex or into (but not beyond) the prostatic capsule is classified not as T3 but as T2.

Abbreviation: PSA, prostate-specific antigen.

because it does not detect the cancer itself, only reaction of the bone to the presence of the cancer itself. Consequently, areas of increased uptake are not always related to metastatic disease. Healing fractures, arthritis, Paget's disease, and other conditions will also cause abnormal uptake. True-positive bone scans are uncommon when the PSA is <10 ng/mL unless the tumor is high-grade.

TREATMENT

Prostate Cancer

CLINICALLY LOCALIZED PROSTATE CANCER

Patients with clinically localized disease are managed by radical prostatectomy, radiation therapy, or active surveillance. Choice of therapy requires the consideration of several factors: the presence of symptoms, the probability that the untreated tumor will adversely affect the quality or duration of survival and thus require treatment, and the probability that the tumor can be cured by single-modality therapy directed to the prostate versus requiring both local and systemic therapy to achieve cure.

There is no clear evidence for the superiority of any one form of local therapy relative to another. This is due to the lack of prospective randomized trials, referral bias and physician bias, variation in the experience of the treating teams, and differences in trial endpoints and the definitions of cancer control. Often, PSA relapse–free survival is used because an effect on metastatic progression or survival may not be apparent for years. For many patients, however, a PSA recurrence does not necessarily mean that the disease will cause symptoms or shorten survival. After radical surgery to remove all prostate tissue, PSA should become undetectable in the blood within 6 weeks. If PSA remains or becomes detectable after radical prostatectomy, the patient is considered to have persistent or recurrent disease. After radiation therapy, in contrast, PSA does not become undetectable because the remaining nonmalignant elements of the gland continue to produce PSA even if all cancer cells have been eliminated. Similarly, cancer control is not well defined for a patient managed by active surveillance because PSA levels may continue to rise in the absence of therapy. Other outcomes are time to objective progression (local or systemic), cancer-specific survival, and overall survival; however, these outcomes may take years to assess.

The more extensive the local disease, the higher the probability of regional lymph node involvement (even when imaging studies are normal), the lower the probability of local control, and the higher the probability of relapse and the development of metastases. More important is that within the categories of clinical stage T1, T2, and T3 disease are cancers with a range of prognoses. Some T3 tumors are curable with therapy directed solely at the prostate, and some T1 lesions have a high probability of systemic relapse that requires the integration of local and systemic therapy to achieve cure. For T1c cancers, stage alone is inadequate to predict outcome and select treatment; other factors must be considered.

To better assess risk and guide treatment selection, many groups have developed prognostic models or nomograms that use a combination of the initial clinical T stage, biopsy Gleason score, the number of biopsy cores in which cancer is detected, and baseline PSA. Some use discrete cut points (PSA <10 or ≥10 ng/mL; Gleason score of ≤6, 7, or ≥8); others employ nomograms that use PSA and Gleason score as continuous variables. More than 100 nomograms have been reported to predict (1) the probability that a clinically significant cancer is present, (2) disease extent (organ-confined vs non–organ-confined, node-negative or -positive), or (3) the probability of treatment success for specific local therapies using pretreatment variables. Considerable controversy exists over what constitutes "high risk" based on a predicted probability of success or failure. In these situations, nomograms and predictive models can only go so far. Exactly what probability of success or failure would lead a physician to recommend and a patient to seek alternative

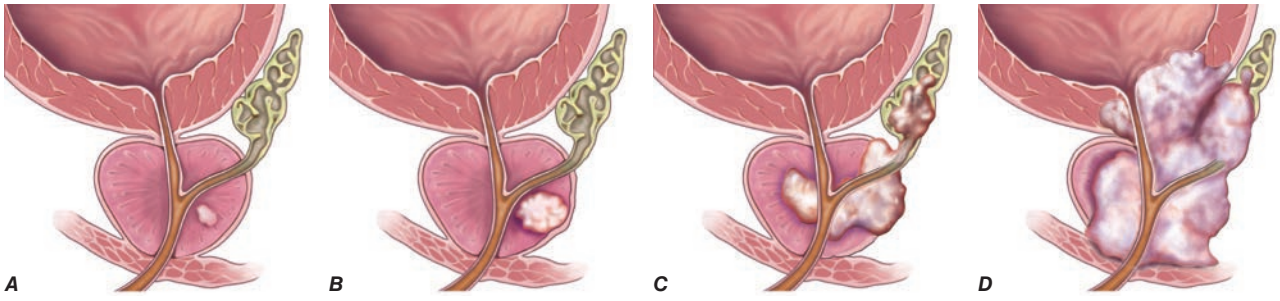

FIGURE 87-2 T stages of prostate cancer. ***A.*** T1—Clinically inapparent tumor, neither palpable nor visible by imaging. ***B.*** T2—Tumor confined within prostate. ***C.*** T3—Tumor extends through prostate capsule and may invade the seminal vesicles. ***D.*** T4—Tumor is fixed or invades adjacent structures. Eighty percent of patients present with local disease (T1 and T2), which is associated with a 5-year survival rate of 100%. An additional 12% of patients present with regional disease (T3 and T4 without metastases), which is also associated with a 100% survival rate after 5 years. Four percent of patients present with distant disease (T4 with metastases), which is associated with a 30% 5-year survival rate. (Three percent of patients are ungraded.) *(Reproduced with permission from MSKCC, data from AJCC, http://seer.cancer.gov/statfacts/html/prost.html. © 2010 Memorial Sloan-Kettering Cancer Center Medical Graphics.)*

approaches is controversial. As an example, it may be appropriate to recommend radical surgery for a younger patient with a low probability of cure. Nomograms are being refined continually to incorporate additional clinical parameters, biologic determinants, and year of treatment, which can also affect outcomes, making treatment decisions a dynamic process.

Radical Prostatectomy The goal of radical prostatectomy is to excise the cancer completely with a clear margin, to maintain continence by preserving the external sphincter, and to preserve potency by sparing the autonomic nerves in the neurovascular bundle. The procedure is advised for patients with a life expectancy of 10 years or more and is performed via a retropubic or perineal approach or via a minimally invasive robotic-assisted or hand-held laparoscopic approach. Outcomes can be predicted using postoperative nomograms that consider pretreatment factors and the pathologic findings at surgery. PSA failure is usually defined as a value >0.1 or 0.2 ng/mL. Specific criteria to guide the choice of one approach over another are lacking. Minimally invasive approaches offer the advantage of a shorter hospital stay and reduced blood loss. Rates of cancer control, recovery of continence, and recovery of erectile function are comparable. The individual surgeon, rather than the surgical approach used, is most important in determining outcomes after surgery.

Neoadjuvant hormonal treatment with gonadotropin-releasing hormone (GnRH) agonists/antagonists alone has also been explored to improve the outcomes of surgery for high-risk patients using a variety of definitions. The results of several large trials testing 3 or 8 months of androgen depletion before surgery showed that serum PSA levels decreased by 96%, prostate volumes decreased by 34%, and margin positivity rates decreased from 41–17%. Unfortunately, these findings have not been shown to improve PSA relapse–free survival.

Factors associated with incontinence following radical prostatectomy include older age and urethral length, which impacts the ability to preserve the urethra beyond the apex and the distal sphincter. The skill and experience of the surgeon are also factors.

The likelihood of recovery of erectile function is associated with younger age, quality of erections before surgery, and the absence of damage to the neurovascular bundles. In general, erectile function begins to return ~6 months after surgery if neurovascular tissue has been preserved. Potency is reduced by half if at least one neurovascular bundle is sacrificed. Overall, with the availability of drugs such as sildenafil, intraurethral inserts of alprostadil, and intracavernosal injections of vasodilators, many patients recover satisfactory sexual function.

Radiation Therapy Radiation therapy is given by external beam, by radioactive sources implanted into the gland, or by a combination of the two techniques.

External beam radiation therapy Contemporary external beam intensity-modulated radiation therapy (IMRT) permits shaping of the dose and allows the delivery of higher doses to the prostate and a dramatic reduction in normal tissue exposure compared with three-dimensional conformal treatment alone. These advances have enabled the safe administration of doses >80 Gy and resulted in higher local control rates and fewer side effects.

Cancer control after radiation therapy has been defined by various criteria, including a decline in PSA to <0.5 or 1 ng/mL, "nonrising" PSA values, and a negative biopsy of the prostate 2 years after completion of treatment. The current standard definition of biochemical failure (the Phoenix definition) is a rise in PSA by ≥2 ng/mL higher than the lowest PSA achieved. Radiation dose is critical to the eradication of prostate cancer. In a representative study, a PSA nadir of <1.0 ng/mL was achieved in 90% of patients receiving 81.0 Gy versus 76% and 56% of those receiving 70.2 and 64.8 Gy, respectively. Positive biopsy rates at 2.5 years were 4% for those treated with 81 Gy versus 27% and 36% for those receiving 75.6 and 70.2 Gy, respectively.

Hypofractionation schedules, utilizing fewer treatments of higher radiation doses, have been evaluated and shown to provide good cancer control rates based on posttreatment biopsies showing no evidence of cancer, with no apparent increase in treatment-related morbidity. Hypofractionated treatments can range from as few as 5 treatments to upward of 26 treatments, both regimens representing substantial reductions in treatment length.

Multiple clinical trials have evaluated the use of androgen deprivation therapy (ADT) in combination with radiation. In patients with unfavorable intermediate-risk prostate cancer, short-course ADT (6 months), when combined with external beam radiotherapy, has demonstrated significant improvements in overall survival. In patients with high-risk disease, longer courses of ADT (18–36 months) have proven superior to shorter courses and represent the current standard of care when combined with radiotherapy.

The Prostate Testing for Cancer and Treatment (ProtecT) trial investigated the effects of active monitoring, radical prostatectomy, and radical radiotherapy with hormones on patient-reported outcomes in men diagnosed with low- and intermediate-risk prostate cancer (~75% with Gleason score 6 or grade group 1 cancer). Patient-reported outcomes among 1643 men who completed questionnaires before diagnosis, at 6 and 12 months, and annually thereafter were compared. Of the three treatments, prostatectomy had the greatest negative effect on sexual function and urinary continence, and although there was some recovery, these outcomes remained worse in the prostatectomy group than in the other groups throughout the trial. The negative effect of radiotherapy on sexual function was greatest at 6 months, but sexual function then recovered somewhat and was stable thereafter; radiotherapy had little effect on urinary continence. Sexual and urinary function declined gradually in the active-monitoring group. Bowel function was worse in the radiotherapy group at 6 months than in the other groups but then recovered somewhat, except for the increasing frequency of bloody stools; bowel function was unchanged in the other groups. Urinary voiding and nocturia were worse in the radiotherapy group at 6 months but then mostly recovered and were like the other groups after 12 months. Effects on quality of life mirrored the reported changes in function. No significant differences were observed among the groups in measures of anxiety, depression, or general health-related or cancer-related quality of life.

Brachytherapy Brachytherapy is the direct implantation of radioactive sources (seeds) into the prostate. It is based on the principle that the deposition of radiation energy in tissues decreases as a function of the square of the distance from the source (Chap. 73). The goal is to deliver intensive irradiation to the prostate, minimizing the exposure of the surrounding tissues. The current standard technique achieves a more homogeneous dose distribution by placing seeds according to a customized template based on imaging assessment of the cancer and computer-optimized dosimetry. The implantation is performed transperineally as an outpatient procedure with real-time imaging.

Improvements in brachytherapy techniques have resulted in fewer complications and a marked reduction in local failure rates. In a series of 197 patients followed for a median of 3 years, 5-year actuarial PSA relapse–free survival for patients with pretherapy PSA levels of 0–4, 4–10, and >10 ng/mL were 98, 90, and 89%, respectively. In a separate report of 201 patients who underwent posttreatment biopsies, 80% were negative, 17% were indeterminate, and 3% were positive. The results did not change with longer follow-up. Brachytherapy is well tolerated, although most patients experience urinary frequency and urgency that can persist for several months. Higher complication rates are observed in patients who have undergone a prior transurethral resection of the prostate (TURP), while those with obstructive symptoms at baseline are at a higher risk for retention and persistent voiding symptoms. Proctitis has been reported in <2% of patients.

Active surveillance With the advent of PSA testing, many patients are diagnosed with low-risk prostate cancers that may

not pose a threat to either the quantity or quality of man's life. Active surveillance, described previously as *watchful waiting* or *deferred therapy*, evolved from (1) studies that evaluated predominantly elderly men with well-differentiated tumors who remained untreated and demonstrated no clinically significant progression for protracted periods, (2) recognition of the contrast between incidence and disease-specific mortality, (3) the high prevalence of autopsy cancers, and (4) an effort to reduce overtreatment and treatment-related side effects. In practice, active surveillance is the treatment recommended to patients with cancers of low aggressiveness that can be safely monitored at fixed intervals with DREs, PSA measurements, imaging (usually prostate MRI), and repeat prostate biopsies as indicated until histopathologic or serologic changes correlative of progression warrant treatment with curative intent.

Case selection is critical, and determining the clinical parameters predictive of cancer aggressiveness that can be used to reliably select men most likely to benefit from active surveillance is an area of intense study. One set of criteria includes men with clinical T1c tumors that are biopsy Gleason grade 6 (grade group 1) involving three or fewer cores, with each core having <50% involvement by tumor, and a PSA density of <0.15. Nomograms to help predict which patients can safely be managed by active surveillance continue to be refined, and as their predictive accuracy improves, it can be anticipated that more patients will be candidates.

RISING PSA AFTER DEFINITIVE LOCAL THERAPY

Patients in this state include those in whom the sole manifestation of disease is a rising PSA after surgery and/or radiation therapy. There is no evidence of disease on imaging studies. For these patients, the central issue is whether the rise in PSA results from persistent disease in the primary site, systemic disease, or both. In theory, disease in the primary site may still be curable by additional local treatment.

The decision to recommend radiation therapy after prostatectomy is guided by the pathologic findings at surgery, the timing of PSA failure, and the PSA level at the time of failure. Traditional imaging (MRI, CT, and radionucleotide bone scans), especially at low levels of PSA, are typically uninformative. New positron emission tomography (PET) tracers such as C-11 choline, F-18 fluciclovine, and F-18 or Ga-68 prostate-specific membrane antigen (PSMA) that directly image the cancer are more sensitive and can detect low-volume disease in the prostate bed or other sites to better inform the decision to recommend additional local therapies. All are FDA approved. Detection rates, both in and outside the prostate bed, correlate with the absolute level of PSA. Factors that predict for response to salvage radiation therapy are a positive surgical margin, lower Gleason score in the radical prostatectomy specimen, long interval from surgery to PSA failure, slow PSA doubling time, and low (<0.5 ng/mL) PSA value at the time of radiation treatment. For patients with a rising PSA after radiation therapy, salvage local therapy can be considered if the disease was "curable" at the outset, if persistent disease has been documented by a biopsy of the prostate, and if no disease is detectable outside of the prostate bed or regional lymph nodes by imaging. Unfortunately, case selection is poorly defined in most series, and morbidities are significant. Options include salvage radical prostatectomy, salvage cryotherapy, salvage radiation therapy, and salvage high-intensity focused ultrasound.

The rise in PSA after surgery or radiation therapy may indicate subclinical or micrometastatic disease with or without local recurrence. In these cases, the need for treatment depends, in part, on the estimated probability that the patient will show evidence of metastatic disease on a scan and in what time frame. That immediate therapy is not always required was shown in a series where patients who developed a rising PSA after radical prostatectomy received no systemic therapy until metastatic disease was documented. Overall, the median time to metastatic progression was 8 years, and 63% of the patients with rising PSA values remained free of metastases at 5 years. Factors associated with progression included the Gleason score of the radical prostatectomy specimen, time to recurrence after surgery, and PSA doubling time. For those with Gleason score ≥8, the probability of metastatic progression was 37, 51, and 71% at 3, 5, and 7 years, respectively. If the time to recurrence was <2 years and PSA doubling time was long (>10 months), the proportions with metastatic disease at the same time intervals were 23, 32, and 53%, versus 47, 69, and 79% if the doubling time was short (<10 months). PSA doubling times are also prognostic for survival. In one series, all patients who succumbed to disease had PSA doubling times of ≤3 months. Most physicians advise treatment when PSA doubling times are ≤12 months. A difficulty with predicting the risk of metastatic spread, symptoms, or death from disease in the rising PSA state is that most patients receive some form of therapy before the development of metastases. Nevertheless, predictive models continue to be refined.

METASTATIC DISEASE: NONCASTRATE

The state of *noncastrate metastatic disease* includes men with metastases visible on an imaging study at the time of diagnosis or after local therapy(ies) who have testosterone levels >150 ng/dL. Symptoms of metastatic disease include pain from osseous spread, although many patients are asymptomatic despite extensive spread. Less common are symptoms related to marrow infiltration by tumor (myelophthisis), coagulopathy, or spinal cord compression. Standard treatment is to deplete or lower androgens via ADT by medical or surgical means, the latter being the least acceptable to patients. A less frequently used approach is to block androgen binding to the AR with antiandrogens. More than 90% of male hormones originate in the testes; <10% are synthesized in the adrenal gland **(Fig. 87-3)**.

Testosterone-Lowering Agents Medical therapies that lower testosterone levels include the GnRH agonists/antagonists, pure GnRH antagonists, 17,20-lyase inhibitors, CYP17 inhibitors, and estrogens such as diethylstilbestrol (DES). The latter are rarely utilized due to the risk of vascular complications that include fluid retention, phlebitis, emboli, and stroke. GnRH agonists/antagonists, such as leuprolide acetate and goserelin acetate, initially produce a rise in luteinizing hormone and follicle-stimulating hormone followed by a downregulation of receptors in the pituitary gland, which effects a chemical castration. Regulatory approval was based on randomized trials showing reduced cardiovascular toxicities relative to DES, with equivalent potency. The initial rise in testosterone may result in a clinical flare of the disease, and as such, these agents are relatively contraindicated in men with significant obstructive symptoms, cancer-related pain, or spinal cord compromise, events that do not occur with GnRH antagonists such as degarelix, given by injection, or relugolix, given orally, that rapidly achieve castrate levels of testosterone. AR antagonists that block testosterone binding to the receptor are also used to prevent flare.

Agents that lower testosterone are associated with an androgen-deprivation syndrome that includes hot flushes, weakness, fatigue, loss of muscle mass, anemia, changes in cognition and personality, and depression. Changes in lipids, obesity, insulin resistance, and an increased risk of diabetes and cardiovascular disease are also seen, along with a decrease in bone density that worsens over time and results in an increased risk of clinical fractures. This is a particular concern in men with preexisting osteopenia that results from hypogonadism that may be worsened with steroid or alcohol use and significantly underappreciated. Baseline fracture risk can be assessed using the FRAX scale, and to minimize fracture risk, patients are advised to take calcium and vitamin D supplementation, along with a bisphosphonate, RANK-ligand inhibitor (denosumab), or toremifene.

Antiandrogens Nonsteroidal first-generation antiandrogens such bicalutamide and nilutamide have largely been replaced by the more potent next-generation agents (enzalutamide, apalutamide, and darolutamide) that do not lower serum androgen levels and result in fewer hot flushes, less of an effect on libido, less muscle wasting, fewer personality changes, and less bone loss relative to testosterone-lowering therapies. However, over time, testosterone

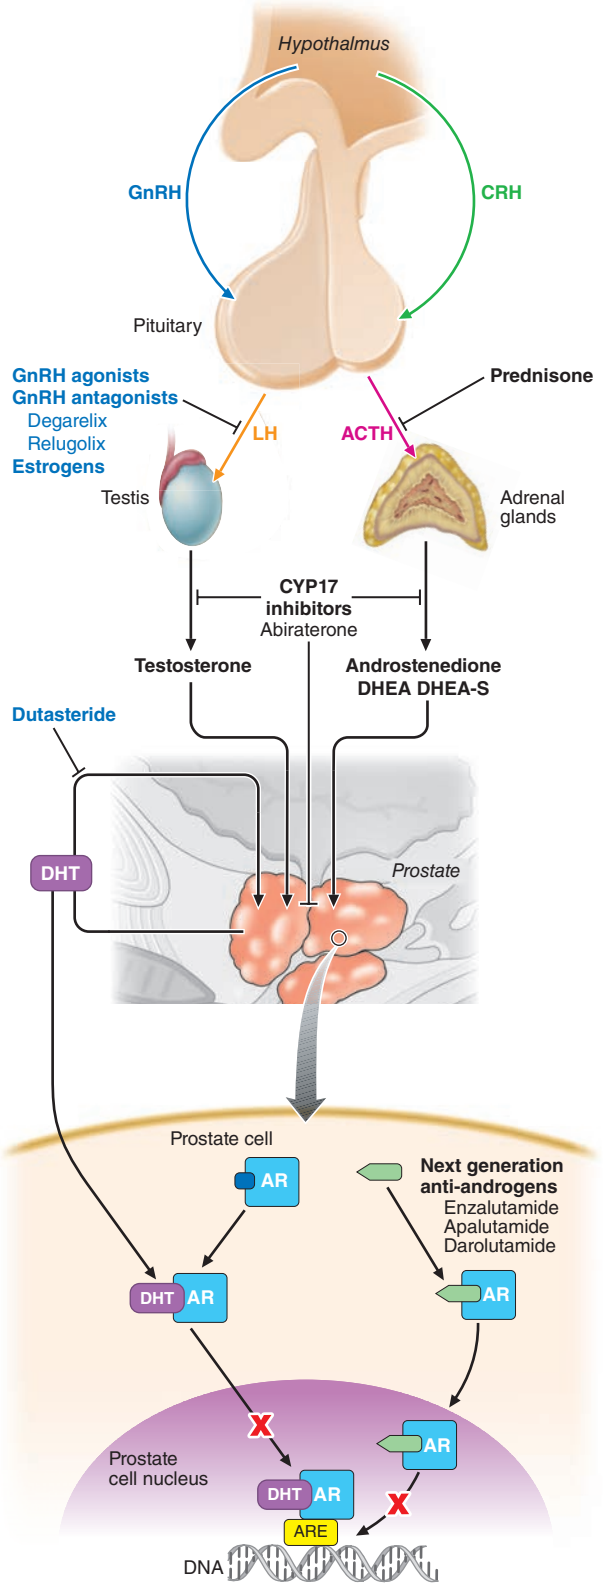

FIGURE 87-3 Sites of action of different hormone therapies.

levels increase and are converted to estrogen, which can result in mastalgia and gynecomastia that limits long-term use but can be prevented in part by tamoxifen or prophylactic breast irradiation.

Most reported randomized trials suggest that the cancer-specific outcomes are inferior when antiandrogens are used alone. Bicalutamide, even at a dose of 150 mg (three times the approved dose for use in combination in GnRH agonists), resulted in a shorter time to progression and inferior survival compared with surgical castration for patients with established metastatic disease.

Improving on the outcomes with ADT alone was a focus of the field for decades. One approach was to combine a first-generation antiandrogen (flutamide, bicalutamide, or nilutamide) with a GnRH analogue or surgical orchiectomy; however, this approach did not improve outcomes, and current use is largely limited to the first 2–4 weeks of treatment to protect against flare.

Practice standards changed when an improvement in time to progression and overall survival was shown when ADT was combined with docetaxel, the first systemic therapy shown to prolong life in metastatic castration-resistant prostate cancer (mCRPC) approved in 2004, relative to ADT alone. The greatest benefit was seen for patients with "high-volume" disease defined as the presence of ≥4 lesions on radionuclide bone scan or visceral disease. For abiraterone acetate and prednisone, benefit was seen across disease states ranging from high-risk localized to metastatic disease. Longer progression-free and overall survival times have been noted in separate phase 3 trials comparing ADT with abiraterone, a CYP17 inhibitor that blocks androgen synthesis, and ADT with the AR antagonists enzalutamide and apalutamide versus the ADT standard, further changing the standards of care.

Intermittent Androgen Deprivation Therapy (IADT) One way to reduce the side effects of androgen depletion is to administer antiandrogens on an intermittent basis. This was proposed as a way to prevent the selection of cells that are resistant to androgen depletion. The hypothesis is that by allowing endogenous testosterone levels to rise, the cells that survive androgen depletion will induce a normal differentiation pathway. In this way, the surviving cells that are allowed to proliferate in the presence of androgen will retain sensitivity to subsequent androgen depletion. Applied in the clinic, androgen depletion is continued for 2–6 months beyond the point of maximal response. Once treatment is stopped, endogenous testosterone levels increase, and the symptoms associated with hormone treatment abate. PSA levels also begin to rise, and at some level, treatment is restarted. With this approach, multiple cycles of regression and proliferation have been documented in individual patients. Unknown is whether the intermittent approach increases, decreases, or does not change the overall duration of sensitivity to androgen depletion. The approach is safe, but long-term data are needed to assess the course in men with low PSA levels. A trial to address this question is ongoing.

Outcomes of Androgen Deprivation The anti–prostate cancer effects of the various androgen depletion strategies are similar, and the clinical course is predictable: an initial response, a period of stability in which tumor cells are dormant and nonproliferative, followed after a variable period of time by a rise in PSA and regrowth that is visible on a scan as a castration-resistant lesion. Androgen depletion is not curative because cells that survive castration are present when the disease is first diagnosed. Considered by disease manifestation, PSA levels return to normal in 60–70% of patients, and measurable disease regression occurs in 50%; improvements in bone scan occur in 25% of cases, but the majority remain stable. Duration of survival is inversely proportional to disease extent at the time androgen depletion is first started and the nadir level of PSA at 6 months. Patients with nadir values above a certain threshold have markedly inferior survival times and should be considered for alternative approaches.

An unresolved question remains on how early systemic therapies should be offered to patients: in the adjuvant setting after surgery or radiation treatment of the primary tumor; at the time that a PSA recurrence is documented; or wait until metastatic disease or symptoms of disease are manifest? Trials in support of early therapy have been largely underpowered relative to the reported benefit or have been criticized on methodologic grounds. One that showed a survival benefit for patients treated with radiation therapy and 3 years of ADT, relative to radiation alone, was criticized for the poor outcomes of the control group. Another showing a survival benefit for patients with positive lymph nodes who were randomized to immediate medical or surgical castration compared with

observation ($p = .02$) was criticized because the confidence intervals around the 5- and 8-year survival distributions for the two groups overlapped.

METASTATIC DISEASE: CASTRATE

Castration-resistant prostate cancer (CRPC), disease that progresses while the measured levels of testosterone in the blood are 50 ng/mL or lower, can produce some of the most feared complications of the disease and is lethal for most men. The most common manifestation is a rising PSA, frequently co-occurring with progression in bone. Nodal and/or visceral spread is less frequent. Symptoms may or may not be present. The bone- and PSA-dominant pattern limits the ability to assess treatment effects reliably because traditional bone imaging is inaccurate and no PSA-based outcome has been shown to be a true surrogate for survival, and accordingly, favorable changes with either can be used to support regulatory approvals. Critical for management is that therapeutic objectives be based on the manifestations of the disease in the individual at the time a change in therapy is being considered. As such, for the patient with symptomatic bone disease, relief of pain can be more clinically relevant than lowering the PSA. Naturally, for all patients, the central focus is delaying or preventing disease progression, symptoms, and death from disease.

Through 2010, docetaxel was the only FDA-approved life-prolonging therapy for CRPC. Since then, our understanding of the biology of the disease has increased significantly, which in turn has led to improved therapies. In particular, it is now recognized that the majority of mCRPCs continue to express the AR and remain AR signaling dependent, and upward of 50% of cases harbor a series of oncogenic changes including overexpression, splice variants lacking the ligand binding domain and that stimulate growth independent of the ligand, and upregulation of the enzymes in the androgen biosynthesis pathway, leading to an increase in intratumoral androgens. These oncogenic changes have been successfully targeted with the next-generation antiandrogens enzalutamide, apalutamide, and darolutamide and the CYP17 inhibitor abiraterone acetate (given in combination with prednisone), all of which have been proven to prolong life and are FDA approved for use in CRPC in both the pre- and postchemotherapy setting.

Large-scale molecular profiling efforts have led to a biologically based disease taxonomy that continues to evolve and showed a markedly higher than expected frequency of germline and somatic *BRCA2* alterations, along with other genes in the DNA damage repair pathway that have been targeted successfully with poly-ADP ribose polymerase (PARP) inhibitors of which two, olaparib and rucaparib, are FDA approved, and one, niraparib, has achieved a breakthrough designation. Also approved is the checkpoint inhibitor pembrolizumab for tumors with high microsatellite instability (MSI) scores, an alteration found in 2–3% of prostate cancers for which a dedicated prostate cancer trial would never have been conducted.

Other classes of therapy are approved based on a demonstrated survival benefits include the biologic agent sipuleucel-T, the second-generation taxane cabazitaxel, and the α-emitting bone-targeting radiopharmaceutical radium-223. Approval is also anticipated for PSMA-directed radionuclide therapy based on the survival benefit of Lu-177 PSMA in the phase 3 VISION trial relative to best supportive care alone. Overall, an intense focus of current CRPC research is to understand the optimal sequence in which to utilize these agents to maximize benefit for the individual patient. Most of these agents are also being tested earlier in the course of the disease when tumor burdens are lower and the disease less heterogeneous. The result has been an increase in the frequency of late-state tumors that have undergone a lineage transformation from epithelial to neuroendocrine phenotypes and are highly resistant to available therapies.

Pain Management Pain secondary to osseous metastases is one of the most feared complications of the disease and a major cause of morbidity, worsened by the narcotics needed to control symptoms. Management requires accurate diagnoses because noncancer etiologies including degenerative disease, spinal stenosis, and vertebral collapse secondary to bone loss are common. Neurologic symptoms, including those suggestive of base of skull disease or spinal cord compromise, require emergency evaluation because loss of function may be permanent if not addressed quickly. Neurologic symptoms and loss of function are best treated with external beam radiation, as are single sites of pain. Diffuse symptoms in the absence of neurologic deficits can be treated with bone-seeking radioisotopes, such as radium-223 or the β emitter ^{153}Sm-EDTMP; mitoxantrone; or other systemic therapies, such as abiraterone acetate, enzalutamide, and docetaxel. Radium-223 is indicated for patients with symptoms, whereas ^{153}Sm-EDTMP and mitoxantrone are approved for the palliation of pain but have not been shown to prolong life. Abiraterone, enzalutamide, and docetaxel do not have a formal indication for pain but were shown to palliate pain in the registration trials that led to their approval by showing a survival benefit.

Other bone-targeting agents, including bisphosphonates such as zoledronic acid and the RANK-ligand inhibitor denosumab, have been shown to reduce the frequency and development of skeletal complications including pain requiring analgesia, neurologic compromise from epidural extension of tumor, and/or the need for surgery or radiation therapy to treat symptomatic osseous disease. It is important to note that, for all of these agents, the direct effect on the tumor is modest, and benefits are seen without declines in PSA or improvements on imaging.

BENIGN DISEASE

BENIGN PROSTATIC HYPERPLASIA

BPH is a pathologic process that contributes to the development of lower urinary tract symptoms (LUTS) in men. LUTS, arising from lower urinary tract dysfunction, are further subdivided into obstructive symptoms (urinary hesitancy, straining, weak stream, terminal dribbling, prolonged voiding, incomplete emptying) and irritative symptoms (urinary frequency, urgency, urge incontinence, small voided volumes). LUTS and other sequelae of BPH are not just due to a mass effect but are also likely due to a combination of the prostatic enlargement and age-related detrusor dysfunction.

Diagnostic Procedures and Treatment LUTS are generally measured using a validated, reproducible index that is designed to determine disease severity and response to therapy—the AUA's Symptom Index (AUASI), also adopted as the International Prostate Symptom Score (IPSS) (Table 87-2). Serial AUASI is particularly useful in following patients as they are treated with various forms of therapy. Asymptomatic patients do not require treatment regardless of the size of the gland, while those with an inability to urinate, gross hematuria, recurrent infection, or bladder stones require evaluation and treatment. In patients with symptoms, uroflowmetry can identify those with normal flow rates who are unlikely to benefit from treatment, and bladder ultrasound can identify those with high postvoid residuals who may need intervention. Pressure-flow (urodynamic) studies detect primary bladder dysfunction. Cystoscopy is recommended if hematuria is documented and to assess the urinary outflow tract before surgery. Imaging of the upper tracts is advised for patients with hematuria, a history of calculi, or prior urinary tract problems.

Symptomatic relief is the most common reason men seek treatment for BPH, and therefore, symptomatic relief is usually the goal of therapy for BPH. α-Adrenergic receptor antagonists are thought to treat the dynamic aspect of BPH by reducing sympathetic tone of the bladder outlet, thereby decreasing resistance and improving urinary flow. 5ARIs are thought to treat the static aspect of BPH by reducing prostate volume and having a similar, albeit delayed effect. 5ARIs have also proven beneficial in the prevention of BPH progression, as measured by prostate volume, the risk of developing acute urinary retention, and the risk of having BPH-related surgery. The use of an alpha-adrenergic

TABLE 87-2 AUA Symptom Index

QUESTIONS TO BE ANSWERED	AUA SYMPTOM SCORE (CIRCLE 1 NUMBER ON EACH LINE)					
	NOT AT ALL	LESS THAN 1 TIME IN 5	LESS THAN HALF THE TIME	ABOUT HALF THE TIME	MORE THAN HALF THE TIME	ALMOST ALWAYS
Over the past month, how often have you had a sensation of not emptying your bladder completely after you finished urinating?	0+	1	2	3	4	5
Over the past month, how often have you had to urinate again less than 2 h after you finished urinating?	0	1	2	3	4	5
Over the past month, how often have you found you stopped and started again several times when you urinated?	0	1	2	3	4	5
Over the past month, how often have you found it difficult to postpone urination?	0	1	2	3	4	5
Over the past month, how often have you had a weak urinary stream?	0	1	2	3	4	5
Over the past month, how often have you had to push or strain to begin urination?	0	1	2	3	4	5
Over the past month, how many times did you most typically get up to urinate from the time you went to bed at night until the time you got up in the morning?	(None)	(1 time)	(2 times)	(3 times)	(4 times)	(5 times)
Sum of 7 circled numbers (AUA Symptom Score): ____

receptor antagonist and a 5ARI as combination therapy seeks to provide symptomatic relief while preventing progression of BPH.

Another class of medications that has shown improvement in LUTS secondary to BPH is phosphodiesterase-5 (PDE5) inhibitors, used currently in the treatment of erectile dysfunction. All four of the PDE5 inhibitors available in the United States—sildenafil, vardenafil, tadalafil, and avanafil—appear to be effective in the treatment of LUTS secondary to BPH. The use of PDE5 inhibitors is not without controversy, however, given the fact that short-acting phosphodiesterase inhibitors such as sildenafil need to be dosed separately from alpha blockers such as tamsulosin because of potential hypotensive effects.

Symptoms due to BPH often coexist with symptoms due to overactive bladder, and the most common pharmacologic agents for the treatment of overactive bladder symptoms are anticholinergics. This has led to multiple studies evaluating the efficacy of anticholinergics for the treatment of LUTS secondary to BPH.

Surgical therapy is now considered second-line therapy and is usually reserved for patients after a trial of medical therapy. The goal of surgical therapy is to reduce the size of the prostate, effectively reducing resistance to urine flow. Surgical approaches include TURP, transurethral incision, or removal of the gland via a retropubic, suprapubic, or perineal approach. Also used are transurethral ultrasound-guided laser-induced prostatectomy (TULIP), stents, and hyperthermia.

88 Testicular Cancer

David J. Vaughn

Testicular germ cell tumors (GCTs) represent 95% of all testicular neoplasms. Non-GCTs of the testis are much less common. Approximately 5% of GCTs arise in extragonadal locations including the mediastinum, retroperitoneum, and pineal gland. Treatment for testicular GCTs is determined by pathology and stage. The development of effective chemotherapy for this disease represents a landmark achievement in oncology. About 95% of newly diagnosed patients with testicular GCTs will be cured. For this reason, testicular cancer has been called "a model for a curable neoplasm."

INCIDENCE

In 2021, ~9500 cases of testicular GCTs will be diagnosed in the United States, with <450 deaths. These tumors are diagnosed most commonly in men between 20 and 40 years. The incidence of GCTs is increasing in men age 50 years and older.

GLOBAL CONSIDERATIONS

The incidence of testicular GCTs appears to be increasing worldwide. The disease has the highest incidence in Scandinavia, Western Europe, and Australia/New Zealand. Africa and Asia have the lowest incidence. The incidence in the United States and the United Kingdom is intermediate. While there does not appear to be a distinct biology related to geography, several countries have reported a migration to earlier stage disease in part related to public awareness and earlier diagnosis.

EPIDEMIOLOGY

GCTs are predominantly seen in young Caucasian men. The disease is much less commonly seen in African Americans. Testicular GCTs have an estimated heritability of almost 50%. Interestingly, the risk of GCT is higher in male siblings than in offspring of the patient. Although epidemiologic studies have been performed attempting to identify a relationship with environmental exposures, no conclusive causal links have been established.

Risk Factors The strongest risk factors for testicular GCT include a prior history of the disease, cryptorchidism, and a history of testicular germ cell neoplasia in situ (GCNIS). Patients with a prior history of testicular GCT have a 2% risk of developing a contralateral GCT. These are more commonly metachronous than synchronous. Men with cryptorchidism have approximately a four- to sixfold increased risk of developing testicular GCT. Orchidopexy before puberty decreases but does not eliminate this risk. Interestingly, the contralateral descended testis is also at risk for this disease. Men undergoing infertility evaluation in which a testicular biopsy demonstrates GCNIS have a significant risk of developing GCT. Although scrotal ultrasound of patients with testicular GCT may demonstrate testicular microcalcifications that may be related to GCNIS, the significance of testicular microcalcifications in the general population is unclear.

BIOLOGY

The primordial germ cell is the cell of origin for GCTs. Most malignant GCTs arise from GCNIS. The molecular events that result in the development of GCNIS and subsequent malignant GCT have not been fully determined. However, genetic analysis of GCTs has demonstrated an excess copy number of isochromosome 12p (i[12p]) in most cases. Several genome-wide association studies have identified multiple independent loci associated with testicular GCT risk. The strongest of these is the *KITLG* (KIT ligand) locus on chromosome 12. These loci contribute significantly to the heritable risk of this disease.

PATHOLOGY

GCTs are either seminomas or nonseminomas. For a tumor to be considered a seminoma, it must be 100% seminoma. Any mixed GCT is best approached as a nonseminomatous GCT (NSGCT). Seminomas represent ~50% of cases. Seminomas arise most commonly in patients in the fourth decade of life. Seminomas may contain syncytiotrophoblastic cells, which may secrete β human chorionic gonadotropin (hCG). Seminomas do not secrete α fetoprotein (AFP). Seminomas are exquisitely sensitive to both chemotherapy and radiation therapy. NSGCTs are most commonly diagnosed in the third decade of life. The histologic subtypes include embryonal carcinoma, yolk sac tumor, choriocarcinoma, and teratoma. Embryonal carcinoma is the most undifferentiated NSGCT subtype with the potential to differentiate into the other subtypes. Embryonal carcinoma may secrete AFP, hCG, both, or neither. Yolk sac tumor often secretes AFP. Choriocarcinoma is an aggressive subtype, often secreting hCG at very high levels. These NSGCT subtypes are all considered chemotherapy sensitive. Teratoma is composed of somatic cell types that are derived from two or more germinal layers (endoderm, mesoderm, and ectoderm). Teratomas are classified as mature, in which cell types resemble normal adult somatic tissue; immature, in which cell types resemble fetal somatic tissue; and malignant, in which the cell types have undergone malignant transformation into the malignant counterpart of the somatic tissue. Teratomas are chemotherapy resistant and must be approached surgically.

INITIAL PRESENTATION

Signs and Symptoms Although a painless testicular mass is pathognomonic of a GCT, most patients present with testicular swelling, firmness, discomfort, or a combination of these. The differential diagnosis may include epididymitis or orchitis and a trial of antibacterials may be considered. Patients with retroperitoneal metastases may complain of back or flank pain. Patients may have cough, shortness of breath, or hemoptysis as a result of lung metastases. In patients with elevation of serum hCG, gynecomastia may be present. Diagnostic delay is not uncommon and may be associated with a more advanced stage at diagnosis.

Physical Examination Careful examination of the affected testis and the contralateral normal testis should be performed. Many tumors will have a hard consistency to palpation. Some patients may show testicular atrophy. Evaluation for supraclavicular lymphadenopathy, gynecomastia, and abdominal mass should be performed. Inguinal lymphadenopathy is rare. Most patients with lung metastases will have normal auscultation of the lungs.

Diagnostic Testing If a firm testicular mass is identified, a scrotal ultrasound should be performed. Patients with suspected epididymitis or orchitis who do not respond to antibiotics should also undergo scrotal ultrasound. Scrotal ultrasound should include both testicles. On ultrasound, a testicular GCT is hypoechoic and may be multifocal. A solid mass identified on ultrasound should be considered malignant until otherwise proven. Transscrotal aspiration or biopsy of a testicular mass should never be performed. Such scrotal violation may result in tumor seeding of the scrotum or inguinal lymph nodes.

Serum Tumor Markers Serum AFP, hCG, and lactate dehydrogenase (LDH) should be measured in patients suspected of testicular GCT. AFP is elevated in ~60–70% of patients who present with NSGCTs. Seminomas never secrete AFP. A patient with a seminoma with elevation of AFP should be approached as having an NSGCT. The half-life of AFP is 5–7 days. A falsely elevated AFP may be seen in patients with hepatic disease or a condition called hereditary persistence of AFP, in which patients may have baseline AFP levels that are mildly elevated. hCG may be elevated in both NSGCTs as well as seminomas. Patients with choriocarcinoma may have markedly elevated levels of hCG. The half-life for hCG is 24–36 h. False-positive elevation of hCG may be seen secondary to hypogonadism, marijuana use, or as a result of interfering substances measured by the assay. LDH is a nonspecific marker for GCT. Its principal use is to help in the assessment of the risk classification of a patient with metastatic disease. Although elevation of serum tumor markers supports the diagnosis of a testicular GCT, it should be remembered that most patients with seminoma and up to a third of patients with NSGCTs do not have elevated levels. Serum microRNA (miR)-371a-3 has been identified as a promising biomarker for GCT, and validation studies are ongoing.

INITIAL MANAGEMENT

Inguinal Orchiectomy Prompt referral to urology should be performed if a testicular GCT is suspected. The initial treatment for most patients suspected of having a testicular GCT is radical inguinal orchiectomy with removal of the testicle and spermatic cord to the level of the internal inguinal ring. In patients who present with metastatic disease and the diagnosis of GCT is certain, orchiectomy may be deferred until completion of chemotherapy. Although some institutions perform testis-sparing surgery in select patients, the gold standard remains radical inguinal orchiectomy. Pathologic examination of the entire testicle is important, since testicular GCTs may be multifocal. Given the rarity of this cancer, review by an experienced pathologist is essential for accurate tumor classification. Serum tumor markers should be obtained before and after orchiectomy.

Staging The staging of testicular GCT is based on an understanding of the pattern of spread. The initial spread is by the lymphatic route to the retroperitoneal lymph nodes. A left-sided testicular GCT spreads first to the primary landing zone of left paraaortic lymph nodes inferior to the left renal vessels. A right-sided testicular GCT spreads first to the primary landing zone of the aortocaval nodes inferior to the right renal vessels. Nodal metastases may extend into the iliac regions. If scrotal violation occurred, inguinal lymph node metastases may be seen. Subsequent lymphatic spread is to the retrocrural, mediastinal, and supraclavicular lymph nodes. Hematogenous spread to the lung is the next most common site of metastasis. Metastases to the liver, bone, and brain are less commonly seen. Patients with newly diagnosed testicular GCTs should undergo computed tomography (CT) scan of the abdomen and pelvis. Chest x-ray should be performed. CT scan of the chest is performed if retroperitoneal metastases are present or if lung nodules are identified on chest x-ray. Bone scan and magnetic resonance imaging (MRI) of the brain are not routinely performed unless clinically indicated. Positron emission tomography (PET) has little role in the initial staging of testicular GCTs.

The American Joint Committee on Cancer tumor-node-metastasis (TNM) staging classification is used. There are three main stages of testicular GCT. Stage I is limited to the testis; stage II involves the retroperitoneal lymph nodes; and stage III includes lymph node involvement beyond the retroperitoneum and/or distant metastatic disease.

STAGE-BASED MANAGEMENT

Treatment of testicular GCT is based on two factors: (1) whether the tumor is seminoma or NSGCT and (2) the stage of the patient. This is summarized in **Fig. 88-1**.

Stage I • **SEMINOMA** About 70% of newly diagnosed patients with seminoma present with stage I disease. This is defined as no evidence of metastatic disease on imaging of the chest, abdomen, and pelvis. Approximately 15% of patients with stage I seminoma have metastatic disease at the microscopic level, usually in the retroperitoneum. Historically, patients with stage I seminoma were treated with a course of adjuvant radiation therapy to the paraaortic lymph nodes. While still an option, this is not usually performed because of concerns for late radiation-induced secondary malignancies. Active surveillance is the most common approach elected by these patients following orchiectomy. With active surveillance, interval physical examination and CT scan of the abdomen are performed. For the 15% of patients who develop metastatic disease during active surveillance, treatment with definitive radiation therapy or chemotherapy is curative in nearly all. A third option for clinical stage I seminoma is adjuvant chemotherapy with carboplatin monotherapy for one or two cycles. While effective in decreasing the risk of recurrence, it should be remembered that most patients are cured by orchiectomy alone, and therefore, the additional treatment is unnecessary. In addition, long-term data on toxicity are not available.

NSGCTs About 40% of newly diagnosed patients with NSGCTs present with stage I disease. Because NSGCTs have an increased potential for invasion and metastasis, spread to the retroperitoneum and beyond is more common than with seminoma. If pre-orchiectomy serum tumor markers are elevated, these must normalize after orchiectomy to be considered stage I. Patients with persistently elevated or rising serum tumor markers after orchiectomy have stage IS disease and should be treated with cisplatin-based chemotherapy. If the tumor is limited to testis without lymphovascular invasion, the risk of recurrence is approximately 20%. However, if the tumor has high-risk features including lymphovascular invasion, invasion of the spermatic cord, or invasion of the scrotum, the risk of recurrence is ~50% or higher. Historically, a prophylactic retroperitoneal lymph node dissection (RPLND) was performed. This surgery is not only diagnostic but also therapeutic. In fact, most patients who undergo prophylactic RPLND will never require chemotherapy. While still an option, this approach subjects many patients to unnecessary major abdominal surgery. RPLND is also associated with a small risk of retrograde ejaculation due to nerve injury, and nerve-sparing techniques have been developed. Active surveillance is frequently performed especially for patients without lymphovascular invasion. Most patients who relapse will be treated with cisplatin-based chemotherapy and achieve cure rates approaching 100%. Active surveillance can also be employed for patients with higher risk features, although the risk of progression is significantly higher. For this reason, some advocate adjuvant cisplatin-based chemotherapy with BEP (bleomycin, etoposide, cisplatin) for one cycle for these patients. Other centers favor a prophylactic RPLND. Almost all patients who present with stage I NSGCTs will achieve cure.

Stage II • **SEMINOMA** Approximately 15–20% of newly diagnosed patients with seminoma present with stage II disease. Patients are subgrouped into IIA, IIB, or IIC based on the size of the retroperitoneal nodes (≤2 cm, >2 to 5 cm, or >5 cm, respectively). Patients with stage IIA disease are usually treated with "dogleg" radiation therapy (referring to the shape of the radiation field), which includes the paraaortic and ipsilateral iliac nodes. Cisplatin-based chemotherapy may also be considered. Stage IIB disease is treated with cisplatin-based chemotherapy or, in select patients, radiation therapy. Most patients treated with radiation therapy who relapse will subsequently be cured with cisplatin-based chemotherapy. For patients with stage IIC disease, cisplatin-based chemotherapy should be used.

NSGCTs Approximately 15% of newly diagnosed patients with NSGCTs present with clinical stage II disease. Patients with stage IIA disease may be treated with primary RPLND. Alternatively, these patients may be treated with cisplatin-based chemotherapy. Patients with stage IIB and IIC disease are best initially managed with cisplatin-based chemotherapy.

Stage III Patients who present with stage III GCT (seminoma or NSGCT) are treated with cisplatin-based chemotherapy. These patients are classified into good-, intermediate-, or poor-risk categories using the International Germ Cell Consensus Classification system, which is based on clinical factors including histology, site of primary, the presence of nonpulmonary visceral metastatic disease, and the level of postorchiectomy serum tumor markers **(Table 88-1)**. Most patients with stage III GCT present with good-risk disease; >90% will be cured. The remainder present with intermediate-risk or poor-risk disease, associated with 5-year survival rates of ~80% and 50%, respectively. Select patients with rapidly progressive metastatic disease and life-threatening symptoms such as hemoptysis in whom there is a high clinical suspicion of GCT should emergently initiate cisplatin-based chemotherapy, even without a tissue diagnosis.

Chemotherapy The development of cisplatin-based chemotherapy represents an important advance in cancer medicine. Through a series of carefully performed clinical trials with the aim of maximizing cure while minimizing the extent of treatment, the chemotherapy approach to the treatment of these patients has been standardized. Patients with good-risk metastatic GCT are treated with either three cycles of BEP or four cycles of etoposide and cisplatin (EP). Patients with intermediate- and poor-risk metastatic disease are treated with either four cycles of BEP or four cycles of etoposide, ifosfamide, and cisplatin (VIP). Maintaining dose and schedule is important, as dose modifications and delays have been associated with inferior outcomes. Serum tumor markers should be monitored throughout treatment and should normalize during or after treatment. Cisplatin-based chemotherapy is associated with myelosuppression, nausea and vomiting, and alopecia. Cisplatin may result in nephrotoxicity, ototoxicity, and peripheral neuropathy. Bleomycin may result in pulmonary toxicity, and risk factors for this include age >40, renal failure, tobacco use, and the cumulative dose of bleomycin received. For patients at increased risk of bleomycin-induced pneumonitis, non-bleomycin-containing regimens as noted above may be given. Cisplatin-based chemotherapy is also associated with sterility. Approximately 30% of newly diagnosed testicular GCT patients have severe oligospermia or azoospermia. For the remainder with normal baseline spermatogenesis who receive cisplatin-based chemotherapy, all will be azoospermic at the completion of therapy. Approximately 80% of these patients will recover spermatogenesis over a period of several years. For this reason, prechemotherapy sperm banking should be offered to all patients treated with chemotherapy.

Stage 1

	Seminoma	NSGCT
Stage IA Testis only, no lymphovascular invasion	Active surveillance; or, Adjuvant carboplatin x 1 or 2 cycles; or, Adjuvant para-aortic RT	Active surveillance; or, Nerve-sparing RPLND; or Adjuvant BEP x 1 cycle
Stage IB Testis only, with lymphovascular invasion or invasion of spermatic cord or scrotum	Active surveillance; or, Adjuvant carboplatin x 1 or 2 cycles; or, Adjuvant para-aortic RT	Active surveillance; or, Adjuvant BEP x 1 cycle; or Nerve-sparing RPLND
Stage IS Elevated serum tumor markers post-orchiectomy	BEP x 3 cycles; or, EP x 4 cycles	BEP x 3 cycles; or, EP x 4 cycles

A

Stage 2

	Seminoma	NSGCT
Stage IIA N1: nodes ≤ 2 cm	Para-aortic and ipsilateral iliac RT; or, BEP x 3 cycles or EP x 4 cycles	Nerve-sparing RPLND; or, BEP x 3 cycles or EP x 4 cycles
Stage IIB N2: nodes > 2 to 5 cm	BEP x 3 cycles or EP x 4 cycles; or, Para-aortic and ipsilateral iliac RT	BEP x 3 cycles or EP x 4 cycles +/– postchemotherapy RPLND
Stage IIC N3: nodes > 5 cm	BEP x 3 cycles or EP x 4 cycles	BEP x 3 cycles or EP x 4 cycles +/– postchemotherapy RPLND

Postchemotherapy Surgery Upon completion of cisplatin-based chemotherapy, many patients with normalized serum tumor markers will have radiographic evidence of residual masses. In approximately half of patients with NSGCT, the residual mass is composed of necrosis and/or fibrosis. About 40% will have residual teratoma and only 10% will have residual viable nonteratomatous GCT. Unfortunately, radiographic imaging cannot accurately differentiate between these entities. For this reason, NSGCT patients with residual masses after chemotherapy undergo resection of all sites of disease. This most commonly includes a postchemotherapy RPLND. However, thoracotomy and neck dissection are required in some patients. If the patients are found to have residual necrosis or teratoma, no additional therapy is required. However, for patients with residual viable nonteratomatous GCT, two additional cycles of chemotherapy are frequently administered. It should be noted that in most centers, patients with minimal residual tumors defined as retroperitoneal lymph nodes of ≤1 cm will forego postchemotherapy RPLND. Patients who experience normalization of serum tumor markers with first-line chemotherapy but have enlarging tumors, most often cystic masses in the retroperitoneum, may have "growing teratoma syndrome." These patients are best approached with surgery.

For patients with metastatic seminoma, most residual masses are necrotic and do not harbor viable tumor. Patients with residual masses of 3 cm or less may be observed without surgery. For patients with residual masses >3 cm, fluorodeoxyglucose (FDG)-PET may be used to distinguish necrosis from viable seminoma and identify patients who should be considered for postchemotherapy surgery or short interval imaging.

RELAPSED DISEASE

Approximately 20–30% of patients with metastatic GCTs treated with cisplatin-based chemotherapy will not achieve durable disease control. Most of these patients will experience disease progression within 2 years following completion of chemotherapy. The International Prognostic Factors Study Group developed a risk stratification classification system for patients in first relapse. Contributors to a worsened prognosis include NSGCT histology, extragonadal primary, incomplete response to first-line chemotherapy, time to relapse of 3 months or less, level of serum tumor markers at relapse, and the presence of nonpulmonary visceral metastatic disease.

Patients in first relapse may be treated with either conventional-dose salvage chemotherapy or high-dose salvage chemotherapy with autologous stem cell rescue. There is controversy concerning which approach is optimal. Some institutions advocate for risk stratification, with more favorable prognosis patients receiving conventional-dose chemotherapy and worse prognosis patients receiving high-dose chemotherapy. The most commonly utilized conventional-dose regimen includes paclitaxel, ifosfamide, and cisplatin (TIP). In one study of TIP in patients with more favorable-risk disease, approximately two-thirds experienced 2-year progression-free survival. High-dose chemotherapy consists of initial salvage therapy followed by stem cell harvest and then two or three cycles of high-dose carboplatin and etoposide (CE) with stem cell rescue. The largest series of patients treated with high-dose chemotherapy was reported by researchers at Indiana University where this approach is considered standard for most patients in first relapse regardless of risk classification. In their study, ~70% of patients in first relapse achieved durable progression-free survival. A large retrospective analysis has compared conventional-dose salvage chemotherapy to high-dose salvage chemotherapy in patients in first relapse. This study reports a more favorable outcome with high-dose salvage chemotherapy across nearly all risk groups. However, given the retrospective nature of this study and the controversy concerning optimal approaches, an international randomized trial comparing conventional-dose chemotherapy (TIP) to high-dose chemotherapy with autologous stem cell rescue (TI-CE) is underway.

Some patients who experience disease progression after conventional-dose salvage chemotherapy may successfully be treated with high-dose salvage chemotherapy with autologous stem cell rescue. Patients with disease progression after high-dose salvage chemotherapy may be treated with subsequent chemotherapy regimens that include gemcitabine/oxaliplatin, gemcitabine/paclitaxel, epirubicin/cisplatin, and oral etoposide. While these patients may benefit from third-line chemotherapy, few will achieve durable disease control. Select patients with relapsed but resectable disease may be candidates for salvage or so-called "desperation" surgery. Studies of molecularly targeted agents and immune checkpoint inhibitors in this population have to date been generally disappointing.

Patients who experience disease progression >2 years after chemotherapy are considered to have "late relapse." Late relapse appears to have a different biology than early relapse. These patients tend to have more chemotherapy-resistant disease. Patients with late relapse usually have NSGCT with elevation of serum AFP. Many of these patients experience recurrence in the retroperitoneum many years after first-line chemotherapy, and this likely represents residual retroperitoneal disease that was not controlled after first-line therapy. These patients are best approached with salvage surgery.

EXTRAGONADAL GCTS

Approximately 5% of patients who present with GCTs have extragonadal primaries. These mainly originate in the mediastinum or retroperitoneum. Patients suspected of extragonadal GCT should undergo scrotal ultrasound to exclude a gonadal primary. Extragonadal seminomas have a similar excellent prognosis as their gonadal counterparts and are approached the same. Mediastinal NSGCTs are classified as poor risk and are treated with either four cycles of BEP or four cycles of VIP. These patients frequently require postchemotherapy thoracic surgery for residual disease. For this reason, some advocate avoiding bleomycin in this patient population. Klinefelter's syndrome is associated with an increased risk of mediastinal NSGCTs. Rarely, mediastinal NSGCTs are associated with hematologic disorders including acute myelogenous leukemia. NSGCTs arising in the retroperitoneum do not have a worse prognosis than their gonadal counterparts. Many patients who present with extragonadal GCTs will undergo core needle biopsy for diagnosis. However, select patients with extragonadal tumors and definitive elevation of serum tumor markers may initiate chemotherapy without a tissue diagnosis.

Cancers of unknown primary are defined as histologically proven metastatic malignancy in which the primary site is not obvious. A subgroup of patients with cancer of unknown primary have occult GCTs. Male gender, age <65 years, midline tumors, and nonsmoking status increase the likelihood of this presentation. Pathology may demonstrate a poorly differentiated malignant neoplasm. Immunohistochemical staining is used to exclude lymphoma. Tumor may be analyzed by fluorescence in situ hybridization for i(12p), which confirms the diagnosis. Even if the diagnosis is not certain, patients should be treated with cisplatin-based chemotherapy, which will cure up to 20% of this patient group.

TESTICULAR NON–GERM CELL TUMORS

Rarely, patients may develop testicular non-GCTs. These include non-Hodgkin's lymphoma, most commonly occurring in men over the age of 50; sex cord stromal tumors including Leydig cell tumors and Sertoli cell tumors; mesothelioma of the tunica vaginalis; and paratesticular sarcoma. Metastasis to the testis is rare, most commonly occurring in patients with advanced prostate cancer and melanoma.

SURVIVORSHIP AND LATE EFFECTS

Because most patients with testicular GCT will experience long-term survival, survivorship care is important. Since many of these patients will be followed by primary care physicians, an understanding of the physical, psychological, and social late effects is important. Late effects are defined as health problems that occur months or years after a disease is diagnosed or after treatment has ended. Late effects may be related to the underlying cancer or to the treatment the patient received. In long-term survivors of testicular GCT, increased cardiovascular risk and increased secondary malignancies have been reported. Patients treated with cisplatin-based chemotherapy have an increased risk of hypertension, hyperlipidemia, metabolic syndrome, and cardiovascular events. Patients treated with high cumulative doses of etoposide (e.g., patients who receive standard chemotherapy, relapse, and then receive salvage high-dose chemotherapy) may experience up to a 1–2% risk of developing acute myelogenous leukemia, typically 2–3 years after completing therapy and associated with an 11q23 translocation. Patients treated with radiation therapy, cisplatin-based chemotherapy, or both have an increased risk of developing secondary solid malignancies.

OVARIAN CANCER

INCIDENCE AND PATHOLOGY

Ovarian cancer remains a leading cause of cancer deaths in American women, ranking behind lung, breast, colon, and pancreatic cancers. The ovary is responsible for hormone and egg production. Between menarche (11–13 years) and menopause (45–55 years), the ovary is responsible for follicle maturation associated with egg maturation, ovulation, and cyclical sex steroid hormone production. These complex biologic functions are linked to stromal and germ cells within the ovary. Cells of the ovary can be broadly grouped into stromal cells and ovarian germ cells and the enveloping epithelial cells. Malignancies arising in each group include multiple histologic variants, each with unique neoplastic behaviors. Epithelial tumors are the most common histologic variant of ovarian neoplasms; they may be benign (50%), frankly malignant (33%), or of borderline malignancy of low malignant potential (16%). In adnexal masses detected by imaging or physical exam, age influences risk of malignancy; tumors in younger women are more likely benign. In the malignant group, the most common tumors are epithelial. In the group of the ovarian epithelial malignancies are the serous tumors (60–70%), mucinous tumors (10%), endometrioid tumors (10–15%), and clear cell tumors (10–15%) tumors. The distribution of histologic types varies in different parts of the world. The less common stromal tumors arise from the ancillary, supportive cells such as steroid hormone–producing cells and likewise have different phenotypes and clinical presentations. Most stromal tumors do not produce estrogen, but ectopic hormone production can be seen in certain subtypes. Tumors arising in the ovarian germ cell lineage are generally similar in biology and behavior to testicular tumors in males, although their intraperitoneal location alters some metastatic behaviors (Chap. 88). Ovarian tissue may also host metastatic tumors arising from breast, colon, gastric, and pancreatic primaries. Bilateral ovarian masses from metastatic mucin-secreting gastrointestinal cancers are termed *Krukenberg tumors*. A survey of other potential primaries is commonly required during the diagnostic workup of ovarian masses.

OVARIAN CANCER OF EPITHELIAL ORIGIN

Epidemiology An American woman has approximately a 1 in 72 lifetime risk (1.6%) of developing ovarian cancer, with the majority of affected women developing epithelial tumors. In 2021 in the United States, ~21,500 cases of ovarian cancer are expected to be diagnosed, with >14,000 deaths. Sporadic (not familial) epithelial tumors of the ovary have a peak incidence in women in their fifties and sixties, although age at presentation ranges from the third decade to the eighties and nineties. Ovarian cancer risk has been linked to an interactive mixture of epidemiologic, environmental, and genetic factors. Nulliparity, obesity, diet, infertility treatments, and possibly hormone replacement therapy have all been linked to an increase in risk. Protective factors include the use of oral contraceptives, multiparity, tubal ligation, aspirin use, and breast-feeding. Other epidemiologic factors such as the historical use of perineal talc agents remain controversial. The mechanisms underlying the various protective factors are largely unknown, but theories include suppression of ovulation, modulation of gonadotropins and progestins, and perhaps reduction of ovarian inflammation and damage associated with the repair of the ovarian cortex associated with ovulation.

Genetics and Pathogenesis Ovarian cancers are divided into type 1 cancers and the more aggressive type 2 variant. The type 1 cancers are characterized by low-grade histology and generally indolent behavior. These tumors include the low malignant potential tumors, low-grade endometrial and mucinous histologies, and clear cell cancers (which are more aggressive). Genetic alterations in type 1 cancers include mutations in *KRAS*, *BRAF*, *PTEN*, and *PIK3CA*. In contrast, studies have implicated serial genetic changes in the fallopian tube as the actual site of origin for most type 2, high-grade serous epithelial ovarian cancers. These aggressive tumors are more common and linked to losses in *TP53* and defective DNA repair. Carcinoma in situ has been identified in the tubal epithelium with early losses in *TP53* and the *BRCA1/BRCA2* gene function characterizing early tubal intraepithelial cancers. Following these early genetic events, additional mutations in these transformed cells lead to tumor cell shedding, metastasis, and invasion. These type 2, poorly differentiated, serous cancer cells can then spread to the ovaries and the peritoneal cavity, aided by the ovarian cancer cell's affinity for mesothelin-expressing cells.

Type 2 serous ovarian cancer is classically a disease characterized by widespread amplifications and deletions rather than single-gene point mutations or common gene fusions. In the Tumor Genome Atlas, loss of tumor-suppressor gene *TP53* function is present in >95% of serous ovarian cancers. Damage to homologous DNA repair genes, especially *BRCA1* and *BRCA2,* is also common in these tumors. Low prevalence but statistically recurrent somatic mutations in seven other genes including *NF1*, *RB1*, and *CDK12* were also seen. The most common heritable abnormality linked to ovarian cancer is a germline mutation in either *BRCA1* (chromosome 17q12–21) or *BRCA2* (chromosome 13q12–13). These genes are essential parts of the homologous DNA repair machinery for double-stranded DNA break repair. Individuals inheriting a single copy of a mutant allele have an increased lifetime risk of breast (46–87% for *BRCA1*; 38–84% for *BRCA2*) and ovarian cancer (39–63% for *BRCA1*; 16.5–27% for *BRCA2*). Many of these women have a family history that includes multiple cases of breast and/or ovarian cancer of at an early age. Male breast cancer, pancreatic cancer, and prostate cancer are also linked to familial *BRCA2* mutations. The most common malignancy in women carrying germline *BRCA1/2* mutations is breast carcinoma, although women harboring germline *BRCA1* mutations also have a marked increased risk of developing ovarian malignancies in their forties and fifties. Women harboring a mutation in *BRCA2* have a lower penetrance of ovarian cancer with onset typically in their fifties or sixties. Other uncommon germline mutation of other genes encoding proteins linked to homologous DNA repair (e.g., *PALB2*) can also contribute to cancer risk, although the frequency of mutation and magnitude of risk increment are much lower and not well defined. Screening studies, even in the mutated *BRCA1/2* families, suggest that any of the available screening techniques, including structured, serial evaluation of the CA-125 serum marker and transvaginal ultrasound, remain insufficient to reliably detect early-stage ovarian cancer in prospective testing. Germline *BRCA1/2* testing is recommended for *all* incident epithelial ovarian cancers to detect probands for therapeutic intervention and identify relatives at risk. Women with these high-risk germline mutations are advised to undergo prophylactic removal of fallopian tubes and ovaries after completing childbearing, ideally before age 40. Early prophylactic salpingo-oophorectomy is highly protective. Salpingo-oophorectomy also appears to protect these women from subsequent breast cancer (risk reduction 50%). Prophylactic salpingectomy is almost certainly a key part of any surgical prophylaxis strategy for ovarian cancer prevention, but the benefits of isolated oophorectomy on either ovarian or breast cancer risk have not yet been clearly defined. Although less common, ovarian cancer is also another familial form of cancer (along with colorectal and endometrial cancer) that may develop in women with type II Lynch syndrome caused by mutations in one of the DNA mismatch repair genes (*MSH2, MLH1, MLH6, PMS1, PMS2*). Ovarian cancer may appear in women younger than 50 years of age in this syndrome.

Neoplasms of the ovary tend to be painless unless they undergo torsion. Nonspecific gastrointestinal symptoms like bloating and early satiety are common at presentation, probably related to compression of local organs or due to symptoms from metastatic disease. Women with ovarian tumors also may have an increased incidence of symptoms including pelvic discomfort, bloating, and perhaps changes in urinary or bowel pattern. Unfortunately, all of these symptoms are common in

TABLE 89-1 Staging and Survival in Gynecologic Malignancies

STAGE	OVARIAN	5-YEAR SURVIVAL, %	ENDOMETRIAL	5-YEAR SURVIVAL, %	CERVIX	5-YEAR SURVIVAL, %
0	—		—		Carcinoma in situ	100
I	Confined to ovary	88–95	Confined to corpus	>90	Confined to uterus	85
II	Confined to pelvic organs	70–80	Involves corpus and cervix	~75	Invades beyond uterus but not to pelvic wall	65
III	Intra-abdominal spread to omentum, diaphragm, or lymph nodes	20–40	Extends outside the uterus but not outside the true pelvis	45–60	Extends to pelvic wall and/or lower third of vagina, or hydronephrosis	35
IV	Spread outside abdominal cavity, parenchymal spread, and pleural effusion cytology	17	Extends outside the true pelvis or involves the bladder or rectum	~20	Invades mucosa of bladder or rectum or extends beyond the true pelvis	7

primary care and are frequently dismissed by either the woman or her health care team until later stages of disease. The pathogenic factors and timing of spread beyond the ovary are still not well understood. The most common symptoms at presentation of advanced disease include a period of progressive complaints of nausea, early satiety, bloating, indigestion, constipation, and abdominal pain. Signs include the rapid increase in abdominal girth due to the accumulation of ascites that typically alerts the patient and her physician that the concurrent gastrointestinal symptoms are likely associated with malignant pathology. Radiologic evaluation typically demonstrates a complex adnexal mass with ascites, carcinomatosis, and pelvic, para-aortic and mesenteric adenopathy in advanced disease. Positron emission tomography (PET) scans are generally not required. Laboratory evaluation often demonstrates a markedly elevated CA-125, a shed mucin component (MUC16) associated with, but not specific for, ovarian cancer. Ovarian cancers are divided into four stages, with stage I tumors confined to the ovary, stage II malignancies confined to the pelvis, and stage III confined to the peritoneal cavity and retroperitoneal nodes (Table 89-1). These three stages are subdivided, with the most common presentation, stage IIIC, defined as tumors with bulky intraperitoneal disease or positive lymph node involvement. About 70% of women present with stage III disease. Stage IV disease includes women with parenchymal metastases (liver, lung, spleen) or, alternatively, abdominal wall or pleural disease. The 30% of patients not presenting with stage III disease are roughly evenly distributed among the other stages.

Screening Ovarian cancer is a highly lethal condition. It is curable in early stages but seldom curable in advanced stages; hence, screening continues to be of considerable interest. Early-stage tumors often secrete excessive amounts of normal proteins that can be measured in the serum such as CA-125, mesothelin, and HE-4. Nevertheless, the incidence of ovarian cancer in the middle-aged female population is very low, with only ~1 in 2000 women between the ages of 50 and 60 carrying an asymptomatic and undetected tumor. Thus, effective screening techniques must be both sensitive and highly specific to minimize the number of false positives. Panels of serum markers have not improved on CA-125 alone, nor have risk assessment strategies using algorithms with multiple CA-125 measurements over time. No other screening strategies have been any more successful to date. Some large studies have suggested that low-specificity screening might even worsen mortality in the screened population. Screening for ovarian cancer is currently not recommended outside of a clinical trial, but large ongoing clinical trials are studying algorithmic detection by serial sampling strategies.

TREATMENT

Ovarian Cancer

Epithelial ovarian cancer can be divided into distinct "disease states" for the purpose of treatment selection, as shown in Fig. 89-1. Surgery by a skilled gynecologic oncologist remains the preferred initial therapy for ovarian cancer. However, the amount of residual visible cancer at the end of a primary operation is strongly predictive of outcome and is paired with histology, grade, and stage to determine prognosis and treatment. In women presenting with a localized ovarian mass, the principal diagnostic and therapeutic maneuver is abdominal surgery to determine if the tumor is benign or malignant. In the event that the tumor is malignant, the surgical specimen will determine if the tumor arises in the ovary or is a site of metastatic disease. Metastatic disease to the ovary can be seen from primary tumors of the colon, appendix, stomach (Krukenberg tumors), and breast. Needle biopsy is contraindicated to avoid malignant contamination of the peritoneal cavity with malignant cells. Typically, women undergo laparoscopic evaluation and unilateral salpingo-oophorectomy for diagnostic purposes. If pathology reveals a primary ovarian malignancy or the laparoscopy proves disseminated disease is present, then the procedure should be followed by a total hysterectomy, removal of the remaining tube and ovary, omentectomy, and pelvic node sampling along with biopsies of the peritoneal cavity and diaphragms. This extensive surgical procedure is performed because ~30% of tumors that, by visual inspection, appear to be confined to the ovary have already disseminated to the peritoneal cavity and/or surrounding lymph nodes. As with axillary dissections in breast cancer, node sampling is diagnostic, but full lymphadenectomy appears to provide little or no additional therapeutic advantage over nodal sampling. The target outcome of an ovarian cancer surgery is always an R0 resection, with no visible residual cancer. The less favorable "optimal resection" (no disease >1 cm in size) is still clinically useful, and the prognosis of those patients is much better than that of patients who are left with >1 cm of disease at the end of surgery. These "suboptimally debulked" patients derive very little benefit from their surgery. If a suboptimal debulking is anticipated, the surgery should be delayed until after several cycles of neoadjuvant chemotherapy. Such "interval debulking" surgery achieves similar results to primary surgery with diminished surgical morbidity and more timely chemotherapy. Patients without gross residual disease after resection have a median survival in excess of 60 months, compared to 28–42 months for those left with macroscopic tumor or those undergoing interval debulking, regardless of treatment strategy.

After appropriate surgical treatment, primary chemotherapy will consist of combination treatment with paclitaxel and carboplatin. Primary chemotherapy can be delivered intravenously, or alternatively, some therapy can be directly administered into the peritoneal cavity via an indwelling catheter. Some, but not all, randomized studies have demonstrated improved survival with intraperitoneal (IP) therapy. The IP approach is technically more difficult and is increasingly replaced by carboplatin and paclitaxel, which appears to offer similar results.

With optimal debulking surgery and platinum-based chemotherapy (usually carboplatin dosed to an area under the curve [AUC] of 6.0 plus paclitaxel 175 mg/m^2 by 3-h infusion in monthly cycles), 70% of women who present with advanced-stage tumors show tumor reduction, and 40–50% experience a complete remission with normalization of their CA-125, CT scans, and physical

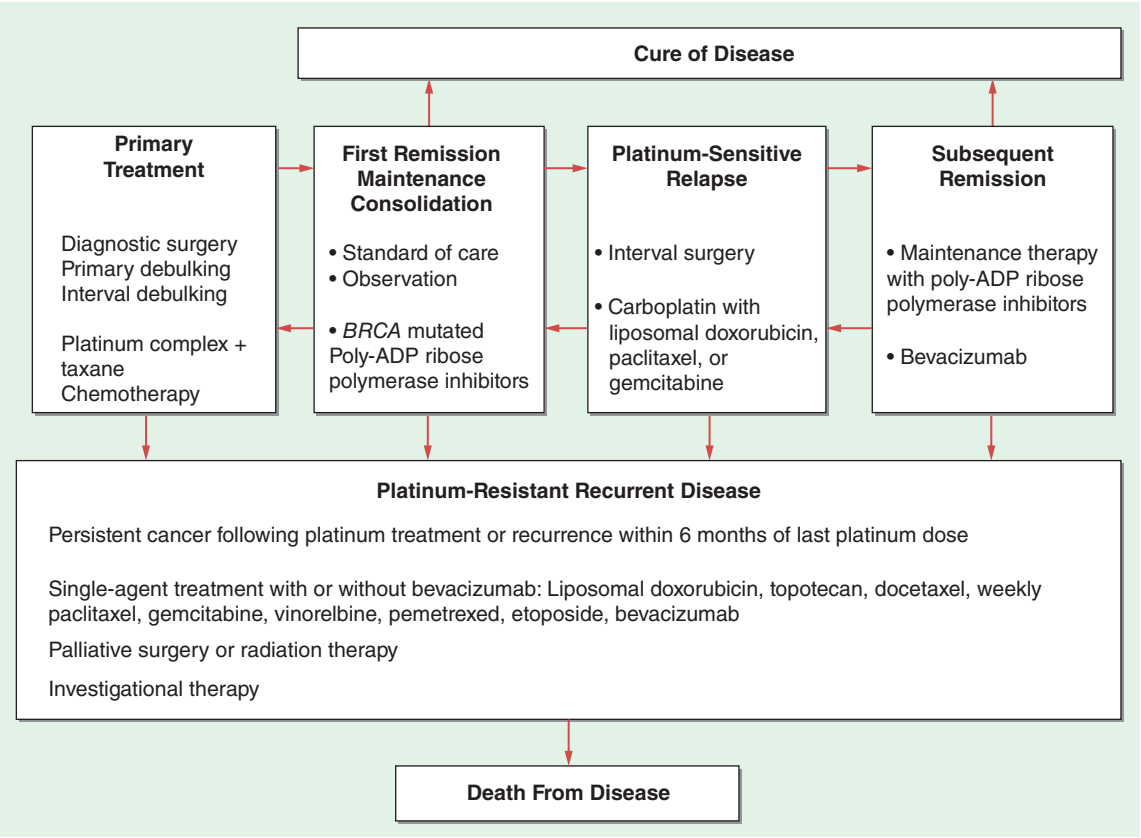

FIGURE 89-1 Disease states model of epithelial ovarian cancer and its treatment. Each box represents a relatively homogenous group of patients who share a palette of potential treatment choices and have a similar prognosis. The *arrows* indicate that a single patient may move from one state to another during the course of her illness, and the choice of treatments will become different in her new disease state.

examination. Poly-ADP ribose polymerase inhibitors (PARPi) such as niriparib or olaparib, when administered at the completion of intravenous chemotherapy, appear to substantially delay recurrence and probably provide survival advantages as well. In the majority of patients, disease still recurs within 1–4 years from the completion of their primary therapy. CA-125 levels often increase as a first sign of relapse, and CT scan findings are confirmatory. Recurrent disease is often successfully managed for years, but rarely cured, with a variety of chemotherapeutic agents. Additional surgical therapy does not appear to extend survival in randomized trials. Patients with a treatment-free interval are often best treated with additional platinum doublets, combining carboplatin with liposomal doxorubicin, gemcitabine, or a taxane. Eventually all women who experience relapse develop chemotherapy-refractory disease. Refractory ascites, poor bowel motility, and obstruction or tumor-infiltrated aperistaltic bowel are all common premorbid events. Limited surgery to relieve intestinal obstruction, localized radiation therapy to relieve pressure or pain from masses, or palliative chemotherapy may be helpful. Agents with >15% response rates include gemcitabine, topotecan, liposomal doxorubicin, and bevacizumab. Five-year survival correlates with the stage of disease: stage I, 90–95%; stage II, 70–80%; stage III, 25–40%; stage IV, 10–15% (Table 89-1). Prognosis is also influenced by histologic grade: 5-year survival is 88% for well-differentiated tumors, 58% for moderately differentiated tumors, and 27% for poorly differentiated tumors. Histologic type has less influence on outcome.

UNCOMMON OVARIAN TUMORS

Low Malignant Potential Tumors (Borderline Tumors) These type 1 tumors are found in younger women (age 30–50 years) and indolent in behavior, and few of these patients will succumb to their tumors (10-year survival may approach 98%), although recurrence is not uncommon. Certain features, such as micropapillary histology and microinvasion, are linked to more aggressive behavior. Tumors of low malignant potential should be carefully distinguished from grade 1 serous carcinomas. Borderline tumor patients are managed primarily by surgery; chemotherapy and radiation therapy do not substantially alter survival.

Stromal Tumors Approximately 7% of ovarian neoplasms are stromal tumors, with ~1800 cases expected each year in the United States. Ovarian stromal tumors or sex cord tumors are most common in women in their fifties or sixties, but tumors can present at any age. These tumors arise from the mesenchymal components of the ovary, including both steroid-producing cells and fibroblasts. Most of these tumors are indolent tumors with limited metastatic potential and present as unilateral solid masses. These tumors primarily are discovered by the detection of an abdominal mass, sometimes with abdominal pain due to ovarian torsion, intratumoral hemorrhage, or rupture. Rarely, stromal tumors can produce estrogen and present with breast tenderness as well as precocious puberty in children, menstrual disturbances in reproductively active women, or postmenopausal bleeding. In some women, estrogen-associated secondary malignancies, such as endometrial or breast cancer, may present as synchronous malignancies. Sertoli-Leydig tumors often present with hirsutism and virilization due to increased production of androgens. Hormonally inert tumors include fibromas, which present as solitary masses often in association with ascites and occasionally hydrothorax, also known as Meigs's syndrome. A subset of these tumors present in individuals with a variety of inherited disorders that predispose them to mesenchymal neoplasia including Ollier's disease (juvenile granulosa cell tumors) and Peutz-Jeghers syndrome (ovarian sex cord tumors). The treatment of these tumors is almost exclusively by surgical resection, without adjuvant chemotherapy. Chemotherapy with carboplatin and

paclitaxel is generally reserved for either unresectable or multiply recurrent tumors.

Germ Cell Tumors of the Ovary Germ cell tumors, like their counterparts in the testis, are cancers of germ cells. These totipotent cells contain the programming for differentiation to essentially all tissue types, and hence, the germ cell tumors include a histologic menagerie of bizarre tumors, including benign teratomas (dermoid cysts) and a variety of malignant tumors, such as dysgerminoma, immature teratomas, yolk sac malignancies, and choriocarcinomas. Benign teratoma (or dermoid cyst) is the most common germ cell neoplasm of the ovary and often presents in young women. These tumors include a complex mixture of differentiated tissue including tissues from all three germ layers. In older women, these differentiated tumors can develop malignant transformation, most commonly squamous cell carcinomas. Malignant germ cell tumors include dysgerminomas, yolk sac tumors, immature teratomas, and embryonal and choriocarcinomas. Germ cell tumors can present at all ages, but the peak age of presentation tends to be in adolescents. Typically, these tumors will become large ovarian masses, which eventually present as palpable low abdominal or pelvic masses. Like sex cord tumors, torsion or hemorrhage may present urgently or emergently as acute abdominal pain. Some germ cell tumors produce elevated levels of human chorionic gonadotropin (hCG) or α-fetoprotein (AFP). Unlike epithelial ovarian cancer, these tumors have a higher proclivity for nodal or hematogenous metastases. Germ cell tumors typically present in women who are of childbearing age, and because bilateral tumors are uncommon (except in dysgerminoma, 10–15%), the typical treatment is unilateral oophorectomy or salpingo-oophorectomy with lymph node sampling. Most commonly, women with advanced malignant germ cell tumors typically receive bleomycin, etoposide, and cisplatin (BEP) chemotherapy, in an analogous fashion to the treatment of testicular cancers. In the majority of these women, even those with advanced-stage disease, cure is expected. Dysgerminoma is the ovarian counterpart of testicular seminoma and is highly curable. Although the tumor is highly radiation-sensitive, radiation produces infertility in many patients. BEP chemotherapy is as effective or more so without causing infertility.

FALLOPIAN TUBE CANCER

Transport of the egg to the uterus occurs through the fallopian tube, with the distal ends of these tubes composed of fimbriae that drape about the ovarian surface and capture the egg as it erupts from the ovarian cortex. As described above, the majority of type 2 ovarian cancers are now thought to arise from the tubal epithelium. As might be expected, fallopian tube malignancies are typically of serous histology and share the same biology and recommended treatment as serous ovarian cancer. These tumors often present as clinically isolated adnexal masses, but like ovarian cancer, these tumors spread relatively early throughout the peritoneal cavity. Fallopian tubal cancers have a natural history and treatment that are essentially identical to ovarian cancer (Table 89-1).

CERVICAL CANCER

ETIOLOGY AND GENETICS

Cervical cancer is the second most common and the most lethal malignancy in women worldwide. Infection with high-risk strains of human papillomavirus (HPV) is the primary neoplastic-initiating event in the vast majority of women with invasive cervical cancer. This double-stranded DNA virus infects epithelium near the transformation zone of the cervix where underlying columnar epithelium becomes squamous epithelium. More than 60 types of HPV are known, with ~20 types having the ability to generate high-grade dysplasia and malignancy. HPV16 and 18 are the types most frequently associated with high-grade dysplasia, but types 31, 33, 35, 52, and 58 are also considered to be high-risk variants. The large majority of sexually active adults are exposed to HPV, and most women clear the infection without specific intervention. The 8-kb HPV genome encodes seven early genes, most notably *E6* and *E7*, which can bind to *RB* and *p53*, respectively. High-risk types of HPV encode *E6* and *E7* molecules that are particularly effective at inhibiting the normal cell cycle checkpoint functions of these regulatory proteins, leading to immortalization but not full transformation of cervical epithelium. A minority of women will fail to clear the infection, with subsequent HPV integration into the host genome. Over as little as a few months to several years, some of these persistently infected women develop worsening dysplasia, a premalignant condition that, untreated, can progress to cervical carcinoma. Complete transformation to cancer occurs over a period of years and almost certainly requires the acquisition of other poorly defined genetic mutations within the infected and immortalized epithelium.

In 2018, ~570,000 new cases of cervical cancer occurred worldwide, with an estimated 311,000 deaths. Cancer incidence is particularly high in women residing in Central and South America, the Caribbean, and southern and eastern Africa. The mortality rate is disproportionately high in Africa. In the United States, an estimated 14,480 women will be diagnosed with cervical cancer in 2021 and ~4290 women will die of the disease.

In the integrated genomic characterization of cervical cancer by The Cancer Genome Atlas (TCGA), integration of HPV sequences was found in all of the HPV18-linked cancers and over three-quarters of the HPV16 cancers. The cervical tumors also showed a characteristic APOBEC (apolipoprotein B mRNA editing enzyme, catalytic polypeptide-like; a family of cytidine deaminases that edit DNA and are endogenous mutagenic enzymes) pattern of mutagenesis, with *ERBB3, CASP8*, and *TGFRB2* identified as significantly mutated genes presumably linked to progression from dysplasia to carcinoma. In the much smaller number of HPV-negative cancers, which are more common in older women, mutations in oncogenes *KRAS, ARID1A,* and *PTEN* were frequently seen. The clinical behavior of these cancers is likely to be different.

HPV INFECTION AND PREVENTION

The Pap smear is the primary detection method for asymptomatic preinvasive cervical dysplasia of squamous epithelial lining during a gynecologic exam. Because the delay between dysplasia and frank cervical cancer is years long, annual (or longer) screening and prevention strategies that detect precancerous dysplasia and carcinoma in situ can be implemented successfully. Annual or biannual cervical scraping for cytology (Pap smear) is highly effective in reducing the incidence of cervical cancer by early detection and subsequent surgical treatment of premalignant disease. The incorporation of HPV testing by polymerase chain reaction (PCR) or other molecular techniques increases the sensitivity of detecting cervical pathology but at the cost of lower sensitivity in that it identifies many women with transient infections who require no specific medical intervention. Unfortunately, both the collection of a Pap smear and its cytologic evaluation require infrastructure beyond the means of many middle- and low-income countries. High-throughput, low-technology prevention strategies and point-of-care testing are needed to identify and treat women bearing high-risk cervical dysplasia to prevent cancer development.

A primary prevention strategy relies on HPV vaccines. Currently approved vaccines include the recombinant proteins to the late proteins, L1 and L2 of HPV16 and 18, as well as other, less common cancer-causing isotypes 11, 31, 33, 45, 52, and 58. Vaccination of girls aged 11–13 years with two injections (1 year apart) before the initiation of sexual activity dramatically reduces the rate of high-risk HPV infection and subsequent dysplasia. Vaccination of both boys and girls is increasingly considered to reduce the risk of HPV-induced cancers of the pharynx. Partial protection is also provided against other HPV types, although vaccinated women are still at risk for HPV infection and still benefit from standard Pap smear screening.

CLINICAL PRESENTATIONS

Risk Factors Clinical risk factors include many HPV infection–linked features: a high number of sexual partners, early age of first intercourse, and history of venereal disease. Smoking is a cofactor;

heavy smokers have a higher risk of dysplasia with HPV infection. HIV infection, especially when associated with low CD4+ T-cell counts, is associated with a higher rate of high-grade dysplasia and likely a shorter latency period between infection and invasive disease. Histologically, the majority of cervical malignancies are squamous cell carcinomas associated with HPV, but adenocarcinomas are also HPV related, and both arise in the transitional zone of the endocervical canal; the lesions in the canal or cervical glands may not be seen by visual inspection of the cervix and can be missed by Pap smear screening. Less common malignancies, such as vulvar cancer, anal cancer, and pharyngeal cancer, are also linked to HPV infection.

Diagnosis of Cervical Cancer Early cancer of the cervix is asymptomatic, and this biology underlies the recommendations for routine gynecologic care. Larger, invasive carcinomas often have symptoms or signs including postcoital spotting or intermenstrual cycle bleeding or menometrorrhagia. Foul-smelling or persistent yellow discharge may also be present. Symptoms such as pelvic or sacral pain suggest lateral extension into the pelvic nerve plexus by either the primary tumor or a pelvic node metastasis and indicate advanced-stage disease. Likewise, flank pain from hydronephrosis from ureteral compression or deep-venous thrombosis from iliac vessel compression suggests either extensive nodal disease or direct extension of the primary tumor to the pelvic sidewall. The most common finding upon physical exam is a visible tumor on the cervix, but deeper tumors in the cervical os and glands should be considered. Larger tumors may be identified by inspection and biopsied directly. Staging of cervical cancer is performed by clinical exam. Stage I cervical tumors are confined to the cervix, whereas stage II tumors extend into the upper vagina or paracervical soft tissue **(Fig. 89-2)**. Stage III tumors extend to the lower vagina or the pelvic sidewalls, whereas stage IV tumors invade the bladder or rectum or have spread to distant sites. While radiographic studies are not part of the formal clinical staging of cervical cancer, treatment planning requires them for appropriate therapy. CT can detect hydronephrosis indicative of pelvic sidewall disease but is not accurate at evaluating other pelvic structures. MRI is more accurate at estimating uterine extension and paracervical extension of disease into soft tissues typically bordered by broad and cardinal ligaments that support the uterus in the central pelvis. Very small stage I cervical tumors can be treated with a variety of surgical procedures, but minimally invasive surgery has inferior outcome compared to standard open hysterectomy. In young women desiring to maintain fertility, radical trachelectomy removes the cervix with subsequent anastomosis of the upper vagina to the uterine corpus; however, subsequent pregnancies may be more problematic. Patients with large stage I cervical tumors (4 cm) confined to the cervix and all stage II to IV patients are treated with radiation therapy in combination with cisplatin-based chemotherapy. This multimodality treatment can offer the patient with advanced-stage disease a 40–80% chance of cure depending on the clinical circumstances. Platinum agents (cisplatin or carboplatin) combined with paclitaxel and bevacizumab are generally considered as the best palliative choice for metastatic cervical cancer patients. Secondary chemotherapy confers minimal improvement in most patients. Immunotherapy with immune checkpoint inhibitors or adoptive T-cell therapies are promising avenues for improved outcomes in recurrent, unresectable cancers of the cervix.

UTERINE CANCER

EPIDEMIOLOGY

Several different tumor types arise in the uterine corpus. Most tumors arise in the glandular lining and are endometrial adenocarcinomas. Benign (leiomyomas) and malignant tumors (leiomyosarcomas) can also arise in the uterine smooth muscle and have very different clinical features. The endometrioid histologic subtype is the most common gynecologic malignancy in the United States. In 2021, the American Cancer Society predicted that 66,570 new cancers of the uterine corpus in 2021 with 12,940 resulting deaths. Development of these tumors is a multistep process, with estrogen playing an important early role in driving endometrial gland proliferation. Relative overexposure to this class of hormones is the principal risk factor for the subsequent development of endometrioid tumors. In contrast, progestins drive glandular maturation and are protective. Hence, women with high endogenous or pharmacologic exposure to estrogens, especially if unopposed by progesterone, are at higher risk for endometrial cancer. Obese women, women treated with postmenopausal estrogens, or women with estrogen-producing tumors are at higher risk for endometrial cancer. In addition, long-term treatment with tamoxifen, which has antiestrogenic effects in breast tissue but can show weak estrogenic effects in uterine epithelium, is associated with an increased risk of endometrial cancer.

Genetics Women with a germline mutation in one of a series of DNA mismatch repair genes associated with the Lynch syndrome, also known as hereditary nonpolyposis colon cancer (HNPCC) syndrome, are at increased risk for endometrioid endometrial carcinoma. These individuals have germline mutations in *MSH2*, *MLH1*, and, in rare cases, *PMS1* and *PMS2*. Individuals who carry these mutations typically have a family history of cancer and are at markedly increased risk for colon cancer and modestly increased risk for ovarian cancer and a variety of other tumors. Middle-aged women with HNPCC carry a 4% annual risk of endometrial cancer and a relative overall risk of ~200-fold as compared to age-matched women without HNPCC. In sporadic cancers, secondary events such as mutation of the *PI3K* gene or the loss of the *PTEN* tumor-suppressor gene likely serve as secondary genetic "hits" in the carcinogenesis related to estrogenic excess. The molecular events that underlie less common endometrial cancers such as clear cell and papillary serous tumors of the uterine corpus are not well understood.

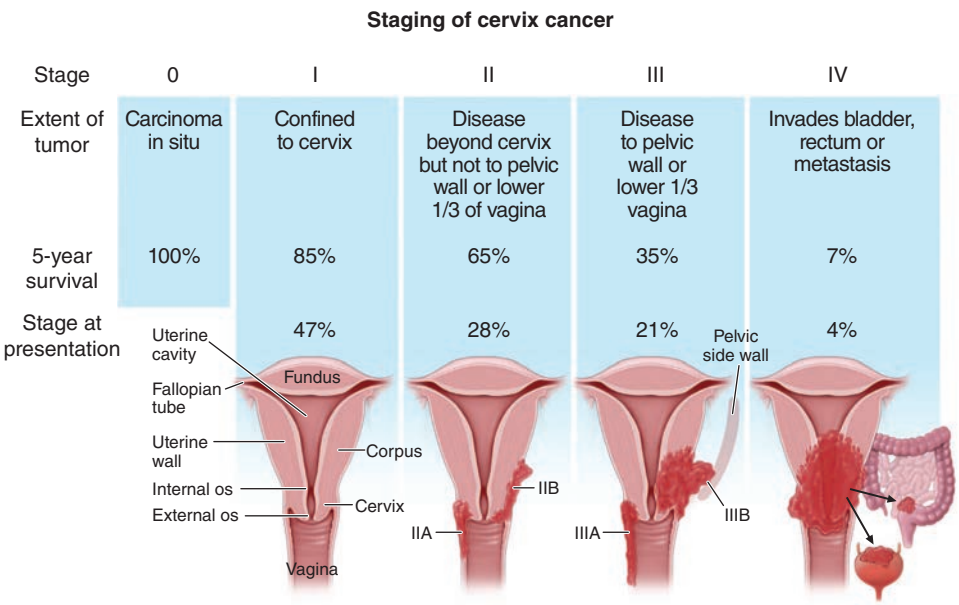

FIGURE 89-2 Anatomic display of the stages of cervix cancer defined by location, extent of tumor, frequency of presentation, and 5-year survival.

PATHOLOGY

Approximately 75–80% of endometrial cancers are adenocarcinomas and have been characterized as type 1 (estrogen-linked) endometrial cancers and type 2 cancers that have less clear associations with estrogens (clear cell cancers, serous cancers, and mucinous cancers). Endometrial serous cancers show *TP53* loss of function and behave clinically more like ovarian cancers with high risk for systemic recurrence. Prognosis for endometrial cancer depends on stage, histologic grade, and depth of myometrial invasion.

CLINICAL PRESENTATION

The majority of women with tumors of the uterine corpus present with postmenopausal vaginal bleeding due to shedding of the malignant endometrial lining. Premenopausal women often will present with atypical bleeding between typical menstrual cycles. These signs typically bring a woman to the attention of a health care professional, and the majority of women present with early-stage disease in which the tumor is confined to the uterine corpus and, consequently, have a high cure rate. Diagnosis is typically established by endometrial biopsy. Type 1 tumors may spread to pelvic or para-aortic lymph nodes and are generally subjected to sentinel lymph node biopsy at the time of primary surgery. Serous tumors tend to have patterns of spread much more reminiscent of ovarian cancer, and patients may present with omental/peritoneal disease and sometimes ascites. Some women with endometrial cancer have a history of endometriosis. Some women presenting with uterine sarcomas will present with pelvic pain. Uterine sarcomas (carcinosarcomas and leiomyosarcomas) commonly are found by detection of symptomatic large pelvic masses that may or may not be associated with dysfunctional bleeding.

TREATMENT

Uterine Cancer

Most women with endometrial cancer have disease that is localized to the uterus (75% are stage I, Table 89-1), and definitive treatment typically involves a hysterectomy with removal of the ovaries and fallopian tubes. The resection of lymph nodes does not improve outcome, but sentinel node resection provides important staging and prognostic information. Node involvement defines stage IIIC disease. Tumor grade and depth of invasion are the two key prognostic variables in early-stage tumors, and women with low-grade and/or minimally invasive tumors (<50% myometrial penetration) are typically observed after definitive surgical therapy. Patients with high-grade tumors or tumors that are deeply invasive (stage IB) are at higher risk for pelvic recurrence or recurrence at the vaginal cuff, which is typically prevented by intravaginal brachytherapy.

The loss of one or more mismatch repair proteins results in microsatellite instability (MSI) with a larger number of mutations in the tumor. MSI testing should be routinely performed in endometrial cancers at the time of diagnosis to help with current and future treatment plans. MSI cancers, when recurrent or present at an advanced stage, are likely to respond to immune checkpoint therapy. Women with regional metastases or metastatic disease (3% of patients) with low-grade tumors can be treated with progesterone or tamoxifen. Poorly differentiated tumors lack hormone receptors and are typically resistant to hormonal manipulation. The role of adjuvant chemotherapy in stage I–II disease is generally restricted to serous endometrial cancers. For more advanced-stage cancers (stage III–IV), chemotherapy and/or immune checkpoint blockade are administered because of the higher rates of recurrent systemic disease. Carboplatin and paclitaxel combinations are the current standard of care. Chemotherapy for metastatic disease is delivered with palliative intent. Patients with advanced cancer and known mismatch repair deficits may respond particularly well to immunotherapy with antagonists of the PD-1/PD-L1 axis. Lenvatinib and pembrolizumab (even for microsatellite-stable tumors) have become the most common second-line treatments, although survival data are not yet available. Other potentially active treatments include bevacizumab, mTOR inhibitors (e.g., temsirolimus), and anthracyclines. Carcinosarcomas of the uterus (also called Müllerian tumors) contain both mesenchymal and epithelial components but will often respond to paclitaxel and platinum complex therapy. Other uterine sarcomas require an entirely different approach and need histology-specific consideration. The most common are the leiomyosarcomas of the uterus, which are treated with docetaxel/gemcitabine at recurrence but do not appear to benefit from adjuvant therapy. Ifosfamide/doxorubicin and trabectedin can have some benefit in refractory disease.

GESTATIONAL TROPHOBLASTIC TUMORS

Gestational trophoblastic diseases represent a spectrum of neoplasia from benign hydatidiform mole to choriocarcinoma due to persistent trophoblastic disease associated most commonly with molar pregnancy but occasionally seen after normal gestation. The most common presentations of trophoblastic tumors are partial and complete molar pregnancies. These represent approximately 1 in 1500 conceptions in developed Western countries. The incidence widely varies globally, with areas in Southeast Asia having a much higher incidence of molar pregnancy. Regions with high molar pregnancy rates are often associated with diets low in carotene and animal fats.

RISK FACTORS

Trophoblastic tumors result from the outgrowth or persistence of placental tissue. They arise most commonly in the uterus but can also arise in other sites such as the fallopian tubes due to ectopic pregnancy. Risk factors include poorly defined dietary and environmental factors as well as conceptions at the extremes of reproductive age, with the incidence particularly high in females conceiving at younger than age 16 or older than age 50. In older women, the incidence of molar pregnancy might be as high as one in three, likely due to increased risk of abnormal fertilization of the aged ova. Most trophoblastic neoplasms are associated with complete moles, diploid tumors with all genetic material from the paternal donor (known as uniparental disomy). This is thought to occur when a single sperm fertilizes an enucleate egg that subsequently duplicates the paternal DNA. Trophoblastic proliferation occurs with exuberant villous stroma. If pseudopregnancy extends out past the 12th week, fluid progressively accumulates within the stroma, leading to "hydropic changes." Fetal development does not occur in complete moles.

Partial moles arise from the fertilization of an egg with two sperm cells; hence, two-thirds of genetic material is paternal in these triploid tumors. Hydropic changes are less dramatic, and fetal development can often occur through late first trimester or early second trimester, at which point spontaneous abortion is common. Laboratory findings will include excessively high human chorionic gonadotropin (hCG) and high AFP. The risk of persistent gestational trophoblastic disease after partial mole is ~5%. Complete and partial moles can be noninvasive or invasive. Myometrial invasion occurs in no more than one in six complete moles and a lower portion of partial moles.

PRESENTATION OF INVASIVE TROPHOBLASTIC DISEASE

The clinical presentation of molar pregnancy is changing in developed countries due to the early detection of pregnancy with home pregnancy kits and the very early use of Doppler and ultrasound to evaluate the early fetus and uterine cavity for evidence of a viable fetus. Thus, in these countries, the majority of women presenting with trophoblastic disease have their moles detected early and have typical symptoms of early pregnancy including nausea, amenorrhea, and breast tenderness. With uterine evacuation of early complete and partial moles, most women experience spontaneous remission of their disease as monitored by serial serum β-hCG levels. These women require no

chemotherapy. Patients with persistent elevation of β-hCG or rising β-hCG after uterine evacuation have persistent or actively growing gestational trophoblastic disease and require therapy. Most series suggest that between 15 and 25% of women will have evidence of persistent gestational trophoblastic disease after molar evacuation.

In women who lack access to prenatal care, presenting symptoms can be life-threatening, including the development of preeclampsia or even eclampsia. Hyperthyroidism can also be seen with very high β-hCG values. Evacuation of large moles can be associated with life-threatening complications including uterine perforation, volume loss, high-output cardiac failure, and adult respiratory distress syndrome (ARDS).

For women with evidence of rising β-hCG or radiologic confirmation of metastatic or persistent regional disease, prognosis can be estimated through a variety of scoring algorithms that identify women at low, intermediate, and high risk for requiring multiagent chemotherapy. In general, women with widely metastatic nonpulmonary disease, very elevated β-hCG, and prior normal antecedent term pregnancy are considered at high risk and typically require multiagent chemotherapy at an expert center for cure. Even very advanced gestational trophoblastic disease is almost uniformly curable when managed by an expert in this rare malignancy.

TREATMENT

Invasive Trophoblastic Disease

Management of invasive trophoblastic disease should be 100% curative, and complex patients should be managed by clinicians experienced in this disease. The management for a persistent and rising β-hCG after evacuation of a molar conception is typically chemotherapy, although surgery can play an important role for chemotherapy-resistant disease that is isolated in the uterus (especially if childbearing is complete) or to control hemorrhage. For women wishing to maintain fertility or with metastatic disease, the preferred treatment is chemotherapy. Trophoblastic disease is exquisitely sensitive to chemotherapy, and guided by serial serum β-hCG testing, successful, curative treatment is the rule. Single-agent treatment with dactinomycin or methotrexate cures 90% of women with low-risk disease. Patients with high-risk disease (very high β-hCG levels, presentation ≥4 months after pregnancy, brain or liver metastases, failure of methotrexate therapy) are typically treated with multiagent chemotherapy (etoposide, methotrexate, and dactinomycin, alternating with cyclophosphamide and vincristine [EMA-CO]), which is typically curative even in women with extensive metastatic disease. A regimen of cisplatin and etoposide alternating with etoposide/methotrexate/dactinomycin is used for the highest-risk patients. In the highest-risk patients with liver, lung, and brain metastases, hemorrhage from the rich tumor vasculature is a major risk during chemotherapy initiation. Cured women may become pregnant again without evidence of increased fetal or maternal complications.

90 Primary and Metastatic Tumors of the Nervous System

Lisa M. DeAngelis, Patrick Y. Wen

An estimated 87,000 people will be diagnosed with a primary brain tumor annually in the United States. At least 25,000 of these tumors are malignant, and most of these are gliomas. Meningiomas account for 35%, vestibular schwannomas 10%, and central nervous system (CNS) lymphomas ~2%. Brain metastases are three times more common than all primary brain tumors combined and are diagnosed in ~150,000 people each year. Metastases to the leptomeninges and epidural space of the spinal cord each occur in ~3–5% of patients with systemic cancer and are also a major cause of neurologic disability.

APPROACH TO THE PATIENT

Primary and Metastatic Tumors of the Nervous System

CLINICAL FEATURES

Brain tumors of any type can present with a variety of symptoms and signs that fall into two categories: general and focal; patients often have a combination of the two **(Table 90-1)**. General symptoms include headache, with or without nausea or vomiting, cognitive difficulties, personality change, and gait disorder. These symptoms arise when the enlarging tumor and its surrounding edema cause an increase in intracranial pressure or compression of cerebrospinal fluid (CSF) circulation leading to hydrocephalus. The classic brain tumor headache predominates in the morning and improves during the day, but this pattern is seen in a minority of patients. Headaches are often holocephalic but can be ipsilateral to the side of a tumor. Occasionally, headaches have features of a typical migraine with unilateral throbbing pain associated with visual scotoma. Personality changes may include apathy and withdrawal from social situations, mimicking depression. Focal or lateralizing findings include hemiparesis, aphasia, or visual field defect. Lateralizing symptoms are typically subacute and progressive; language difficulties may be mistaken for confusion. Seizures are common, occurring in ~25% of patients with brain metastases or malignant gliomas, and are the presenting symptom in up to 90% of patients with a low-grade glioma. All seizures arising from a brain tumor will have a focal onset whether or not it is apparent clinically.

NEUROIMAGING

Cranial magnetic resonance imaging (MRI) is the preferred diagnostic test for any patient suspected of having a brain tumor and should be performed with gadolinium contrast administration. Computed tomography (CT) scan should be reserved for those patients unable to undergo MRI. Malignant brain tumors—whether primary or metastatic—typically enhance with gadolinium, have central areas of necrosis, and are surrounded by edema of the neighboring white matter. Low-grade gliomas usually do not enhance with gadolinium and are best appreciated on fluid-attenuated inversion recovery (FLAIR) MRI sequences. Meningiomas have a typical appearance on MRI because they are dural-based enhancing tumors with a dural tail and compress but do not invade the brain. Dural metastases or a dural lymphoma can have a similar appearance. Imaging is characteristic for many primary and metastatic tumors and sometimes will suffice to establish a diagnosis when the location precludes surgical intervention (e.g., brainstem glioma).

TABLE 90-1 Symptoms and Signs at Presentation of Brain Tumors

	HIGH-GRADE GLIOMA (%)	LOW-GRADE GLIOMA (%)	MENINGIOMA (%)	METASTASES (%)
Generalized				
Impaired cognitive function	50	10	30	60
Hemiparesis	40	10	36	60
Headache	50	40	37	50
Lateralizing				
Seizures	20	70+	17	18
Aphasia	20	<5	—	18
Visual field deficit	—	—	—	7

Functional MRI is useful in presurgical planning to define eloquent sensory, motor, or language cortex. Positron emission tomography (PET) is useful in determining the metabolic activity of the lesions seen on MRI; MR perfusion and spectroscopy can provide information on blood flow or tissue composition. These techniques may help distinguish tumor progression from tissue necrosis due to treatment with radiation and chemotherapy. Neuroimaging is the only test necessary to diagnose a brain tumor. Laboratory tests are rarely useful, although patients with metastatic disease may have elevation of a serum tumor marker (e.g., β human chorionic gonadotropin [β-hCG] from testicular cancer). Additional testing such as cerebral angiogram, electroencephalogram (EEG), or lumbar puncture is rarely indicated or helpful.

TREATMENT

Brain Tumors

Therapy of any intracranial malignancy requires both symptomatic and definitive treatments. Definitive treatment is based on the specific tumor type and includes surgery, radiotherapy, and chemotherapy. However, symptomatic treatments apply to brain tumors of any type. Most high-grade malignancies are accompanied by substantial surrounding edema, which contributes to neurologic disability and raised intracranial pressure. Glucocorticoids are highly effective at reducing perilesional edema and improving neurologic function, often within hours of administration. Dexamethasone has been the glucocorticoid of choice because of its relatively low mineralocorticoid activity; initial doses are 8–12 mg/d. Glucocorticoids rapidly ameliorate symptoms and signs, but their long-term use causes substantial toxicity including insomnia, weight gain, diabetes mellitus, steroid myopathy, and personality changes. Consequently, a taper is indicated as definitive treatment is administered and the patient improves.

Patients with brain tumors who present with seizures require antiepileptic drug therapy. Prophylactic antiepileptic drugs are used in the perioperative setting, but there is no role for extended use in patients who have not had a seizure. The agents of choice are those drugs that do not induce the hepatic microsomal enzyme system. These include levetiracetam, topiramate, lamotrigine, valproic acid, and lacosamide **(Chap. 425)**. Other drugs, such as phenytoin and carbamazepine, are used less frequently because they are potent enzyme inducers that can interfere with both glucocorticoid and chemotherapy metabolism. Venous thromboembolic disease occurs in 20–30% of patients with high-grade gliomas or brain metastases. Prophylactic anticoagulants should be used during hospitalization and in nonambulatory patients. Those who have had either a deep vein thrombosis or a pulmonary embolus can receive therapeutic doses of anticoagulation safely and without increasing the risk for hemorrhage into the tumor. Inferior vena cava filters are reserved for patients with absolute contraindications to anticoagulation such as recent craniotomy.

PRIMARY BRAIN TUMORS

EPIDEMIOLOGY

No etiology has been identified for most primary brain tumors. The only established risk factors are exposure to ionizing radiation (meningiomas, gliomas, and schwannomas) and immunosuppression (primary CNS lymphoma). There is no proven evidence for any association with exposure to electromagnetic fields including cellular telephones, head injury, foods containing *N*-nitroso compounds, or occupational risk factors. A small minority of patients have a family history of brain tumors. Some of these familial cases are associated with genetic syndromes **(Table 90-2)**.

MOLECULAR PATHOGENESIS

As with other neoplasms, brain tumors arise as a result of a multistep process driven by the sequential acquisition of genetic alterations. These include loss of tumor-suppressor genes (e.g., *p53*, cyclin-dependent kinase inhibitor 2A and 2B [*CDKN2A/B*], and phosphatase and tensin homolog on chromosome 10 [*PTEN*]) and amplification and overexpression of protooncogenes such as the epidermal growth factor receptor (*EGFR*) and platelet-derived growth factor receptors (*PDGFR*). The accumulation of these genetic abnormalities results in uncontrolled cell growth and tumor formation. Many brain tumors, including glioblastomas, are characterized by significant molecular heterogeneity, which contributes to the difficulty in developing effective therapies.

Important progress has been made in understanding the molecular pathogenesis of several types of brain tumors, including glioblastoma and medulloblastoma, allowing them to be separated into different subtypes with different prognoses. This has led the World Health Organization (WHO) to issue an update on the classification of CNS tumors in 2016 that for the first time incorporates molecular parameters in addition to traditional histology into the diagnosis of brain tumors.

INTRINSIC "MALIGNANT" TUMORS

DIFFUSE GLIOMAS

Gliomas are the most common type of malignant primary brain tumor and are derived, based on their presumed lineage, into astrocytomas and oligodendrogliomas. These tumors are classified based on two highly recurrent molecular alterations, isocitrate dehydrogenase (*IDH*) mutations and 1p/19q codeletion, in addition to more conventional histopathologic parameters. Most lower-grade astrocytomas have *IDH* mutations but intact 1p/19q and often mutations in *ATRX* and *p53*. Oligodendrogliomas usually have *IDH* mutations and codeletion of 1p/19q. A minority of astrocytomas and oligodendrogliomas that lack *IDH* mutations (20–30%) have a worse prognosis.

Diffuse gliomas can present rarely as widespread infiltration of the brain tissue without a focal mass. Such tumors usually present with cognitive problems, and the MRI demonstrates confluent, typically nonenhancing areas of increased signal on FLAIR sequences without significant mass effect. Formerly known as gliomatosis cerebri, these lesions are now categorized by the pathology identified on biopsy, but they can be diagnostically challenging when the nature of the imaging

TABLE 90-2 Genetic Syndromes Associated with Primary Brain Tumors

SYNDROME	INHERITANCE	GENE/PROTEIN	ASSOCIATED TUMORS
Cowden's syndrome	AD	Mutations of *PTEN* (ch10p23)	Dysplastic cerebellar gangliocytoma (Lhermitte-Duclos disease), meningioma, astrocytoma Breast, endometrial, thyroid cancer, trichilemmomas
Familial schwannomatosis	Sporadic Hereditary	Mutations in *INI1/SNF5* (ch22q11)	Schwannomas, gliomas
Gardner's syndrome	AD	Mutations in *APC* (ch5q21)	Medulloblastoma, glioblastoma, craniopharyngioma Familial polyposis, multiple osteomas, skin and soft tissue tumors
Gorlin syndrome (basal cell nevus syndrome)	AD	Mutations in *Patched 1* gene (ch9q22.3)	Medulloblastomas Basal cell carcinoma
Li-Fraumeni syndrome	AD	Mutations in *p53* (ch17p13.1)	Gliomas, medulloblastomas Sarcomas, breast cancer, leukemias, others
Lynch syndrome	AD	Mutations in *MSH2, MSH1, MSH6, PMS2*	Glioblastoma and other gliomas Gastrointestinal, endometrial, and other cancers
Multiple endocrine neoplasia 1 (Wermer's syndrome)	AD	Mutations in *Menin* (ch11q13)	Pituitary adenoma, malignant schwannomas Parathyroid and pancreatic islet cell tumors
NF1	AD	Mutations in *NF1*/neurofibromin (ch17q12-22)	Schwannomas, astrocytomas, optic nerve gliomas, meningiomas Neurofibromas, neurofibrosarcomas, others
NF2	AD	Mutations in *NF2*/merlin (ch22q12)	Bilateral vestibular schwannomas, astrocytomas, multiple meningiomas, ependymomas
TSC (Bourneville disease)	AD	Mutations in *TSC1/TSC2* (ch9q34/16)	Subependymal giant cell astrocytoma, ependymomas, glioma, ganglioneuroma, hamartoma
Turcot syndrome	AD AR	Mutations in *APC*[a] (ch5) hMLH1 (ch3p21)	Gliomas, medulloblastomas Adenomatous colon polyps, adenocarcinoma
VHL	AD	Mutations in *VHL* gene (ch3p25)	Hemangioblastomas Retinal angiomas, renal cell carcinoma, pheochromocytoma, pancreatic tumors and cysts, endolymphatic sac tumors of the middle ear

[a]Various DNA mismatch repair gene mutations may cause a similar clinical phenotype, also referred to as Turcot syndrome, in which there is a predisposition to nonpolyposis colon cancer and brain tumors.

Abbreviations: AD, autosomal dominant; APC, adenomatous polyposis coli; AR, autosomal recessive; ch, chromosome; NF, neurofibromatosis; PTEN, phosphatase and tensin homologue; TSC, tuberous sclerosis complex; VHL, von Hippel-Lindau.

abnormalities is unclear. Often diagnosis is delayed until the patient develops worsening deficits or there is clear progression on imaging. Treatment is then determined by the pathology.

ASTROCYTOMAS

These are infiltrative tumors with a presumptive glial cell of origin. The WHO classifies astrocytomas into four prognostic grades based on histologic features: grade I (pilocytic astrocytoma, subependymal giant cell astrocytoma); grade II (astrocytoma); grade III (anaplastic astrocytoma); and grade IV (glioblastoma). Grades I and II are considered low-grade, and grades III and IV high-grade, astrocytomas.

Low-Grade Astrocytoma • **GRADE I ASTROCYTOMAS** Pilocytic astrocytomas (WHO grade I) are the most common tumor of childhood. They occur typically in the cerebellum but may also be found elsewhere in the neuraxis, including the optic nerves and brainstem. Frequently they appear as cystic lesions with an enhancing mural nodule. Often they have *BRAF* fusions or mutations. These are well-demarcated lesions that are potentially curable if they can be resected completely. Giant cell subependymal astrocytomas are usually found in the ventricular wall of patients with tuberous sclerosis. They often do not require intervention but can be treated surgically or with inhibitors of the mammalian target of rapamycin (mTOR).

GRADE II ASTROCYTOMAS These are infiltrative tumors that usually present with seizures in young adults. They appear as nonenhancing tumors with increased T2/FLAIR signal **(Fig. 90-1)**. If feasible, patients should undergo maximal surgical resection, although complete resection is rarely possible because of the invasive nature of the tumor. In patients at higher risk for recurrence (subtotal resection or above the age of 40 years), there is evidence that radiation therapy (RT) followed by PCV (procarbazine, cyclohexylchloroethylnitrosourea [CCNU], and vincristine) chemotherapy may possibly be of benefit. The tumor transforms to a malignant astrocytoma in most patients, leading to variable survival with a median of ~5–10 years.

High-Grade Astrocytoma • **GRADE III (ANAPLASTIC) ASTROCYTOMA** These account for ~15–20% of high-grade

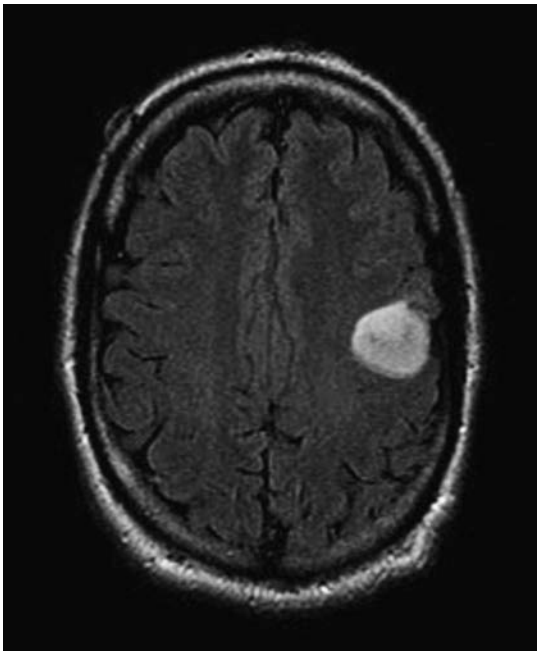

FIGURE 90-1 Fluid-attenuated inversion recovery (FLAIR) MRI of a left frontal low-grade astrocytoma. This lesion did not enhance.

astrocytomas. They generally present in the fourth and fifth decades of life as variably enhancing tumors. Treatment is the same as for glioblastoma, consisting of maximal safe surgical resection followed by RT and adjuvant temozolomide alone or RT with concurrent and adjuvant temozolomide.

GRADE IV ASTROCYTOMA (GLIOBLASTOMA) Glioblastoma accounts for the majority of high-grade astrocytomas. Approximately 10% of glioblastomas have *IDH* mutations. These tend to arise from lower-grade tumors (secondary glioblastomas) and have a better prognosis. In the next update of the WHO classification, the term glioblastoma will be restricted to tumors without *IDH* mutations. Glioblastomas with *IDH* mutations have a different biology and better prognosis and will be termed astrocytomas, *IDH*-mutant, grade 4. In addition, astrocytomas without the classic histologic features of glioblastoma (necrosis and endothelial proliferation) but that have the molecular features of glioblastoma (epidermal growth factor amplification, combined with whole chromosome 7 gain and 10 loss, or telomerase reverse transcriptase [*TERT*] promoter mutations) will also be considered glioblastomas.

Glioblastomas are the most common malignant primary brain tumor, with >12,000 cases diagnosed each year in the United States. Patients usually present in the sixth and seventh decades of life with headache, seizures, or focal neurologic deficits. The tumors appear as ring-enhancing masses with central necrosis and surrounding edema **(Fig. 90-2)**. These are highly infiltrative tumors, and the areas of increased T2/FLAIR signal surrounding the main tumor mass contain invading tumor cells. Treatment involves maximal surgical resection followed by partial-field external-beam RT (6000 cGy in thirty 200-cGy fractions) with concomitant temozolomide, followed by 6 months of adjuvant temozolomide. With this regimen, median survival is increased to 14.6–18 months compared to only 12 months with RT alone, and 5-year survival is ~10%. Efforts to increase the dose of RT locally using brachytherapy or stereotactic radiosurgery (SRS) have failed to improve the outcome and these treatments are not used. Patients whose tumor contains the DNA repair enzyme O^6-methylguanine-DNA methyltransferase (MGMT) are relatively resistant to temozolomide and have a worse prognosis compared to those whose tumors contain low levels of MGMT as a result of silencing of the *MGMT* gene by promoter hypermethylation. Implantation of biodegradable polymers containing carmustine chemotherapy into the tumor bed after resection of the tumor or addition of tumor treating fields (scalp electrodes delivering low-intensity electric currents) produces a modest improvement in survival.

For elderly patients aged >65–70 years, a hypofractionated RT regimen of 40 Gy over 3 weeks with temozolomide is well tolerated and likely leads to similar outcomes as the 6-week standard RT regimen.

Despite optimal therapy, glioblastomas invariably recur. Treatment options for recurrent disease may include reoperation, re-irradiation with bevacizumab, and alternate chemotherapeutic regimens. Bevacizumab, a humanized vascular endothelial growth factor (VEGF) monoclonal antibody, has activity in recurrent glioblastoma, increasing progression-free survival but not overall survival and reducing peritumoral edema and glucocorticoid use **(Fig. 90-3)**. Immune checkpoint inhibitors have been successful in a variety of solid tumors but have failed to demonstrate substantial activity in glioblastoma. A recent phase III trial comparing bevacizumab with nivolumab in recurrent glioblastoma demonstrated an identical median overall survival of 9.8–10 months in the two arms, with similar toxicities. Treatment decisions for patients with recurrent glioblastoma must be made on an individual basis, taking into consideration such factors as previous therapy, time to relapse, performance status, and quality of life. Whenever feasible, patients should be enrolled in clinical trials. Novel therapies

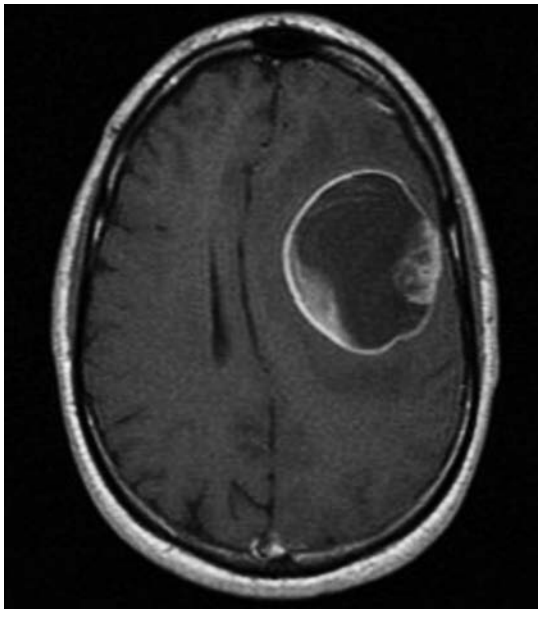

FIGURE 90-2 Postgadolinium T1 MRI of a large cystic left frontal glioblastoma.

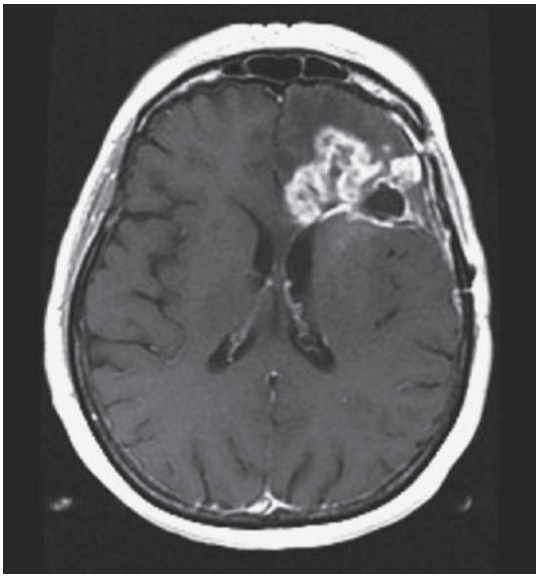
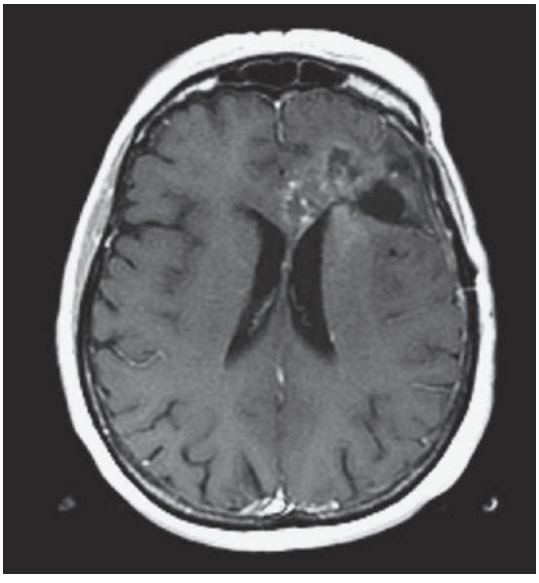


A



B

FIGURE 90-3 Postgadolinium T1 MRI of a recurrent glioblastoma before (***A***) and after (***B***) administration of bevacizumab. Note the decreased enhancement and mass effect.

undergoing evaluation in patients with glioblastoma include targeted molecular agents directed at receptor tyrosine kinases and signal transduction pathways; immunotherapy using vaccines, novel checkpoint inhibitors, or chimeric antigen receptor (CAR) T cells; oncolytic viruses; antiangiogenic agents; chemotherapeutic agents that cross the blood-brain barrier more effectively than currently available drugs; and infusion of radiolabeled drugs and targeted toxins into the tumor and surrounding brain by means of convection-enhanced delivery.

The most important adverse prognostic factors in patients with glioblastomas are older age, absence of *IDH* mutations, unmethylated MGMT promoter, poor Karnofsky performance status, and unresectable tumor.

Gliosarcomas are a variant of glioblastoma containing both an astrocytic and a sarcomatous component and are treated in the same way as glioblastomas.

OLIGODENDROGLIOMA

Oligodendrogliomas account for ~15–20% of gliomas. They are characterized by codeletion of 1p/19q and have *IDH* mutations. Oligodendrogliomas are classified by the WHO into oligodendrogliomas (grade II) or anaplastic oligodendrogliomas (AOs) (grade III). Oligodendrogliomas have distinctive pathologic features such as perinuclear clearing—giving rise to a "fried-egg" appearance—and a reticular pattern of blood vessel growth. Some tumors have both an oligodendroglial as well as an astrocytic component. With molecular testing, it is now clear that almost all of these mixed tumors (oligoastrocytomas) are genetically either astrocytomas or oligodendrogliomas. As a result, the diagnosis of oligoastrocytoma is now rarely made unless molecular testing is not available.

Grade II oligodendrogliomas are generally more responsive to therapy and have a better prognosis than pure astrocytic tumors. These tumors present similarly to grade II astrocytomas in young adults. The tumors are nonenhancing and often partially calcified. They should be treated with surgery and, in patients with residual disease or aged >40 years, RT and chemotherapy. Patients with oligodendrogliomas have a median survival in excess of 10 years.

AOs present in the fourth and fifth decades as variably enhancing tumors. They are more responsive to therapy than grade III astrocytomas. Treatment involves maximal safe resection followed by RT and PCV or temozolomide chemotherapy. Median survival of patients with AO is in excess of 10 years.

EPENDYMOMAS

Ependymomas are tumors derived from ependymal cells that line the ventricular surface. They account for ~5% of childhood tumors, frequently arise from the wall of the fourth ventricle in the posterior fossa, are associated with *RELA* fusions, and are classified as type A and B ependymoma subtypes. Although adults can have intracranial ependymomas, they occur more commonly in the spine, especially in the filum terminale of the spinal cord where they have a myxopapillary histology. Ependymomas that can be completely resected are potentially curable. Partially resected ependymomas will recur and require irradiation. The less common anaplastic ependymoma is more aggressive and is treated with resection and RT; chemotherapy has limited efficacy. Subependymomas are slow-growing benign lesions arising in the wall of ventricles that often do not require treatment.

OTHER LESS COMMON GLIOMAS

Gangliogliomas and pleomorphic xanthoastrocytomas occur in young adults. They behave as more indolent forms of grade I gliomas and are usually treated with surgery. Frequently they will have *BRAF* V600E mutations. Brainstem gliomas usually occur in children or young adults and often have *H3K27M* mutations. Despite treatment with RT and chemotherapy, the prognosis is poor, with a median survival of only 1 year.

PRIMARY CENTRAL NERVOUS SYSTEM LYMPHOMA

Primary central nervous system lymphoma (PCNSL) is a rare non-Hodgkin's lymphoma accounting for <3% of primary brain tumors. For unclear reasons, its incidence is increasing, particularly in immunocompetent, older individuals.

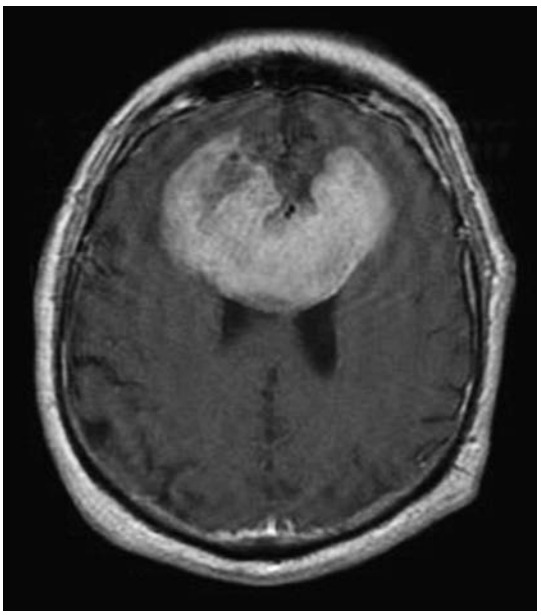


FIGURE 90-4 Postgadolinium T1 MRI demonstrating a large bifrontal primary central nervous system lymphoma (PCNSL). The periventricular location and diffuse enhancement pattern are characteristic of lymphoma.

PCNSL in immunocompetent patients is usually a diffuse large B-cell lymphoma. Immunocompromised patients, especially those infected with the human immunodeficiency virus (HIV) or organ transplant recipients, are at risk for PCNSL that is typically large cell with immunoblastic and more aggressive features. Epstein-Barr virus (EBV) plays an important role in the pathogenesis of PCNSL in this population. These patients are usually severely immunocompromised, with CD4 counts of <50/mL.

Immunocompetent patients with PCNSL are older (median 60 years) than those with HIV-related PCNSL (median 31 years). PCNSL usually presents as a mass lesion, with neuropsychiatric symptoms, lateralizing signs, or seizures. Ocular and leptomeningeal involvement each occur in 15–20% of patients, and involvement of these compartments may be asymptomatic. Rarely, it may present as isolated ocular lymphoma or as primary leptomeningeal lymphoma. When restricted to the leptomeninges, it may present as a subacute or chronic meningitis that causes progressive cranial and spinal nerve dysfunction. CSF cytologic examination or flow cytometry is required to establish the diagnosis.

On contrast-enhanced MRI, PCNSL usually appears as a densely enhancing tumor **(Fig. 90-4)**. Immunocompetent patients have solitary lesions more often than immunosuppressed patients. Frequently there is involvement of the basal ganglia, corpus callosum, or periventricular region. Stereotactic biopsy is necessary to obtain a histologic diagnosis. Whenever possible, glucocorticoids should be withheld until after the biopsy has been obtained because they have a cytolytic effect on lymphoma cells and may lead to nondiagnostic tissue. In addition, patients should be tested for HIV, and the extent of disease should be assessed by performing PET or CT of the body, MRI of the spine, CSF analysis, and slit-lamp examination of the eye. Bone marrow biopsy and testicular ultrasound are occasionally performed.

TREATMENT

Primary Central Nervous System Lymphoma

PCNSL is more sensitive to glucocorticoids, chemotherapy, and RT than other primary brain tumors. Durable complete responses and long-term survival are possible with these treatments. High-dose methotrexate, a folate antagonist that interrupts DNA synthesis, produces response rates ranging from 35 to 80% and median survival

of up to 50 months. The combination of methotrexate with other chemotherapeutic agents such as cytarabine increases the response rate to 70–100%. The addition of whole-brain RT (WBRT) to methotrexate-based chemotherapy prolongs progression-free survival but not overall survival, but it is associated with delayed neurotoxicity, especially in patients aged >60 years. As a result, full-dose RT is frequently omitted, but there may be a role for reduced-dose RT. The anti-CD20 monoclonal antibody rituximab is often incorporated into the chemotherapy regimen, although there are studies questioning its benefit. For some patients, high-dose chemotherapy with autologous stem cell rescue may offer the best chance of preventing relapse. At least 50% of patients will eventually develop recurrent disease. Treatment options include RT for patients who have not had prior irradiation, retreatment with methotrexate, as well as other chemotherapeutic agents such as temozolomide and pemetrexed. High-dose chemotherapy with autologous stem cell rescue may be appropriate in selected patients with relapsed disease. Bruton's tyrosine kinase (BTK) inhibitors such as ibrutinib, immunomodulatory drugs such as pomalidomide and lenalidomide, and immune checkpoint inhibitors have shown promising preliminary activity and are being evaluated in clinical trials, as are CAR T cells.

PCNSL IN IMMUNOCOMPROMISED PATIENTS

PCNSL in immunocompromised patients often produces multiple ring-enhancing lesions that can be difficult to differentiate from metastases or infections such as toxoplasmosis. The diagnosis is usually established by examination of the CSF for cytology and EBV DNA; toxoplasmosis serologic testing; brain PET imaging for hypermetabolism of the lesions, which, although nonspecific, can be consistent with tumor; and, if necessary, brain biopsy. Since the advent of highly active antiretroviral drugs, the incidence of HIV-related PCNSL has declined. These patients are preferably treated with high-dose methotrexate-based regimens and initiation of highly active antiretroviral therapy; WBRT is reserved for those who cannot tolerate systemic chemotherapy. In organ transplant recipients, reduction of immunosuppression may improve outcome.

MEDULLOBLASTOMAS

Medulloblastomas are the most common malignant brain tumor of childhood, accounting for ~20% of all primary CNS tumors among children. They arise from granule cell progenitors or from multipotent progenitors from the ventricular zone. Approximately 5% of children with medulloblastoma have an inherited syndrome, such as Gorlin, Turcot, or Li-Fraumeni, which predisposes to the development of medulloblastoma. Histologically, medulloblastomas are highly cellular tumors with abundant dark staining, round nuclei, and rosette formation (Homer-Wright rosettes). In the 2016 WHO pathologic classification, they have been divided into four molecular subgroups: (1) WNT-activated (primarily affects children and has the best outcome); (2) SHH-activated (affects adults, infants, and children, with the younger patients having the better outcome and adults doing poorly); (3) non-WNT/non-SHH, group 3 (frequently has disseminated CNS disease at diagnosis and has the worst outcome); and (4) non-WNT/non-SHH, group 4 (30% have metastases at diagnosis, but 5-year progression-free survival is 95%). Regardless of subtype, patients present with headache, ataxia, and signs of brainstem involvement. On MRI, they appear as densely enhancing tumors in the posterior fossa, sometimes associated with hydrocephalus. Treatment involves maximal surgical resection, craniospinal irradiation, and chemotherapy with agents such as cisplatin, lomustine, cyclophosphamide, and vincristine. Approximately 70% of patients overall have long-term survival but usually at the cost of significant neurocognitive impairment. A major goal of current research is to improve survival while minimizing long-term complications, and clinical trials are now being designed for specific molecular subgroups.

PINEAL REGION TUMORS

A large variety of tumors can arise in the region of the pineal gland. These typically present with headache, visual symptoms, and hydrocephalus. Patients may have Parinaud's syndrome characterized by impaired upgaze and accommodation. Some pineal tumors such as pineocytomas and benign teratomas can be treated by surgical resection. Germinomas respond to irradiation, whereas pineoblastomas and nongerminomatous germ cell tumors require craniospinal radiation and chemotherapy.

EXTRINSIC "BENIGN" TUMORS

MENINGIOMAS

Meningiomas are diagnosed with increasing frequency as more people undergo neuroimaging for various indications. They are now the most common primary brain tumor, accounting for ~35% of the total. Their incidence increases with age. They tend to be more common in women and in patients with neurofibromatosis type 2 (NF2). They also occur more commonly in patients with a history of cranial irradiation.

Meningiomas arise from the dura mater and are composed of neoplastic meningothelial (arachnoidal cap) cells. They are most commonly located over the cerebral convexities, especially adjacent to the sagittal sinus, but they can also occur in the skull base and along the dorsum of the spinal cord. Meningiomas are classified by the WHO into three histologic grades of increasing aggressiveness: grade I (benign), grade II (atypical), and grade III (malignant).

Many meningiomas are found incidentally following neuroimaging for unrelated reasons. They can also present with headaches, seizures, or focal neurologic deficits. On imaging studies, they have a characteristic appearance usually of a densely enhancing extra-axial tumor arising from the dura **(Fig. 90-5)**. Typically they have a dural tail, consisting of thickened, enhanced dura extending like a tail from the mass. The main differential diagnosis of meningioma is a dural metastasis.

If the meningioma is small and asymptomatic, no intervention is necessary and the lesion can be observed with serial MRI studies. Larger, symptomatic lesions should be resected. If complete resection is achieved, the patient is cured. Incompletely resected tumors tend to recur, although the rate of recurrence can be very slow with grade I tumors. Tumors that cannot be resected, or can only be partially removed, may benefit from external-beam RT or SRS. These treatments may also be helpful in patients whose tumor has recurred after surgery. Hormonal therapy and chemotherapy are currently unproven.

Rarer tumors that resemble meningiomas include hemangiopericytomas and solitary fibrous tumors. Since they share similar molecular alterations (*NAB2-STAT6* fusion), the 2016 WHO classification introduced the combined term *solitary fibrous tumor/hemangiopericytoma* for this entity. These tumors are treated with surgery and RT but have a higher propensity to recur locally or metastasize systemically.

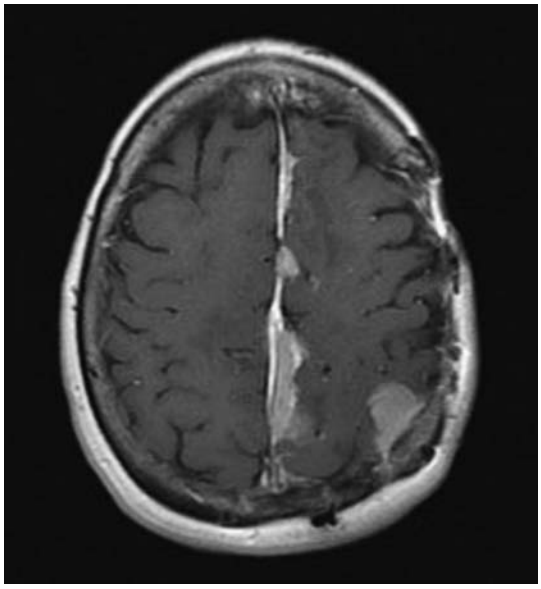

FIGURE 90-5 Postgadolinium T1 MRI demonstrating multiple meningiomas along the falx and left parietal cortex.

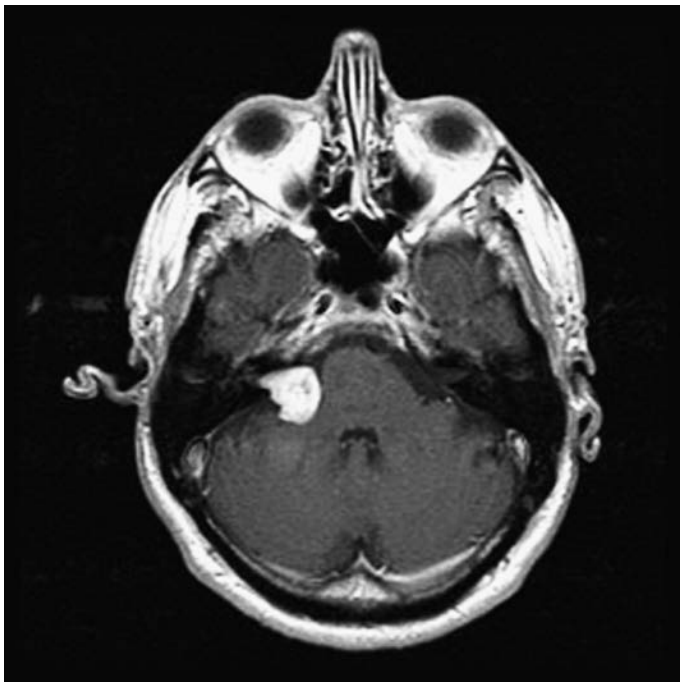

FIGURE 90-6 Postgadolinium MRI of a right vestibular schwannoma. The tumor can be seen to involve the internal auditory canal.

SCHWANNOMAS

These are generally benign tumors arising from the Schwann cells of cranial and spinal nerve roots. The most common schwannomas, termed *vestibular schwannomas* or *acoustic neuromas*, arise from the vestibular portion of the eighth cranial nerve and account for ~9% of primary brain tumors. Patients with NF2 have a high incidence of vestibular schwannomas that are frequently bilateral. Schwannomas arising from other cranial nerves, such as the trigeminal nerve (cranial nerve V), occur with much lower frequency. Neurofibromatosis type 1 (NF1) is associated with an increased incidence of schwannomas of the spinal nerve roots.

Vestibular schwannomas may be found incidentally on neuroimaging or present with progressive unilateral hearing loss, dizziness, tinnitus, or, less commonly, symptoms resulting from compression of the brainstem and cerebellum. On MRI, they appear as densely enhancing lesions, enlarging the internal auditory canal and often extending into the cerebellopontine angle **(Fig. 90-6)**. The differential diagnosis includes meningioma. Very small, asymptomatic lesions can be observed with serial MRIs. Larger lesions should be treated with surgery or SRS. The optimal treatment will depend on the size of the tumor, symptoms, and the patient's preference. In patients with small vestibular schwannomas and relatively intact hearing, early surgical intervention increases the chance of preserving hearing.

PITUITARY TUMORS

These are discussed in detail in **Chap. 380**.

CRANIOPHARYNGIOMAS

Craniopharyngiomas are rare, usually suprasellar, partially calcified, solid, or mixed solid-cystic benign tumors that arise from remnants of Rathke's pouch. They have a bimodal distribution, occurring predominantly in children but also between the ages of 55 and 65 years. They present with headaches, visual impairment, and impaired growth in children and hypopituitarism in adults. Treatment involves surgery, RT, or a combination of the two. The papillary subtype of craniopharyngiomas often has *BRAF* V600E mutations and can be treated with RAF/MEK inhibitors.

OTHER BENIGN TUMORS

Dysembryoplastic Neuroepithelial Tumors (DNTs) These are benign, supratentorial tumors, usually in the temporal lobe. They typically occur in children and young adults with a long-standing history of seizures. Surgical resection is curative.

Epidermoid Cysts These consist of squamous epithelium surrounding a keratin-filled cyst. They are usually found in the cerebellopontine angle and the intrasellar and suprasellar regions. They may present with headaches, cranial nerve abnormalities, seizures, or hydrocephalus. MRI demonstrates an extra-axial lesion with characteristics that are similar to CSF but have restricted diffusion. Treatment involves surgical resection.

Dermoid Cysts Like epidermoid cysts, dermoid cysts arise from epithelial cells that are retained during closure of the neural tube. They contain both epidermal and dermal structures such as hair follicles, sweat glands, and sebaceous glands. Unlike epidermoid cysts, these tumors usually have a midline location. They occur most frequently in the posterior fossa, especially the vermis, fourth ventricle, and suprasellar cistern. On MRI, dermoid cysts resemble lipomas, demonstrating T1 hyperintensity and variable signal on T2. Symptomatic dermoid cysts can be treated with surgery.

Colloid Cysts These usually arise in the anterior third ventricle and may present with headaches, hydrocephalus, and, very rarely, sudden death. Surgical resection is curative, or a third ventriculostomy may relieve the obstructive hydrocephalus and be sufficient therapy.

NEUROCUTANEOUS SYNDROMES (PHAKOMATOSES)

A number of genetic disorders are characterized by cutaneous lesions and an increased risk of brain tumors. Most of these disorders have an autosomal dominant inheritance with variable penetrance.

NEUROFIBROMATOSIS TYPE 1 (von RECKLINGHAUSEN'S DISEASE)

NF1 is an autosomal dominant disorder with variable penetrance and an incidence of ~1 in 2600–3000. Approximately one-half of cases are familial; the remainder are caused by new mutations arising in patients with unaffected parents. The *NF1* gene is located on chromosome 17q11.2 and encodes neurofibromin, a guanosine triphosphatase (GTPase) activating protein (GAP) that is a negative regulator of the RAS–mitogen-activated protein (MAP) kinase signaling pathway, which includes the downstream kinase MEK. It is a classic tumor suppressor, and biallelic loss can result in a variety of nervous system tumors including neurofibromas, plexiform neurofibromas, optic nerve gliomas, astrocytomas, and meningiomas. In addition to neurofibromas, which appear as multiple, soft, rubbery cutaneous tumors, other cutaneous manifestations of NF1 include café-au-lait spots and axillary freckling. NF1 is also associated with hamartomas of the iris termed Lisch nodules, pheochromocytomas, pseudoarthrosis of the tibia, scoliosis, epilepsy, and mental retardation. The MEK inhibitor selumetinib has activity against inoperable plexiform neurofibromas and is the only treatment that targets the dysregulated signaling pathway.

NEUROFIBROMATOSIS TYPE 2

NF2 is less common than NF1, with an incidence of 1 in 25,000–40,000. It is an autosomal dominant disorder with full penetrance. As with NF1, approximately one-half of cases arise from new mutations. The *NF2* gene on 22q encodes a cytoskeletal protein, merlin (moesin, ezrin, radixin-like protein), that functions as a tumor suppressor. NF2 is characterized by bilateral vestibular schwannomas in >90% of patients, multiple meningiomas, and spinal ependymomas and astrocytomas. Treatment of bilateral vestibular schwannomas can be challenging because the goal is to preserve hearing for as long as possible. These patients may also have diffuse schwannomatosis that may affect the cranial, spinal, or peripheral nerves; posterior subcapsular lens opacities; and retinal hamartomas.

TUBEROUS SCLEROSIS (BOURNEVILLE DISEASE)

This is an autosomal dominant disorder with an incidence of ~1 in 5000–10,000 live births. It is caused by mutations in either the *TSC1*

gene, which maps to chromosome 9q34 and encodes a protein termed hamartin, or the *TSC2* gene, which maps to chromosome 16p13.3 and encodes the protein tuberin. Hamartin forms a complex with tuberin, which inhibits cellular signaling through mTOR, and acts as a negative regulator of the cell cycle. Patients with tuberous sclerosis may have seizures, mental retardation, adenoma sebaceum (facial angiofibromas), shagreen patch, hypomelanotic macules, periungual fibromas, renal angiomyolipomas, and cardiac rhabdomyomas. These patients have an increased incidence of subependymal nodules, cortical tubers, and subependymal giant cell astrocytomas (SEGAs). Patients frequently require anticonvulsants for seizures. SEGAs do not always require therapeutic intervention, but the most effective therapy is with the mTOR inhibitors sirolimus or everolimus, which often decrease seizures as well as SEGA size.

TUMORS METASTATIC TO THE BRAIN

Brain metastases arise from hematogenous spread and frequently originate from a lung primary or are associated with pulmonary metastases. Most metastases develop at the gray matter–white matter junction in the watershed distribution of the brain where intravascular tumor cells lodge in terminal arterioles. The distribution of metastases in the brain approximates the proportion of blood flow such that ~85% of all metastases are supratentorial and 15% occur in the posterior fossa. The most common sources of brain metastases are lung and breast carcinomas; melanoma has the greatest propensity to metastasize to the brain, being found in 80% of patients at autopsy **(Table 90-3)**. Other tumor types such as ovarian and esophageal carcinoma rarely metastasize to the brain. Prostate and breast cancers also have a propensity to metastasize to the dura and can mimic meningioma. Leptomeningeal metastases are common from hematologic malignancies and also breast and lung cancers. Spinal cord compression primarily arises in patients with prostate and breast cancer, tumors with a strong propensity to metastasize to the axial skeleton.

DIAGNOSIS OF METASTASES

Brain metastases are best visualized on MRI, where they usually appear as well-circumscribed lesions **(Fig. 90-7)**. The amount of perilesional edema can be highly variable, with large lesions causing minimal edema and sometimes very small lesions causing extensive edema. Enhancement may be in a ring pattern or diffuse. Occasionally, intracranial metastases will hemorrhage; melanoma, thyroid, and kidney cancer have the greatest propensity to hemorrhage, but the most common cause of a hemorrhagic metastasis is lung cancer because it accounts for the majority of brain metastases. The radiographic appearance of brain metastasis is nonspecific, and similar-appearing lesions can occur with infection including brain abscesses, demyelinating lesions, sarcoidosis, radiation necrosis in a previously treated patient, or a primary brain tumor that may be a second malignancy in a patient with systemic cancer. Biopsy is rarely necessary for diagnosis because imaging alone in the appropriate clinical situation usually suffices. However, in ~10% of patients, a systemic cancer may present with a brain metastasis, and if there is not an easily accessible systemic site to biopsy, a brain lesion must be removed for diagnostic purposes.

TABLE 90-3 Frequency of Nervous System Metastases by Common Primary Tumors

	BRAIN (%)	LM (%)	ESCC (%)
Lung	41	17	15
Breast	19	57	22
Melanoma	10	12	4
Prostate	1	1	10
GIT	7	—	5
Renal	3	2	7
Lymphoma	<1	10	10
Sarcoma	7	1	9
Other	11	—	18

Abbreviations: ESCC, epidural spinal cord compression; GIT, gastrointestinal tract; LM, leptomeningeal metastases.

TREATMENT

Tumors Metastatic to the Brain

DEFINITIVE TREATMENT

The number and location of brain metastases often determine the therapeutic options. The patient's overall condition and current or potential control of systemic disease are also major determinants. Brain metastases are single in approximately one-half of patients and multiple in the other half.

RADIATION THERAPY

The standard treatment for brain metastases has previously been WBRT usually administered to a total dose of 3000 cGy in 10 fractions. This affords rapid palliation, and ~80% of patients improve with glucocorticoids and RT. However, it is not curative, is associated with neurocognitive toxicity, and produces median survival of only 4–6 months. Recent data demonstrate that hippocampal avoidance during WBRT preserves cognitive function without increasing the risk of an intracranial relapse. If feasible, SRS has become the primary radiation oncology approach to brain metastases. It can be delivered through a variety of equally effective techniques including the gamma knife, linear accelerator, proton beam, or CyberKnife, all of which can deliver highly focused doses of RT, usually in a single fraction. SRS can effectively sterilize the visible lesions and afford local disease control in 80–90% of patients. Some patients have been cured of their brain metastases using SRS, whereas this is distinctly rare with WBRT. Traditionally SRS was used only for patients with 1–3 metastases, but recent data suggest that SRS can effectively treat up to 10 lesions. It is, however, confined to lesions of ≤3 cm and is most effective in metastases of ≤1 cm. The addition of WBRT to SRS improves disease control in the nervous system but does not prolong survival and thus is rarely employed.

SURGERY

Randomized controlled trials have demonstrated that surgical extirpation of a single brain metastasis followed by WBRT is superior to WBRT alone. Removal of two lesions or a single symptomatic mass, particularly if compressing the ventricular system, can also be useful. This is particularly important in patients who have highly radioresistant lesions such as renal carcinoma. Surgical resection can produce rapid amelioration of symptoms, improve control of edema, and result in prolonged survival. WBRT administered after complete resection of a brain metastasis improves disease control but does not prolong survival. Some centers administer focal RT or even SRS to a resected cavity, especially if there is concern that tumor has been left behind, but most avoid postoperative WBRT because of its cognitive effects.

CHEMOTHERAPY

Chemotherapy is becoming increasingly useful for brain metastases. Metastases from tumor types that are highly chemosensitive, such as germ cell tumors or small-cell lung cancer, may respond to chemotherapeutic regimens chosen according to the underlying malignancy. Increasingly, data demonstrate responsiveness of brain metastases to chemotherapy including targeted therapeutics, such as for patients with lung cancer harboring *EGFR* mutations that sensitize them to EGFR inhibitors. Immunotherapy is also effective against those primary tumors that are sensitive to this approach, such as melanoma. Antiangiogenic agents such as bevacizumab are effective in the treatment of CNS metastases in those primary tumors for which it is approved.

LEPTOMENINGEAL METASTASES

Leptomeningeal metastases are also described as carcinomatous meningitis, meningeal carcinomatosis, or, in the case of specific tumors, leukemic or lymphomatous meningitis. Among the hematologic malignancies, acute leukemias most commonly metastasize to the subarachnoid space, followed in frequency by aggressive diffuse lymphomas. Among solid tumors, breast and lung carcinomas and melanoma most frequently spread in this fashion. Tumor cells reach the subarachnoid space via the arterial circulation or occasionally through retrograde flow in venous systems that drain metastases along the bony spine or cranium. In addition, leptomeningeal metastases may develop as a direct consequence of prior brain metastases and occur in almost 40% of patients who have a metastasis resected from the cerebellum.

CLINICAL FEATURES

Leptomeningeal metastases are characterized by multilevel symptoms and signs along the neuraxis. Combinations of lumbar and cervical radiculopathies, cranial neuropathies, seizures, confusion, and encephalopathy from hydrocephalus or raised intracranial pressure can be present. Focal deficits such as hemiparesis or aphasia are rarely due to leptomeningeal metastases unless there is direct brain infiltration. New-onset limb pain in patients with breast cancer, lung cancer, or melanoma should prompt consideration of leptomeningeal spread.

LABORATORY AND IMAGING DIAGNOSIS

Leptomeningeal metastases are particularly challenging to diagnose because identification of tumor cells in the subarachnoid compartment may be elusive. MRI can be definitive when there are clear tumor nodules adherent to the cauda equina or spinal cord, enhancing cranial nerves, or subarachnoid enhancement on brain imaging **(Fig. 90-8)**.

A

B

FIGURE 90-8 Postgadolinium MRI images of extensive leptomeningeal metastases from breast cancer. Nodules along the dorsal surface of the spinal cord (***A***) and cauda equina (***B***) are seen.

Imaging is diagnostic in ~75% of patients and is more often positive in patients with solid tumors. Demonstration of tumor cells in the CSF is definitive and often considered the gold standard. However, CSF cytologic examination is positive in only 50% of patients on the first lumbar puncture and still misses 10% after three CSF samples. New technologies, such as rare cell capture, enhance identification of tumor cells in the CSF; molecular profiling of the CSF can also identify tumor-specific mutations, indicating malignancy in the leptomeninges. CSF cytologic examination is most useful in hematologic malignancies, especially when combined with flow cytometry to identify a clonal population. Accompanying CSF abnormalities include an elevated protein concentration and an elevated white blood cell count; hypoglycorrhachia is noted in <25% of patients but is useful when present. Identification of tumor markers may be helpful in some solid tumors.

TREATMENT

Leptomeningeal Metastases

The treatment of leptomeningeal metastasis is palliative because there is no curative therapy. RT to the symptomatically involved areas, such as skull base for cranial neuropathy, can relieve pain and sometimes improve function. Craniospinal irradiation (CSI) is avoided because it has significant toxicity with myelosuppression and gastrointestinal irritation as well as limited effectiveness. However, recent data on proton beam CSI suggest better disease control with fewer systemic toxicities. Systemic chemotherapy, targeted therapeutics, and immunotherapy have all demonstrated efficacy in the appropriate setting. Alternatively, intrathecal chemotherapy can be effective, particularly in hematologic malignancies. This is optimally delivered through an intraventricular cannula (Ommaya reservoir) rather than by lumbar puncture. Few drugs can be delivered safely into the subarachnoid space, and they have a limited spectrum of antitumor activity, perhaps accounting for the relatively poor response to this approach, particularly in solid tumors. In addition, impaired CSF flow dynamics can compromise intrathecal drug delivery. Surgery has a limited role in leptomeningeal metastasis. A ventriculoperitoneal shunt can relieve raised intracranial pressure; once placed, intrathecal drug cannot be used.

EPIDURAL METASTASIS

Epidural metastasis occurs in 3–5% of patients with a systemic malignancy and causes neurologic compromise by compressing the spinal cord or cauda equina. The most common cancers that metastasize to the epidural space are those malignancies that spread to bone, such as breast and prostate. Lymphoma can cause bone involvement and compression, but it can also invade an intervertebral foramen and cause spinal cord compression without bone destruction. The thoracic spine is affected most commonly, followed by the lumbar and then cervical spine.

CLINICAL FEATURES

Back pain is the presenting symptom of epidural metastasis in virtually all patients; the pain may precede neurologic findings by weeks or months. The pain is usually exacerbated by lying down; by contrast, arthritic pain is often relieved by recumbency. Leg weakness is seen in ~50% of patients, as is sensory dysfunction. Sphincter problems are present in ~25% of patients at diagnosis.

DIAGNOSIS

Diagnosis is established by imaging, preferably with an MRI of the entire spine (Fig. 90-9). Contrast is not required to identify bony or epidural lesions. Any patient with cancer who has severe back pain should undergo an MRI. Plain films, bone scans, or even CT scans may show bone metastases, but only MRI can reliably delineate epidural tumor. For patients unable to have an MRI, CT myelography should be performed to outline the epidural space. The differential diagnosis of epidural tumor includes epidural abscess, acute or chronic hematomas, epidural lipomatosis, and, rarely, extramedullary hematopoiesis.

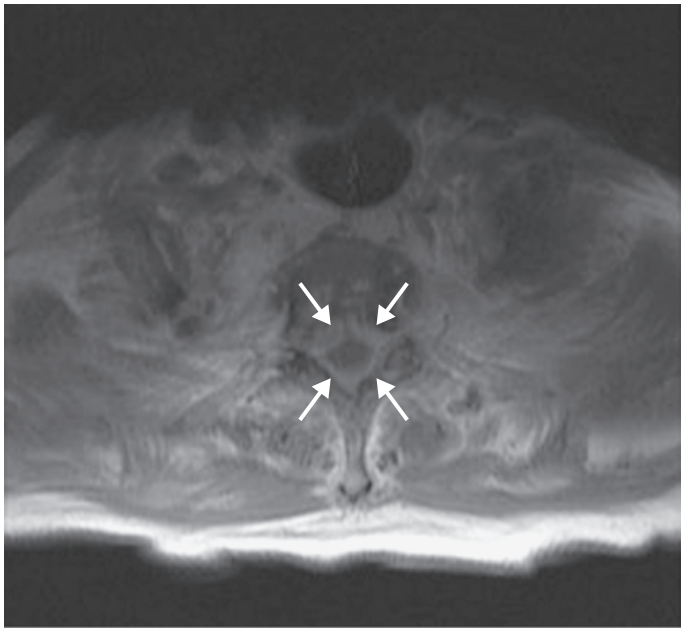

FIGURE 90-9 Postgadolinium T1 MRI showing circumferential epidural tumor around the thoracic spinal cord from esophageal cancer.

TREATMENT

Epidural Metastasis

Epidural metastasis requires immediate treatment. A randomized controlled trial demonstrated the superiority of surgical resection followed by RT compared to RT alone. However, patients must be able to tolerate surgery, and the surgical procedure of choice is a complete removal of the mass, which is typically anterior to the spinal canal, necessitating an extensive approach and resection. Otherwise, RT is the mainstay of treatment and can be used for patients with radiosensitive tumors, such as lymphoma, or for those unable to undergo surgery. SRS is increasingly being used, especially for radioresistant tumor types or for re-irradiation. Chemotherapy is rarely used for epidural metastasis unless the patient has minimal to no neurologic deficit and a highly chemosensitive tumor such as lymphoma or germinoma. Patients generally fare well if treated before there is a severe neurologic deficit. Recovery from paraparesis is better after surgery than with RT alone, but survival is often short due to widespread metastatic tumor.

NEUROLOGIC TOXICITY OF THERAPY

TOXICITY FROM RADIOTHERAPY

RT can cause a variety of toxicities in the CNS. These are usually described based on their relationship in time to the administration of RT: acute (occurring within days of RT), early delayed (months), or late delayed (years). In general, the acute and early delayed syndromes resolve and do not result in persistent deficits, whereas the late delayed toxicities are usually permanent and sometimes progressive.

Acute Toxicity Acute cerebral toxicity may occur during RT to the brain. RT can cause a transient disruption of the blood-brain barrier, resulting in edema and elevated intracranial pressure. This is usually manifest as headache, lethargy, nausea, and vomiting and can be both prevented and treated with the administration of glucocorticoids. There is no acute RT toxicity that affects the spinal cord.

Early Delayed Toxicity Early delayed toxicity is usually apparent weeks to months after completion of cranial irradiation and is likely due to focal demyelination. Clinically it may be asymptomatic or take the form of worsening or reappearance of a preexisting neurologic deficit. At times, a contrast-enhancing lesion can be seen on MRI/CT

that can mimic the tumor for which the patient received the RT. For patients with a malignant glioma, this has been described as "pseudoprogression" because it mimics tumor recurrence on MRI, but it represents inflammation and necrotic debris engendered by effective therapy. This is seen with increased frequency when chemotherapy, particularly temozolomide, is given concurrently with RT. Pseudoprogression can resolve on its own or, if very symptomatic, may require glucocorticoids, resection, or bevacizumab.

In the spinal cord, early delayed RT toxicity is manifest as a Lhermitte symptom with paresthesias of the limbs or along the spine when the patient flexes the neck. Although frightening, it is benign, resolves on its own, and does not portend more serious problems.

Late Delayed Toxicity Late delayed toxicities are the most serious because they are often irreversible and cause severe neurologic deficits. In the brain, late toxicities can take several forms, the most common of which include radiation necrosis and leukoencephalopathy. Radiation necrosis is a focal mass of necrotic tissue that is contrast enhancing on CT/MRI and may be associated with significant edema. This may appear identical to pseudoprogression but is seen months to years after RT and is always symptomatic. Clinical symptoms and signs include seizures and findings referable to the location of the necrotic mass. The necrosis is caused by the effect of RT on cerebral vasculature with fibrinoid necrosis and occlusion of blood vessels. It can mimic tumor radiographically, but unlike tumor, it is typically hypometabolic on a PET scan and has reduced perfusion on perfusion MR sequences. It may require resection for diagnosis and treatment unless it can be managed with glucocorticoids. There are reports of improvement with hyperbaric oxygen or bevacizumab, but symptomatic benefit does not always accompany radiographic improvement.

Leukoencephalopathy is seen most commonly after WBRT as opposed to focal RT. On T2 or FLAIR MR sequences, there is diffusely increased signal seen throughout the hemispheric white matter, often bilaterally and symmetrically. There tends to be a periventricular predominance that may be associated with atrophy and ventricular enlargement. Clinically, patients develop cognitive impairment, a gait disorder, and later urinary incontinence, all of which can progress over time. These symptoms mimic those of normal pressure hydrocephalus, and placement of a ventriculoperitoneal shunt can improve function in some patients but does not reverse the deficits completely. Increased age is a risk factor for leukoencephalopathy but not for radiation necrosis. Necrosis appears to depend on an unidentified predisposition.

Other late neurologic toxicities include endocrine dysfunction if the pituitary or hypothalamus was included in the RT port. An RT-induced neoplasm can occur many years after therapeutic RT for either a prior CNS or a head and neck tumor; accurate diagnosis requires surgical resection or biopsy. In addition, RT causes accelerated atherosclerosis, which can cause stroke either from intracranial vascular disease or carotid plaque from neck irradiation.

The peripheral nervous system is relatively resistant to RT toxicities. Peripheral nerves are rarely affected by RT, but the plexus is more vulnerable. Plexopathy develops more commonly in the brachial than in the lumbosacral distribution. It must be differentiated from tumor progression in the plexus, which is usually visualized by CT/MRI or PET scan demonstrating tumor infiltrating the region. Clinically, tumor progression is usually painful, whereas RT-induced plexopathy is painless. Radiation plexopathy is also more commonly associated with lymphedema and myokymia of the affected limb. Sensory loss and weakness are seen in both.

TOXICITY FROM CHEMOTHERAPY

Neurotoxicity is second to myelosuppression as the dose-limiting toxicity of chemotherapeutic agents (Table 90-4). Chemotherapy causes peripheral neuropathy from many commonly used agents, and the type of neuropathy can vary depending on the drug. Vincristine causes paresthesias but little sensory loss and is associated with motor dysfunction, autonomic impairment (frequently ileus), and, rarely, cranial nerve compromise. Cisplatin causes large-fiber sensory loss resulting in sensory ataxia but little cutaneous sensory loss and no weakness.

TABLE 90-4 Neurologic Signs Caused by Agents Commonly Used in Patients with Cancer

Acute encephalopathy (delirium)	Seizures
Methotrexate (high-dose IV, IT)	Methotrexate
Cisplatin	Etoposide (high-dose)
Vincristine	Cisplatin
Asparaginase	Vincristine
Procarbazine	Asparaginase
5-Fluorouracil (± levamisole)	Nitrogen mustard
Cytarabine (high-dose)	Carmustine
Nitrosoureas (high-dose or arterial)	Dacarbazine (intraarterial or high-dose)
Ifosfamide	Busulfan (high-dose)
Etoposide (high-dose)	Myelopathy (IT drugs)
Bevacizumab (PRES)	Methotrexate
Chronic encephalopathy (dementia)	Cytarabine
Methotrexate	Thiotepa
Carmustine	Peripheral neuropathy
Cytarabine	Vinca alkaloids
Fludarabine	Cisplatin
Visual loss	Procarbazine
Tamoxifen	Etoposide
Gallium nitrate	Teniposide
Cisplatin	Cytarabine
Fludarabine	Taxanes
Cerebellar dysfunction/ataxia	Suramin
5-Fluorouracil (± levamisole)	Bortezomib
Cytarabine	
Procarbazine	

Abbreviations: IT, intrathecal; IV, intravenous; PRES, posterior reversible encephalopathy syndrome.

The taxanes also cause a predominately sensory neuropathy. Agents such as bortezomib and thalidomide also cause neuropathy. Sometimes a severe neuropathy emerges after multiple neurotoxic agents have been used together or in sequence.

Encephalopathy and seizures are common toxicities from chemotherapeutic drugs. Ifosfamide can cause a severe encephalopathy, which is reversible with discontinuation of the drug and the use of methylene blue for severely affected patients. Fludarabine also causes a severe global encephalopathy that may be permanent. Bevacizumab and other anti-VEGF agents can cause posterior reversible encephalopathy syndrome. Cisplatin can cause hearing loss and less frequently vestibular dysfunction. Immunotherapy with monoclonal antibodies such as ipilimumab or nivolumab can cause an autoimmune hypophysitis, Guillain-Barré syndrome, or an autoimmune encephalitis.

91 Soft Tissue and Bone Sarcomas and Bone Metastases

Shreyaskumar R. Patel

Sarcomas are rare (<1% of all malignancies) mesenchymal neoplasms that arise in bone and soft tissues. These tumors are usually of mesodermal origin, although a few are derived from neuroectoderm, and they are biologically distinct from the more common epithelial malignancies. Sarcomas affect all age groups; 15% are found in children <15 years of age, and 40% occur after age 55 years. Sarcomas are one of the most common solid tumors of childhood and are the fifth most common cause of cancer deaths in children. Sarcomas may be divided into two groups, those derived from bone and those derived from soft tissues.

SOFT TISSUE SARCOMAS

Soft tissues include muscles, tendons, fat, fibrous tissue, synovial tissue, vessels, and nerves. Approximately 60% of soft tissue sarcomas arise in the extremities, with the lower extremities involved three times as often as the upper extremities. Thirty percent arise in the trunk, with the retroperitoneum accounting for 40% of all trunk lesions. The remaining 10% arise in the head and neck.

INCIDENCE

Approximately 13,130 new cases of soft tissue sarcomas occurred in the United States in 2020. The annual age-adjusted incidence is 3 per 100,000 population, but the incidence varies with age. Soft tissue sarcomas constitute 0.7% of all cancers in the general population and 6.5% of all cancers in children.

EPIDEMIOLOGY

Malignant transformation of a benign soft tissue tumor is extremely rare, with the exception that malignant peripheral nerve sheath tumors (neurofibrosarcoma, malignant schwannoma) can arise from neurofibromas in patients with neurofibromatosis. Several etiologic factors have been implicated in soft tissue sarcomas.

Environmental Factors Trauma or previous injury is rarely involved, but sarcomas can arise in scar tissue resulting from a prior operation, burn, fracture, or foreign body implantation. Chemical carcinogens such as polycyclic hydrocarbons, asbestos, and dioxin may be involved in the pathogenesis.

Iatrogenic Factors Sarcomas in bone or soft tissues occur in patients who are treated with radiation therapy. The tumor nearly always arises in the irradiated field. The risk increases with time.

Viruses Kaposi's sarcoma (KS) in patients with HIV type 1, classic KS, and KS in HIV-negative homosexual men is caused by human herpesvirus (HHV) 8 **(Chap. 195)**. No other sarcomas are associated with viruses.

Immunologic Factors Congenital or acquired immunodeficiency, including therapeutic immunosuppression, increases the risk of sarcoma.

GENETIC CONSIDERATIONS

Li-Fraumeni syndrome is a familial cancer syndrome in which affected individuals have germline abnormalities of the tumor-suppressor gene *p53* and an increased incidence of soft tissue sarcomas and other malignancies, including breast cancer, osteosarcoma, brain tumor, leukemia, and adrenal carcinoma **(Chap. 71)**. Neurofibromatosis 1 (NF-1, peripheral form, von Recklinghausen's disease) is characterized by multiple neurofibromas and café-au-lait spots. Neurofibromas occasionally undergo malignant degeneration to become malignant peripheral nerve sheath tumors. The gene for *NF1* is located in the pericentromeric region of chromosome 17 and encodes neurofibromin, a tumor-suppressor protein with guanosine 5′-triphosphate (GTP)ase-activating activity that inhibits ras function **(Chap. 90)**. Germline mutation of the *RB1* locus (chromosome 13q14) in patients with inherited retinoblastoma is associated with the development of osteosarcoma in those who survive the retinoblastoma and of soft tissue sarcomas unrelated to radiation therapy. Other soft tissue tumors, including desmoid tumors, lipomas, leiomyomas, neuroblastomas, and paragangliomas, occasionally show a familial predisposition.

Ninety percent of synovial sarcomas contain a characteristic chromosomal translocation t(X;18)(p11;q11) involving a nuclear transcription factor on chromosome 18 called *SYT* and two breakpoints on X. Patients with translocations to the second X breakpoint (*SSX2*) may have longer survival than those with translocations involving *SSX1*.

Insulin-like growth factor (IGF) type II is produced by some sarcomas and may act as an autocrine growth factor and as a motility factor that promotes metastatic spread. IGF-II stimulates growth through IGF-I receptors, but its effects on motility are through different receptors. If secreted in large amounts, IGF-II may produce hypoglycemia **(Chaps. 93** and **406)**. A large international sarcoma kindred study including 1162 patients and 6545 Caucasian controls revealed that about half the patients with sarcoma have putatively pathogenic monogenic and polygenic variation in previously reported and new cancer genes, some of them representing therapeutically actionable targets. These patients were diagnosed with sarcoma at an earlier age compared to controls.

CLASSIFICATION

Approximately 20 different groups of sarcomas are recognized on the basis of the pattern of differentiation toward normal tissue. For example, rhabdomyosarcoma shows evidence of skeletal muscle fibers

with cross-striations; leiomyosarcomas contain interlacing fascicles of spindle cells resembling smooth muscle; and liposarcomas contain adipocytes. When precise characterization of the group is not possible, the tumors are called *unclassified sarcomas*. All of the primary bone sarcomas can also arise from soft tissues (e.g., extraskeletal osteosarcoma). The entity *malignant fibrous histiocytoma* (MFH) includes many tumors previously classified as fibrosarcomas or as pleomorphic variants of other sarcomas and is characterized by a mixture of spindle (fibrous) cells and round (histiocytic) cells arranged in a storiform pattern with frequent giant cells and areas of pleomorphism. As immunohistochemical suggestion of differentiation, particularly myogenic differentiation, may be found in a significant fraction of these patients, many are now characterized as poorly differentiated leiomyosarcomas, and the terms *undifferentiated pleomorphic sarcoma* (UPS) and *myxofibrosarcoma* are replacing MFH and myxoid MFH.

For purposes of treatment, most soft tissue sarcomas can be considered together. However, some specific tumors have distinct features. For example, *liposarcoma* can have a spectrum of behaviors. Pleomorphic liposarcomas and dedifferentiated liposarcomas behave like other high-grade sarcomas; in contrast, well-differentiated liposarcomas (better termed *atypical lipomatous tumors*) lack metastatic potential, and myxoid liposarcomas metastasize infrequently, but, when they do, they have a predilection for unusual metastatic sites containing fat, such as the retroperitoneum, mediastinum, and subcutaneous tissue. Rhabdomyosarcomas, Ewing's sarcoma, and other small-cell sarcomas tend to be more aggressive and are more responsive to chemotherapy than other soft tissue sarcomas.

Gastrointestinal stromal tumors (GISTs), previously classified as gastrointestinal leiomyosarcomas, are now recognized as a distinct entity within soft tissue sarcomas. Its cell of origin resembles the interstitial cell of Cajal, which controls peristalsis. The majority of malignant GISTs have activating mutations of the c-*kit* gene that result in ligand-independent phosphorylation and activation of the KIT receptor tyrosine kinase, leading to tumorigenesis. Approximately 5–10% of tumors will have a mutation in the platelet-derived growth factor receptor α (*PDGFRA*). GISTs that are wild type for both *KIT* and *PDGFRA* mutations may show mutations in *SDH* B, C, or D and may be driven by the IGF-I pathway.

DIAGNOSIS

The most common presentation is an asymptomatic mass. Mechanical symptoms referable to pressure, traction, or entrapment of nerves or muscles may be present. All new and persistent or growing masses should be biopsied, either by a small incision or by a cutting needle (core-needle biopsy) placed so that it can be encompassed in the subsequent excision without compromising a definitive resection. Lymph node metastases occur in 5%, except in synovial and epithelioid sarcomas, clear-cell sarcoma (melanoma of the soft parts), angiosarcoma, and rhabdomyosarcoma, where nodal spread may be seen in 17%. The pulmonary parenchyma is the most common site of metastases. Exceptions are GISTs, which metastasize to the liver; myxoid liposarcomas, which seek fatty tissue; and clear cell sarcomas, which may metastasize to bones. Central nervous system metastases are rare, except in alveolar soft part sarcoma.

Radiographic Evaluation Imaging of the primary tumor is best with plain radiographs and magnetic resonance imaging (MRI) for tumors of the extremities or head and neck and by computed tomography (CT) for tumors of the chest, abdomen, or retroperitoneal cavity. A radiograph and CT scan of the chest are important for the detection of lung metastases. Other imaging studies may be indicated, depending on the symptoms, signs, or histology.

STAGING AND PROGNOSIS

The histologic grade and size of the primary tumor are the most important prognostic factors. The current American Joint Committee on Cancer (AJCC) staging system is shown in **Table 91-1**. Prognosis is related to the stage. Cure is common in the absence of metastatic disease, but a small number of patients with metastases can also be cured. Historically, most patients with stage IV disease used to die within 12 months, but with availability of multiple lines of treatments, median survival in second-line and beyond ranges from 13 to 14 months, and some patients may live with stable or slowly progressive disease for many years.

TABLE 91-1 American Joint Commission on Cancer Staging System for Sarcomas, Eighth Edition

T1	Tumor ≤5 cm in greatest dimension
T2	Tumor >5 cm and ≤10 cm in greatest dimension
T3	Tumor >10 cm and ≤15 cm in greatest dimension
T4	Tumor >15 cm in greatest dimension
N0	No regional lymph node metastasis or unknown lymph node status
N1	Regional lymph node metastasis
M0	No distant metastasis
M1	Distant metastasis
Stage Groups	
Stage IA	T1; N0; M0; G1
Stage IB	T2, T3, T4; N0; M0; G1
Stage II	T1; N0; M0; G2/3
Stage IIIA	T1A, T2; N0; M0; G2/3
Stage IIIB	T3, T4; N0; M0; G2/3
Stage IV	Any T; N1; M0; any G Any T; any N; M1; any G

TREATMENT

Soft Tissue Sarcomas

AJCC stage I patients are adequately treated with surgery alone. Stage II patients are considered for adjuvant radiation therapy. Stage III patients may benefit from neoadjuvant or adjuvant chemotherapy. Stage IV patients are managed primarily with systemic therapy, with or without other modalities.

SURGERY

Soft tissue sarcomas tend to grow along fascial planes, with the surrounding soft tissues compressed to form a pseudocapsule that gives the sarcoma the appearance of a well-encapsulated lesion. This is invariably deceptive because "shelling out," or marginal excision, of such lesions results in a 50–90% probability of local recurrence. Wide excision with a negative margin, incorporating the biopsy site, is the standard surgical procedure for local disease. The adjuvant use of radiation therapy and/or chemotherapy improves the local control rate and permits the use of limb-sparing surgery with a local control rate (85–90%) comparable to that achieved by radical excisions and amputations. Limb-sparing approaches are indicated except when negative margins are not obtainable, when the risks of radiation are prohibitive, or when neurovascular structures are involved so that resection will result in serious functional consequences to the limb.

RADIATION THERAPY

External-beam radiation therapy is an adjuvant to limb-sparing surgery for improved local control. Preoperative radiation therapy allows the use of smaller fields and smaller doses but results in a higher rate of wound complications. Postoperative radiation therapy must be given to larger fields, because the entire surgical bed must be encompassed, and in higher doses to compensate for hypoxia in the operated field. This results in a higher rate of late complications. Brachytherapy or interstitial therapy, in which the radiation source is inserted into the tumor bed, is comparable in efficacy (except in low-grade lesions), less time consuming, and less expensive.

With the advent of stereotactic body radiotherapy (SBRT), the role of radiation therapy in oligometastatic disease in various visceral sites is being investigated and evolving.

ADJUVANT CHEMOTHERAPY

Chemotherapy is the mainstay of treatment for Ewing's sarcomas/primitive neuroectodermal tumors (PNETs) and rhabdomyosarcomas. Meta-analysis of 14 randomized trials in non-small-cell sarcomas revealed a significant improvement in local control and disease-free survival in favor of doxorubicin-based chemotherapy. Overall survival improvement was 4% for all sites and 7% for the extremity site. An updated meta-analysis including four additional trials with doxorubicin and ifosfamide combination reported a statistically significant 6% survival advantage in favor of chemotherapy. A chemotherapy regimen including an anthracycline and ifosfamide with growth factor support improved overall survival by 19% for high-risk (high-grade, ≥5 cm primary, or locally recurrent) extremity soft tissue sarcomas. Long-term follow-up of a trial evaluating neoadjuvant use of the same combination confirms survival advantage and reports a 10-year survival of 61%. A more contemporary randomized trial compared the standard anthracycline and ifosfamide combination to specific histology-tailored chemotherapy as an active control and confirmed superiority of the standard regimen.

ADVANCED DISEASE

Metastatic soft tissue sarcomas are largely incurable, but up to 20% of patients who achieve a complete response become long-term survivors. The therapeutic intent, therefore, is to produce a complete remission with chemotherapy (<10%) and/or surgery (30–40%). Surgical resection of metastases, whenever possible, is an integral part of the management. Some patients benefit from repeated surgical excision of metastases. The two most active chemotherapeutic agents are doxorubicin and ifosfamide. These drugs show a steep dose-response relationship in sarcomas. Gemcitabine with or without docetaxel has become an established second-line regimen and is particularly active in patients with UPS and leiomyosarcomas. Dacarbazine also has some modest activity. Taxanes have selective activity in angiosarcomas, and vincristine, etoposide, and irinotecan are effective in rhabdomyosarcomas and Ewing's sarcomas. Pazopanib, an inhibitor of the vascular endothelial growth factor, platelet-derived growth factor (PDGF), and c-kit, is now approved for patients with advanced soft tissue sarcomas excluding liposarcomas after failure of chemotherapy. Two additional chemotherapy drugs have gained approval from the U.S. Food and Drug Administration (FDA). Trabectedin was compared to dacarbazine in a large phase 3 randomized study in advanced leiomyosarcomas and liposarcomas after failure of an anthracycline and resulted in significant improvement in progression-free survival. Eribulin was also tested in a similar trial and showed improvement in survival, predominantly in the liposarcoma subgroup, and is therefore now approved for that subset. Tazemetostat, an EZH2 inhibitor, is now approved for use in metastatic epithelioid sarcomas characterized by loss of tumor-suppressor gene *INI1*, resulting in activation of the EZH2 pathway. Imatinib targets KIT and PDGF tyrosine kinase activity and is standard therapy for advanced/metastatic GISTs and dermatofibrosarcoma protuberans. Imatinib is also indicated as adjuvant therapy for completely resected primary GISTs. Three years of adjuvant imatinib appear to be superior to 1 year of therapy for high-risk GISTs, although the optimal treatment duration remains unknown. Sunitinib and regorafenib are approved for second- and third-line use, respectively, in metastatic GIST after failure of or intolerance to imatinib. Ripretinib, an inhibitor of c-kit and PDGFRA, was approved for fourth-line use in metastatic GIST based on a placebo-controlled randomized trial reporting an improved median progression-free and overall survival. Avapritinib also received approval for use in the specific molecular subset of *PDGFRA* D842V–mutant metastatic GIST.

BONE SARCOMAS

INCIDENCE AND EPIDEMIOLOGY

Bone sarcomas are rarer than soft tissue sarcomas; they accounted for only 0.2% of all new malignancies and 3600 new cases in the United States in 2020. Several benign bone lesions have the potential for malignant transformation. Enchondromas and osteochondromas can transform into chondrosarcoma; fibrous dysplasia, bone infarcts, and Paget's disease of bone can transform into either UPS or osteosarcoma.

CLASSIFICATION

Benign Tumors The common benign bone tumors include enchondroma, osteochondroma, chondroblastoma, and chondromyxoid fibroma, of cartilage origin; osteoid osteoma and osteoblastoma, of bone origin; fibroma and desmoplastic fibroma, of fibrous tissue origin; hemangioma, of vascular origin; and giant cell tumor, of unknown origin.

Malignant Tumors The most common malignant tumors of bone are plasma cell tumors (Chap. 111). The four most common malignant nonhematopoietic bone tumors are osteosarcoma, chondrosarcoma, Ewing's sarcoma, and UPS. Rare malignant tumors include chordoma (of notochordal origin), malignant giant cell tumor, adamantinoma (of unknown origin), and hemangioendothelioma (of vascular origin).

Musculoskeletal Tumor Society Staging System Sarcomas of bone are staged according to the Musculoskeletal Tumor Society staging system based on grade and compartmental localization. A Roman numeral reflects the tumor grade: stage I is low grade, stage II is high grade, and stage III includes tumors of any grade that have lymph node or distant metastases. In addition, the tumor is given a letter reflecting its compartmental localization. Tumors designated A are intracompartmental (i.e., confined to the same soft tissue compartment as the initial tumor), and tumors designated B are extracompartmental (i.e., extending into the adjacent soft tissue compartment or into bone). The tumor-node-metastasis (TNM) staging system is shown in Table 91-2.

TABLE 91-2 Staging System for Bone Sarcomas

Primary tumor (T)	TX	Primary tumor cannot be assessed
	T0	No evidence of primary tumor
	T1	Tumor ≤8 cm in greatest dimension
	T2	Tumor >8 cm in greatest dimension
	T3	Discontinuous tumors in the primary bone site
Regional lymph nodes (N)	NX	Regional lymph nodes cannot be assessed
	N0	No regional lymph node metastasis
	N1	Regional lymph node metastasis
Distant metastasis (M)	MX	Distant metastasis cannot be assessed
	M0	No distant metastasis
	M1	Distant metastasis
	M1a	Lung
	M1b	Other distant sites
Histologic grade (G)	GX	Grade cannot be assessed
	G1	Well differentiated—low grade
	G2	Moderately differentiated—low grade
	G3	Poorly differentiated—high grade
	G4	Undifferentiated—high grade (Ewing's is always classed G4)

Stage Grouping				
Stage IA	T1	N0	M0	G1,2 low grade
Stage IB	T2	N0	M0	G1,2 low grade
Stage IIA	T1	N0	M0	G3,4 high grade
Stage IIB	T2	N0	M0	G3,4 high grade
Stage III	T3	N0	M0	Any G
Stage IVA	Any T	N0	M1a	Any G
Stage IVB	Any T	N1	Any M	Any G
	Any T	Any N	M1b	Any G

OSTEOSARCOMA

Osteosarcoma, accounting for almost 45% of all bone sarcomas, is a spindle cell neoplasm that produces osteoid (unmineralized bone) or bone. Approximately 60% of all osteosarcomas occur in children and adolescents in the second decade of life, and ~10% occur in the third decade of life. Osteosarcomas in the fifth and sixth decades of life are frequently secondary to either radiation therapy or transformation in a preexisting benign condition, such as Paget's disease. Males are affected 1.5–2 times as often as females. Osteosarcoma has a predilection for metaphyses of long bones; the most common sites of involvement are the distal femur, proximal tibia, and proximal humerus. The classification of osteosarcoma is complex, but 75% of osteosarcomas fall into the "classic" category, which includes osteoblastic, chondroblastic, and fibroblastic osteosarcomas. The remaining 25% are classified as "variants" on the basis of (1) clinical characteristics, as in the case of osteosarcoma of the jaw, postradiation osteosarcoma, or Paget's osteosarcoma; (2) morphologic characteristics, as in the case of telangiectatic osteosarcoma, small-cell osteosarcoma, or epithelioid osteosarcoma; or (3) location, as in parosteal or periosteal osteosarcoma. Diagnosis usually requires a synthesis of clinical, radiologic, and pathologic features. Patients typically present with pain and swelling of the affected area. A plain radiograph reveals a destructive lesion with a moth-eaten appearance, a spiculated periosteal reaction (sunburst appearance), and a cuff of periosteal new bone formation at the margin of the soft tissue mass (Codman's triangle). A CT scan of the primary tumor is best for defining bone destruction and the pattern of calcification, whereas MRI is better for defining intramedullary and soft tissue extension. A chest radiograph and CT scan are used to detect lung metastases. Metastases to the bony skeleton should be imaged by a bone scan or by fluorodeoxyglucose positron emission tomography (FDG-PET). Almost all osteosarcomas are hypervascular and PET-avid. Pathologic diagnosis is established either with a core-needle biopsy, where feasible, or with an open biopsy with an appropriately placed incision that does not compromise future limb-sparing resection. Most osteosarcomas are high grade. The most important predictive factor for long-term survival is response to chemotherapy. Preoperative chemotherapy followed by limb-sparing surgery (which can be accomplished in >80% of patients) followed by postoperative chemotherapy is standard management. The effective drugs are doxorubicin, ifosfamide, cisplatin, and high-dose methotrexate with leucovorin rescue. The various combinations of these agents that have been used have all been about equally successful. Long-term survival rates in extremity osteosarcoma range from 60 to 80%. Osteosarcoma is radioresistant; radiation therapy has no role in the routine management. UPS is considered a part of the spectrum of osteosarcoma and is managed similarly. A randomized trial has shown improved progression-free survival with regorafenib compared to placebo.

CHONDROSARCOMA

Chondrosarcoma, which constitutes ~20–25% of all bone sarcomas, is a tumor of adulthood and old age with a peak incidence in the fourth to sixth decades of life. It has a predilection for the flat bones, especially the shoulder and pelvic girdles, but can also affect the diaphyseal portions of long bones. Chondrosarcomas can arise de novo or as a malignant transformation of an enchondroma or, rarely, of the cartilaginous cap of an osteochondroma. Chondrosarcomas have an indolent natural history and typically present as pain and swelling. Radiographically, the lesion may have a lobular appearance with mottled or punctate or annular calcification of the cartilaginous matrix. It is difficult to distinguish low-grade chondrosarcoma from benign lesions by x-ray or histologic examination. The diagnosis is therefore influenced by clinical history and physical examination. A new onset of pain, signs of inflammation, and progressive increase in the size of the mass suggest malignancy. The histologic classification is complex, but most tumors fall within the classic category. Like other bone sarcomas, high-grade chondrosarcomas spread to the lungs. Most chondrosarcomas are resistant to chemotherapy, and surgical resection of primary or recurrent tumors, including pulmonary metastases, is the mainstay of therapy with the exception of two histologic variants. Dedifferentiated chondrosarcoma has a high-grade osteosarcoma or a malignant fibrous histiocytoma component that responds to chemotherapy. Mesenchymal chondrosarcoma, a rare variant composed of a small-cell element, also is responsive to systemic chemotherapy and is treated like Ewing's sarcoma.

EWING'S SARCOMA

Ewing's sarcoma, which constitutes ~10–15% of all bone sarcomas, is common in adolescence and has a peak incidence in the second decade of life. It typically involves the diaphyseal region of long bones and also has an affinity for flat bones. The plain radiograph may show a characteristic "onion peel" periosteal reaction with a generous soft tissue mass, which is better demonstrated by CT or MRI. This mass is composed of sheets of monotonous, small, round, blue cells and can be confused with lymphoma, embryonal rhabdomyosarcoma, and small-cell carcinoma. The presence of p30/32, the product of the *mic-2* gene (which maps to the pseudoautosomal region of the X and Y chromosomes), is a cell-surface marker for Ewing's sarcoma (and other members of the Ewing family of tumors, previously also called PNETs). Most PNETs arise in soft tissues; they include peripheral neuroepithelioma, Askin's tumor (chest wall), and esthesioneuroblastoma. Glycogen-filled cytoplasm detected by staining with periodic acid–Schiff is also characteristic of Ewing's sarcoma cells. The classic cytogenetic abnormality associated with this disease is a reciprocal translocation of the long arms of chromosomes 11 and 22, t(11;22), which creates a chimeric gene product of unknown function with components from the *fli-1* gene on chromosome 11 and *ews* on chromosome 22. This disease is very aggressive, and it is therefore considered a systemic disease. Common sites of metastases are lung, bones, and bone marrow. Systemic chemotherapy is the mainstay of therapy, often being used before surgery. Doxorubicin, cyclophosphamide or ifosfamide, etoposide, vincristine, and dactinomycin are active drugs. Topotecan or irinotecan in combination with an alkylating agent is often used in relapsed patients. Local treatment for the primary tumor includes surgical resection, usually with limb salvage or radiation therapy. Patients with lesions below the elbow and below the mid-calf have a 5-year survival rate of 80% with effective treatment. Ewing's sarcoma at first presentation is a curable tumor, even in the presence of obvious metastatic disease, especially in children <11 years old.

TUMORS METASTATIC TO BONE

Bone is a common site of metastasis for carcinomas of the prostate, breast, lung, kidney, bladder, and thyroid and for lymphomas and sarcomas. Prostate, breast, and lung primaries account for 80% of all bone metastases. Metastatic tumors of bone are more common than primary bone tumors. Tumors usually spread to bone hematogenously, but local invasion from soft tissue masses also occurs. In descending order of frequency, the sites most often involved are the vertebrae, proximal femur, pelvis, ribs, sternum, proximal humerus, and skull. Bone metastases may be asymptomatic or may produce pain, swelling, nerve root or spinal cord compression, pathologic fracture, or myelophthisis (replacement of the marrow). Symptoms of hypercalcemia may be noted in cases of bony destruction.

Pain is the most frequent symptom. It usually develops gradually over weeks, is usually localized, and often is more severe at night. When patients with back pain develop neurologic signs or symptoms, emergency evaluation for spinal cord compression is indicated (Chap. 75). Bone metastases exert a major adverse effect on quality of life in cancer patients.

Cancer in the bone may produce osteolysis, osteogenesis, or both. Osteolytic lesions result when the tumor produces substances that can directly elicit bone resorption (vitamin D–like steroids, prostaglandins, or parathyroid hormone–related peptide) or cytokines that can induce the formation of osteoclasts (interleukin 1 and tumor necrosis factor). Osteoblastic lesions result when the tumor produces cytokines that activate osteoblasts. In general, purely osteolytic lesions are best detected by plain radiography, but they may not be apparent until they are >1 cm. These lesions are more commonly associated with hypercalcemia and with the excretion of hydroxyproline-containing peptides indicative of matrix destruction. When osteoblastic activity is prominent, the lesions may be readily detected using radionuclide

bone scanning (which is sensitive to new bone formation), and the radiographic appearance may show increased bone density or sclerosis. Osteoblastic lesions are associated with higher serum levels of alkaline phosphatase and, if extensive, may produce hypocalcemia. Although some tumors may produce mainly osteolytic lesions (e.g., kidney cancer) and others mainly osteoblastic lesions (e.g., prostate cancer), most metastatic lesions produce both types of lesion and may go through stages where one or the other predominates.

In older patients, particularly women, it may be necessary to distinguish metastatic disease of the spine from osteoporosis. In osteoporosis, the cortical bone may be preserved, whereas cortical bone destruction is usually noted with metastatic cancer.

TREATMENT

Metastatic Bone Disease

Treatment of metastatic bone disease depends on the underlying malignancy and the symptoms. Some metastatic bone tumors are curable (lymphoma, Hodgkin's disease), and others are treated with palliative intent. Pain may be relieved by local radiation therapy. Hormonally responsive tumors are responsive to hormone inhibition (antiandrogens for prostate cancer, antiestrogens for breast cancer). Strontium-89, samarium-153, and radium-223 are bone-seeking radionuclides that can exert antitumor effects and relieve symptoms. Denosumab, a monoclonal antibody that binds to RANK ligand, inhibits osteoclastic activity and increases bone mineral density. Bisphosphonates such as pamidronate may relieve pain and inhibit bone resorption, thereby maintaining bone mineral density and reducing risk of fractures in patients with osteolytic metastases from breast cancer and multiple myeloma. Careful monitoring of serum electrolytes and creatinine is recommended. Monthly administration prevents bone-related clinical events and may reduce the incidence of bone metastases in women with breast cancer. When the integrity of a weight-bearing bone is threatened by an expanding metastatic lesion that is refractory to radiation therapy, prophylactic internal fixation is indicated. Overall survival is related to the prognosis of the underlying tumor. Bone pain at the end of life is particularly common; an adequate pain relief regimen including sufficient amounts of narcotic analgesics is required. The management of hypercalcemia is discussed in Chap. 410.

92 Carcinoma of Unknown Primary

Kanwal Raghav, James L. Abbruzzese, Gauri R. Varadhachary

Carcinoma (or cancer) of unknown primary (CUP) is a biopsy-proven malignancy for which the anatomic site of origin remains unidentified after a standardized detailed diagnostic evaluation. CUP is one of the 10 most frequently diagnosed cancers globally, accounting for 3–5% of all malignancies. Most investigators limit CUP to epithelial or undifferentiated cancers and do not include lymphomas, metastatic melanomas, and metastatic sarcomas because these cancers have specific histology and stage-based management guidelines, even in the absence of a primary site. CUP can occur in patients of all age groups including adolescents and young adults.

The emergence of sophisticated imaging, robust immunohistochemistry (IHC), and genomic and proteomic tools has challenged the "unknown" designation. Additionally, effective targeted therapies in several cancers and tissue agnostic biomarker-driven therapies have endorsed a change in paradigm from empiricism to a personalized approach to CUP management. The reasons cancers present as CUP remain unclear. One hypothesis is that the primary tumor either regresses after seeding the metastasis or remains so small that it is not detected. It is possible that CUP falls on the continuum of cancer presentation where the primary has been contained or eliminated by the natural body defenses, including the immune system. Alternatively, CUP may represent a specific malignant event that results in an increase in metastatic spread or survival relative to the primary. Whether the CUP metastases truly define a clone that is genetically and phenotypically unique to this diagnosis remains to be determined.

Since liver is a common site of CUP presentation, intrahepatic cholangiocarcinoma (ICC) can be often misdiagnosed as CUP. Of note, the incidence of ICC is increasing, whereas at the same time, that of CUP is declining. Improvements in diagnostic technologies including next-generation sequencing and other molecular techniques and awareness among clinicians to differentiate the two are possibly contributing to an increased recognition and incidence of ICC.

CUP BIOLOGY

Studies looking for unique signature abnormalities in CUP tumors have not been positive. Abnormalities in chromosomes 1 and 12 and other complex cytogenetic abnormalities have been reported. Aneuploidy has been described in 70% of CUP patients with metastatic adenocarcinoma or undifferentiated carcinoma. The overexpression of various genes, including *RAS*, *BCL2* (40%), *HER2* (11%), and *P53* (26–53%), has been identified in CUP samples, but they are found in many other malignancies and have no effect on response to therapy or survival. The extent of angiogenesis in CUP relative to that in metastases from known primaries has also been evaluated, but no consistent findings have emerged. Although current comprehensive genomic profiling efforts may help identify targeted therapeutic approaches to improve outcomes for this disease as discussed below, they have failed thus far to reveal a distinct molecular signature. More comprehensive and integrated multiomic efforts are needed to provide insights into CUP biology through recognition of molecular aberrations that especially drive metastatic growth.

APPROACH TO THE PATIENT

Carcinoma (or Cancer) of Unknown Primary

Initial CUP evaluation has two goals: search for the primary tumor based on pathologic evaluation of the metastases and determine the extent of disease. Focused evaluation directed by clinicopathologic

cues allows for judicious and efficient use of diagnostic tests. Obtaining a thorough medical history from CUP patients is essential, including paying particular attention to previous surgeries, removed lesions, and family medical history to assess potential hereditary cancers. Adequate physical examination, including a digital rectal examination in men and breast and pelvic examinations in women, should be performed based on clinical presentation. Finally, all patients with CUP, in the absence of contraindication, must undergo a computed tomographic (CT) scan of chest, abdomen and pelvis as a part of their standard work-up.

ROLE OF SERUM TUMOR MARKERS AND CYTOGENETICS

Most tumor markers, including carcinoembryonic antigen (CEA), CA-125, CA 19-9, and CA 15-3, when elevated, are nonspecific and not helpful in determining the primary site. Men who present with adenocarcinoma and predominant osteoblastic metastasis should undergo a prostate-specific antigen (PSA) test. In patients with undifferentiated or poorly differentiated carcinoma (especially with a midline tumor), elevated β-human chorionic gonadotropin (β-hCG) and α fetoprotein (AFP) levels suggest the possibility of an extragonadal germ cell (testicular) tumor. With the availability of advanced immunohistochemistry (IHC), cytogenetic studies are rarely needed.

ROLE OF IMAGING STUDIES

In the absence of contraindications, a baseline IV contrast computed tomography (CT) scan of the chest, abdomen, and pelvis is the standard of care. This helps to search for the primary tumor, evaluate the extent of disease, and select the most accessible biopsy site. With precise imaging and reporting, latent primary cancers, defined as appearance of a new primary cancer after a latent period of several months to years, is uncommon and seen in ≤5% of CUP patients, usually in patients with very indolent presentations and/or highly responsive metastatic cancers that allows a latent primary to emerge (grow) over time.

Mammography should be performed in all women who present with metastatic adenocarcinoma, specifically in those with isolated axillary lymphadenopathy. Magnetic resonance imaging (MRI) of the breast can be considered in patients with axillary adenopathy and suspected occult primary breast carcinoma following a negative mammography and ultrasound. The results of these imaging modalities can influence surgical management; a negative MRI of the breast predicts a low tumor yield at mastectomy.

A conventional workup for a squamous cell carcinoma and cervical CUP (neck lymphadenopathy with no known primary tumor) includes a CT scan or MRI and invasive studies, including indirect and direct laryngoscopy, bronchoscopy, and upper endoscopy. Ipsilateral (or bilateral) staging tonsillectomy has been recommended for these patients. 18-Fluorodeoxyglucose positron emission tomography (18-FDG-PET) scans are useful in this patient population and may help guide the biopsy; determine the extent of disease; facilitate the appropriate treatment, including planning radiation fields; and help with disease surveillance. A smaller radiation field encompassing the metastatic adenopathy decreases the risk of chronic xerostomia. Several studies have evaluated the utility of PET in patients with squamous cervical CUP, and head and neck primary tumors were identified in ~21–30%.

The diagnostic contribution of PET to the evaluation of other CUP presentations (outside of the neck adenopathy indication) remains controversial and is not routinely recommended. PET-CT can be helpful for patients with bone metastases and those deemed candidates for aggressive multimodality therapy (surgical intervention/radiation) such as patients with solitary metastatic disease because the identification of disease in addition to the solitary metastatic site may affect treatment planning.

Invasive studies, including upper endoscopy, colonoscopy, and bronchoscopy, should be limited to symptomatic patients or those with laboratory, imaging, or pathologic abnormalities that suggest that these techniques will result in a high yield in finding a primary cancer.

ROLE OF PATHOLOGIC STUDIES

A detailed pathologic examination of the most accessible biopsied tissue specimen is mandatory in CUP patients. Pathologic evaluation typically consists of hematoxylin and eosin stains and IHC tests. The importance of adequate tissue acquisition cannot be overemphasized in CUP. In addition to pathologic evaluation, tissue is also needed for tests of biomarkers of targeted agents, immunotherapy, and clinical trials.

Light Microscopy Evaluation Adequate tissue obtained preferably by excisional biopsy or core needle biopsy (instead of only a fine-needle aspiration) is stained with hematoxylin and eosin and subjected to light microscopic examination. On light microscopy, 60–65% of CUP is adenocarcinoma, and 5% is squamous cell carcinoma. The remaining 30–35% is poorly differentiated adenocarcinoma, poorly differentiated carcinoma, or poorly differentiated neoplasm. A small percentage of lesions are diagnosed as neuroendocrine cancers (2%), mixed tumors (adenosquamous or sarcomatoid carcinomas), or undifferentiated neoplasms (Table 92-1).

Role of IHC Analysis IHC stains are peroxidase-labeled antibodies against specific tumor antigens that are used to define tumor lineage. The number of available IHC stains is ever-increasing. However, a tiered and uniform approach to tissue evaluation in the CUP setting is lacking. For CUP cases, more is not necessarily better, and IHC stains should be used in conjunction with the patient's clinical presentation and imaging studies to select the best therapy. Communication between the clinician and pathologist is essential. No stain is 100% sensitive or specific, and under-/overinterpretation should be avoided. Poor differentiation, even in known primary tumors, decreases sensitivity of hallmark IHC markers. PSA and thyroglobulin tissue markers, which are positive in prostate and thyroid cancer, respectively, are the most specific of the current marker panel. However, these cancers rarely present as CUP, so the yield of these tests may be low. Figure 92-1 delineates a simple algorithm for immunohistochemical staining in CUP cases. Table 92-2 lists additional tests that may be useful to further define the tumor lineage. A more comprehensive algorithm may improve the diagnostic accuracy but can make the process complex and increase cost. With the use of IHC markers, electron microscopic analysis, which is time-consuming and expensive, is rarely needed.

There are >20 subtypes of cytokeratin (CK) intermediate filaments with different molecular weights and differential expression in various cell types and cancers. Monoclonal antibodies to specific CK subtypes have been used to help classify tumors according to their site of origin; commonly used CK stains in adenocarcinoma CUP are CK7 and CK20. CK7 is found in tumors of the lung, ovary, endometrium, breast, and upper gastrointestinal tract including pancreaticobiliary cancers, whereas CK20 is normally expressed in the gastrointestinal epithelium, urothelium, and Merkel cells. The nuclear CDX-2 transcription factor, which is the product of a homeobox gene necessary for intestinal organogenesis, is often used to aid in the diagnosis of gastrointestinal adenocarcinomas. However, CDX-2 positivity can be seen with enteric or mucinous differentiation in tumors from diverse primary sites (e.g., mucinous ovarian cancers).

Thyroid transcription factor 1 (TTF-1) nuclear staining is frequently positive in lung and thyroid cancers. Approximately 68% of adenocarcinomas and 25% of squamous cell lung cancers stain positive for TTF-1, which helps differentiate a lung primary tumor from metastatic

TABLE 92-1 Major Histologies in Carcinoma of Unknown Primary

HISTOLOGY	PROPORTION, %
Well to moderately differentiated adenocarcinoma	60
Squamous cell cancer	5
Poorly differentiated adenocarcinoma, poorly differentiated carcinoma	30
Neuroendocrine	2
Undifferentiated malignancy	3

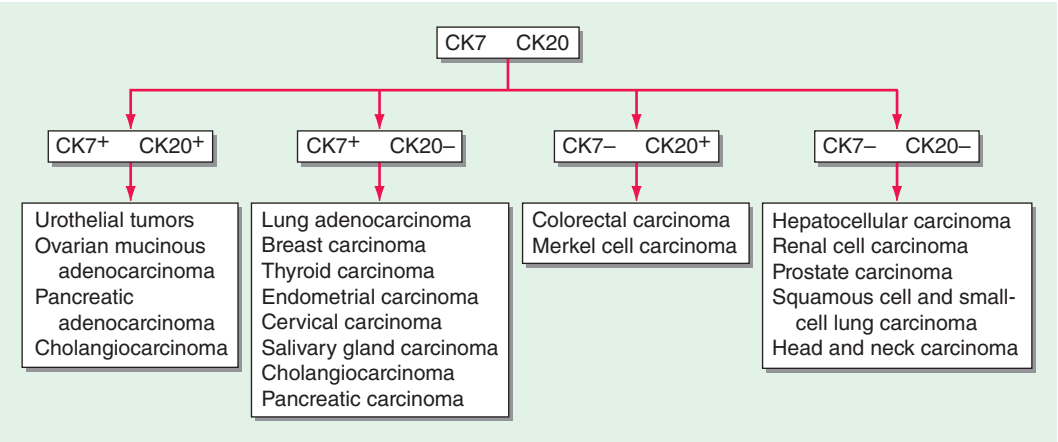

FIGURE 92-1 Approach to cytokeratin (CK7 and CK20) markers used in adenocarcinoma of unknown primary.

adenocarcinoma in a pleural effusion, the mediastinum, or the lung parenchyma.

Gross cystic disease fibrous protein-15 (GCDFP-15), a 15-kDa monomer protein, is a marker of apocrine differentiation that is detected in 62–72% of breast carcinomas. GATA3 is being increasingly used in the CUP setting when there is concern for a breast primary and can be particularly useful as a marker for metastatic breast carcinoma, especially triple-negative and metaplastic carcinomas, which lack specific endocrine markers of mammary origin. UROIII, high-molecular-weight cytokeratin, thrombomodulin, and CK20 are the markers used to diagnose lesions of urothelial origin.

TABLE 92-2 Select Immunohistochemical Stains Useful in the Diagnosis of CUP

LIKELY PRIMARY PROFILE	COMMONLY CONSIDERED IHC TO ASSIST IN DIFFERENTIAL DIAGNOSIS OF CUP[a]
Breast	ER, GCDFP-15, mammaglobin, HER2/neu, GATA3
Ovarian/mullerian	ER, WT1, CK7, PAX8, PAX2
Lung adenocarcinoma	TTF-1; nuclear staining, napsin A, SP-A1
Germ cell	β-hCG, AFP, OCT3/4, CKIT, CD30 (embryonal), SALL4
Prostate	PSA, α-methylacyl CoA racemase/P504S (AMACR/P504S), P501S (prostein), PSMA, NKX3-1
Intestinal	CK7, CK20, CDX-2, CEA
Neuroendocrine	Chromogranin, synaptophysin, CD56
Sarcoma	Desmin (desmoid tumors), factor VIII (angiosarcomas), CD31, smooth muscle actin (leiomyosarcoma), MyoD1 (rhabdomyosarcoma)
Renal	RCC, CD10, PAX8, CD10
Hepatocellular carcinoma	Hep Par-1, Arg-1, glypican-3
Melanoma	S100, SOX-10, vimentin, HMB-45, tyrosinase, melan-A
Urothelial	CK7, CK20, thrombomodulin, uroplakin III
Mesothelioma	Calretinin, WT1, D2-40, mesothelin
Lymphoma	LCA, CD3, CD4, CD5, CD20, CD45
SCC	p63, p40 (lung SCC), CK5/6

[a]Patterns emerging from coexpression of stains are better than individual stains to suggest putative primary site. Even with optimization, no IHC panel is 100% sensitive or specific (e.g., ovarian mucinous carcinoma can exhibit positivity with intestinal markers).

Abbreviations: AFP, α fetoprotein; Arg-1, arginase-1; β-hCG, β-human chorionic gonadotropin; CEA, carcinoembryonic antigen; CUP, carcinoma of unknown primary; ER, estrogen receptor; GCDFP-15, gross cystic disease fibrous protein-15; IHC, immunohistochemistry; LCA, leukocyte common antigen; PSA, prostate-specific antigen; PSMA, prostate-specific membrane antigen; SCC, squamous cell carcinoma; SP-A1, surfactant protein A precursor; TTF, thyroid transcription factor; WT, Wilms' tumor.

IHC performs the best when used in groups that give rise to patterns that are strongly indicative of certain profiles. For example, the TTF-1/CK7+ and CK20+/CDX-2+/CK7– phenotypes have been reported as very suggestive of lung and lower gastrointestinal cancer profiles, respectively. Despite their practical utility, these patterns have not been validated prospectively in CUP patients. IHC is not without its limitations; several factors affect tissue antigenicity (antigen retrieval, specimen processing, and fixation), interpretation of stains in tumor (nuclear, cytoplasmic, membrane) versus normal tissue, inter- and intraobserver variability, variable performance of different antibodies said to recognize the same antigen, and tissue heterogeneity and inadequacy (given small biopsy sizes). Communication with the pathologist is critical to determine if additional tissue will be beneficial in the pathologic evaluation. Pathologic features should not always supersede clinical or radiologic findings when considering testing for biomarkers of therapeutic response (e.g., epidermal growth factor receptor [EGFR], *ALK* mutations, human epidermal growth factor receptor 2 [HER-2]).

Role of Cancer Classifier Molecular Profiling In the absence of a known primary, developing therapeutic strategies for CUP is challenging. The current diagnostic yield with imaging and immunochemistry is ~20–30% for CUP patients. To reduce diagnostic uncertainty, sophisticated molecular analytics have been applied to CUP samples. These include gene expression profiling, messenger RNA (mRNA), microRNA, and epigenetic profiling to classify the CUP cancer.

Gene expression profiles are most commonly generated using quantitative reverse transcriptase polymerase chain reaction (RT-PCR) or DNA microarray. Neural network programs are then used to develop predictive algorithms from the gene expression profiles. Typically, a training set of gene profiles from known cancers (preferably from metastatic sites) is used to train the software. Comprehensive gene expression databases that have become available for common malignancies are then applied to CUP samples, and the program can then be used to predict the putative origin of a CUP sample.

mRNA- or microRNA-based tissue of origin cancer classifier assays have also been studied in prospective and retrospective CUP trials. More recently, a classifier based on microarray DNA methylation signatures has been studied and validated in known cancers. The DNA methylation profiling predicted a primary cancer in 87% of the 216 CUP patients.

Despite the sophistication of the cancer classifier molecular assays, most of the CUP studies have evaluated assay *performance*, although the challenge with validating the accuracy of an assay for CUP is that, by definition, the primary cancer diagnosis cannot be verified. Thus, current estimates of tissue of origin test accuracy have relied on indirect metrics, including comparison with pathology/IHC, clinical presentation, appearance of latent primaries, and autopsies. Using

these measures, the assays suggest a plausible primary in ~70–80% of patients studied. Three outcomes-based studies have been performed. First, a single-arm study reported a median survival of 12.5 months for patients who received assay-directed site-specific therapy. Second, a phase 2 trial of site-specific therapy, including molecularly targeted therapy, based on predicted tumor site from an algorithm using gene expression and alteration profile showed a 1-year survival of 53.1%. However, a randomized clinical trial evaluating site-specific therapy directed by gene expression profiling versus empirical chemotherapy with paclitaxel and carboplatin failed to show a significant improvement in 1-year survival (44% vs 55%, $p = .264$) with this approach. Firm conclusions of therapeutic impact cannot be drawn from these studies given the sample size, design, statistical biases, confounding variables including use of subsequent lines of (empiric) therapy, and heterogeneity of the CUP cancers. Additional studies are needed to better understand the clinical impact of tissue of origin profiling tools and how these assays complement IHC and help guide therapy.

Role of Next-Generation Sequencing A significant push is being made toward personalized medicine across all cancer types with the goal of identifying driver mutation(s) in a patient who can be treated with targeted agents independent of the site of origin. A retrospective study of 200 CUP tumor specimens reported on genomic alterations using the hybrid capture–based FoundationOne assay. The authors reported that a large number of CUP samples (85%) harbored at least one clinically relevant genomic alteration with the potential to influence and personalize therapy. The mean number of genomic alterations was 4.2 per tumor, and the most common genetic alterations included *TP53* (55%), *KRAS* (20%), *CDKN2A* (19%), and *ARID1A* (11%). The adenocarcinoma CUP tumors were more frequently driven by genetic alterations in the receptor tyrosine kinase (RTK)/Ras/mitogen-activated protein kinase (MAPK) signaling pathway than nonadenocarcinoma CUP tumors. Although, druggable genetic lesions seen in CUP are comparable to those in defined large entities, whether molecularly stratified approaches for CUP will successfully improve outcomes remains to be seen and clinical trials are needed. In a single-arm phase 2 study of 97 patients with molecularly targeted therapy, five patients were found to have targetable *EGFR* mutations. Of these, four patients were treated with afatinib, an anti-EGFR drug, and two patients achieved a progression-free survival of >6 months. The emerging role of assays looking for circulating tumor cells, so-called liquid biopsies, within known tumor types has stirred interest in their potential utility in CUP.

Ongoing histology and cellular-context agnostic prospective clinical trials are studying the presence of actionable mutations and matching patients to the right targeted drug. Should this approach eventually be appropriately validated, CUP would be a natural fit for genomic alteration (GA)-based targeted therapy independent of tumor site. Immune checkpoint inhibitors (pembrolizumab) for microsatellite instability high (MSI-H) or deficient mismatch repair (dMMR) tumors and NTRK inhibitors for *NTRK* fusion–positive tumors can help a small minority of CUP patients.

TREATMENT

Carcinoma (or Cancer) of Unknown Primary

GENERAL CONSIDERATIONS

The treatment of CUP continues to evolve, albeit slowly. The median survival of most patients with disseminated CUP is ~6–10 months. Systemic chemotherapy is the primary treatment modality in most patients with disseminated disease, but the careful integration of surgery, radiation therapy, and even periods of observation is important in the overall management of this condition (**Figs. 92-2** and **92-3**). Prognostic factors include performance status, site and number of metastases, response to chemotherapy, and serum lactate dehydrogenase (LDH) levels. Culine and colleagues developed a prognostic model using performance status and serum LDH levels, which allowed the assignment of patients into two subgroups with divergent outcomes. Raghav and colleagues developed a prognostic nomogram to provide individualized survival estimates for patients with CUP based on baseline gender, ECOG performance status, histology, number of metastatic

sites and neutrophil-lymphocyte ratio. Future prospective trials using this prognostic model are warranted. Clinically, some CUP diagnoses fall into a favorable prognostic subset. Others, including those with disseminated CUP, have a more unfavorable prognosis.

TREATMENT OF FAVORABLE CUP SUBSETS

Women with Isolated Axillary Adenopathy Women with isolated axillary adenopathy with adenocarcinoma or carcinoma are usually treated for stage II or III breast cancer based on pathologic findings. These patients should undergo a breast MRI if mammogram and ultrasound are negative. Radiation therapy to the ipsilateral breast is indicated if the MRI of the breast is positive. Chemotherapy and/or hormonal therapy are indicated based on patient's age (premenopausal or postmenopausal), nodal disease bulk, and hormone receptor and HER2 status **(Chap. 79)**. It is important to verify that the pathology suggests a breast cancer profile (morphology, IHC breast markers including estrogen receptor, mammaglobin, GCDFP-15, GATA3, HER-2 gene expression) before embarking on a breast cancer therapeutic program.

Women with Peritoneal Carcinomatosis The term *primary peritoneal papillary serous carcinoma* (PPSC) has been used to describe CUP with carcinomatosis with the pathologic and laboratory (elevated CA-125 antigen) characteristics of ovarian cancer but no ovarian primary tumor identified on transvaginal sonography or laparotomy. Studies suggest that ovarian cancer and PPSC, which are both of müllerian origin, have similar gene expression profiles. Similar to patients with ovarian cancer, patients with PPSC are candidates for cytoreductive surgery, followed by adjuvant taxane- and platinum-based chemotherapy. In one retrospective study of 258 women with peritoneal carcinomatosis who had undergone cytoreductive surgery and chemotherapy, 22% of patients had a complete response to chemotherapy; the median survival duration was 18 months (range 11–24 months). However, not all peritoneal carcinomatosis in women is PPSC. Careful pathologic evaluation can help diagnose a colon cancer profile (CDX-2+, CK20+, CK7−) or a pancreaticobiliary cancer or even a mislabeled peritoneal mesothelioma (calretinin, D2-40 positive; BerEp4, MOC-31 negative).

Poorly Differentiated Carcinoma with Midline Adenopathy (Chap. 88) Men with poorly differentiated or undifferentiated carcinoma who present with midline adenopathy should be evaluated for extragonadal germ cell malignancy. If diagnosed and treated as such, they often experience a good response to treatment with platinum-based combination chemotherapy. Response rates of >50% have been noted, and long-term survival rates of 10–15% have been reported. Older patients, especially smokers, who present with mediastinal adenopathy are more likely to have a lung or head and neck cancer profile.

Neuroendocrine Cancer (Chap. 84) Low-grade neuroendocrine tumor (NET) often has an indolent course, and treatment decisions are based on symptoms and tumor bulk. Urine 5-HIAA and serum chromogranin may be elevated and can be followed as markers. Often the patient is treated with somatostatin analogues alone for hormone-related symptoms (diarrhea, flushing, nausea). Specific local therapies or systemic therapy would only be indicated if the patient is symptomatic with local pain secondary to significant growth of the metastasis or the hormone-related symptoms are not controlled with endocrine therapy. Novel therapy options have demonstrated benefit in patients with low-grade NET, including sunitinib (which targets the vascular endothelial growth factor pathway), everolimus (which inhibits the mammalian target of rapamycin), and lutetium-177 dotatate (a somatostatin peptide receptor radioligand). Patients with high-grade NET are treated with platinum-based doublet therapy; 20–25% show a complete response, and up to 10% patients with limited/oligo presentations survive for >5 years. Some degree of neuroendocrine differentiation can be seen in diverse poorly differentiated carcinomas.

Squamous Cell Carcinoma Presenting as Neck Adenopathy Patients with early-stage squamous cell carcinoma involving the cervical lymph nodes are candidates for node dissection and radiation therapy, which can result in long-term survival. The role of chemotherapy in these patients is undefined, although chemoradiation therapy or induction chemotherapy is often used and is beneficial in bulky N2/N3 lymph node disease.

Solitary Metastatic Sites Patients with solitary metastases can also experience good treatment outcomes. Some patients who present with locoregional disease are candidates for aggressive trimodality (chemotherapy, radiation, and surgery) management—both prolonged disease-free survival and, occasionally, cure are possible.

Men with Blastic Skeletal Metastases and Elevated PSA (Chap. 87) Blastic bone-only metastasis is a rare presentation, and elevated serum PSA or tumor staining with PSA may provide confirmatory evidence of prostate cancer in these patients. Those with elevated levels are candidates for hormonal or other therapy for prostate cancer, although it is important to rule out other primary tumors (lung most common).

MANAGEMENT OF DISSEMINATED CUP

Patients who present with liver, brain, and adrenal metastatic disease usually have a poor prognosis. Patients with peritoneal carcinomatosis secondary to metastatic adenocarcinoma have a broad differential diagnosis, which includes mainly gastrointestinal cancers including gastric, appendiceal, colon, and pancreaticobiliary cancers.

Traditionally, platinum-based combination chemotherapy regimens have been used to treat CUP. Several broadly used regimens have been studied in the past two decades; these include paclitaxel-carboplatin, gemcitabine-cisplatin, gemcitabine-oxaliplatin, and irinotecan and fluoropyrimidine-based therapies. These chemotherapeutic agents used as empiric regimens have shown response rates of 25–40%, and their use obtains median survival times of 6–13 months.

Outside of favorable subsets, there is a small group of patients with a "definitive" IHC profile. These patients usually have a single diagnosis based on their clinicopathologic presentation and are often treated for the putative primary tumor. This does not guarantee a response, although it increases the probability of response when select drugs are chosen from a class of drugs known to be effective in that cancer type. Efforts should be made to search for biomarkers of response to tumor-agnostic effective therapies such as immunotherapy for MSI-H/dMMR tumors. Patients who do not fall into those categories are candidates for broad-spectrum platinum-based regimens, clinical trials, and additional trial-based genomic and proteomic tests. Today, we do not have many effective drugs for several CUP cancer profiles, and treatments overlap for some cancers. Immunotherapy has been an area of active interest due to robust and durable responses in cancers with known primaries and has shown some activity in CUP. However, biomarkers of response and immune-sensitive subsets need to be defined within CUP.

SUMMARY

Patients with CUP should undergo a directed diagnostic search for the primary tumor on the basis of clinical and pathologic data. Subsets of patients have prognostically favorable disease, as defined by clinical or histologic criteria, and may substantially benefit from aggressive treatment; in these patients, prolonged survival can be expected. However, for most patients who present with advanced CUP, the prognosis remains poor with early resistance to available cytotoxic therapy. The current focus has shifted away from empirical chemotherapeutic trials to understanding the metastatic phenotype, tissue of origin profiling in select patients, and next-generation sequencing to identify actionable mutations in CUP patients. As novel therapies evolve in cancers with known primaries, investigations to assess their value in CUP will likely have an impact on management of CUP patients.

93 Paraneoplastic Syndromes: Endocrinologic/Hematologic

J. Larry Jameson, Dan L. Longo

Neoplastic cells can produce a variety of substances that can alter the physiology of hormonal, hematologic, dermatologic, rheumatologic, renal, and neurologic systems. *Paraneoplastic syndromes* refer to the disorders that accompany benign or malignant tumors but are not directly related to mass effects or invasion. Tumors of neuroendocrine origin, such as small-cell lung carcinoma (SCLC) and carcinoids are common causes of paraneoplastic syndromes, but they have been associated with many types of tumors that produce peptide hormones, cytokines, and growth factors and induce the production of antibodies. Studies of the prevalence of paraneoplastic syndromes indicate that they are more common than is generally appreciated. The signs, symptoms, and metabolic alterations associated with paraneoplastic disorders are easily overlooked in the context of a malignancy and its treatment. Consequently, atypical clinical manifestations in a patient with cancer should prompt consideration of a paraneoplastic syndrome. The most common hormonal and hematologic syndromes associated with underlying neoplasia will be discussed here.

ENDOCRINE PARANEOPLASTIC SYNDROMES

Etiology Hormones can be produced from eutopic or ectopic sources. *Eutopic* refers to the expression of a hormone from its normal tissue of origin, whereas *ectopic* refers to hormone production from an atypical tissue source. For example, adrenocorticotropic hormone (ACTH) is expressed eutopically by the corticotrope cells of the anterior pituitary, but it can be expressed ectopically in SCLC. Many hormones are produced at low levels from tissues other than the classic endocrine source. Thus, ectopic expression is often a quantitative change rather than an absolute change in tissue expression. Nevertheless, the term *ectopic expression* is firmly entrenched and conveys the abnormal physiology associated with hormone production by neoplastic cells. In addition to high levels of hormones, ectopic expression is often characterized by abnormal regulation of hormone production (e.g., defective feedback control in ectopic ACTH) and peptide processing (resulting in large, unprocessed precursor peptide such as proopiomelanocortin [POMC]).

Many different molecular mechanisms can cause ectopic hormone production. In rare instances, genetic rearrangements account for aberrant hormone expression. For example, translocation of the parathyroid hormone (*PTH*) gene can result in high levels of PTH expression in tissues other than the parathyroid gland because the genetic rearrangement brings the *PTH* gene under the control of atypical regulatory elements. A related phenomenon is well documented in many forms of leukemia and lymphoma, in which somatic genetic rearrangements confer a growth advantage and alter cellular differentiation and function. Although genetic rearrangements cause selected cases of ectopic hormone production, this mechanism is rare, as many tumors are associated with excessive production of numerous peptides. Cellular dedifferentiation probably underlies most cases of ectopic hormone production. Many cancers are poorly differentiated, and certain tumor products, such as human chorionic gonadotropin (hCG), PTH–related protein (PTHrP), and α fetoprotein, are characteristic of gene expression at earlier developmental stages. In contrast, the propensity of certain cancers to produce particular hormones (e.g., squamous cell carcinomas produce PTHrP) suggests that dedifferentiation is partial or that selective pathways are derepressed. These expression profiles probably reflect epigenetic modifications that alter transcriptional

repression, microRNA expression, and other pathways that govern cell differentiation.

In SCLC, the pathway of differentiation has been relatively well defined. The neuroendocrine phenotype is dictated in part by the basic-helix-loop-helix (bHLH) transcription factor human achaete-scute homologue 1 (hASH1), which is expressed at abnormally high levels in SCLC associated with ectopic ACTH. The abnormal expression of hASH1 and other developmental transcription factors appears to provide a link between cell proliferation and differentiation.

Ectopic hormone production might be considered merely epiphenomenon associated with cancer if it did not cause clinical manifestations. Excessive and unregulated production of hormones such as ACTH, PTHrP, and vasopressin can lead to substantial morbidity and complicate the cancer treatment plan. Moreover, the paraneoplastic endocrinopathies may be a presenting clinical feature of underlying malignancy and prompt the search for an unrecognized tumor.

A large number of paraneoplastic endocrine syndromes have been described, linking overproduction of particular hormones with specific types of tumors. However, certain recurring syndromes emerge from this group **(Table 93-1)**. The most common paraneoplastic endocrine syndromes include hypercalcemia from overproduction of PTHrP and other factors, hyponatremia from excess vasopressin, and Cushing's syndrome from ectopic ACTH.

HYPERCALCEMIA CAUSED BY ECTOPIC PRODUCTION OF PTHRP

(See also **Chap. 410**)

Etiology Humoral hypercalcemia of malignancy (HHM) occurs in up to 20% of patients with cancer. HHM is most common in cancers of the lung, head and neck, skin, esophagus, breast, and genitourinary tract and in multiple myeloma and lymphomas, as well as metastases associated with these, and other cancers. There are several distinct humoral causes of HHM, but it is caused most commonly by overproduction of PTHrP. In addition to acting as a circulating humoral factor, bone metastases (e.g., breast, multiple myeloma) may produce PTHrP and other chemokines, leading to local osteolysis and hypercalcemia. PTHrP may also affect the initiation and progression of tumors by acting through pro-survival and chemokine pathways.

PTHrP is structurally related to PTH and binds to the PTH receptor, explaining the similar biochemical features of HHM and hyperparathyroidism. PTHrP plays a key physiologic role in skeletal development and regulates cellular proliferation and differentiation in other tissues, including skin, bone marrow, breast, and hair follicles. The mechanism of PTHrP induction in malignancy is incompletely understood; however, tumor-bearing tissues commonly associated with HHM normally produce PTHrP during development or cell renewal. PTHrP expression is stimulated by hedgehog pathways and Gli transcription factors that are active in many malignancies. Transforming growth factor β (TGF-β), which is produced by many tumors, also stimulates PTHrP. Mutations in certain oncogenes, such as *Ras*, also can activate PTHrP expression, as does loss of the tumor suppressor, p53. In addition to its role in HHM, the PTHrP pathway may also provide a potential target for therapeutic intervention to impede cancer growth.

TABLE 93-1 Paraneoplastic Syndromes Caused by Ectopic Hormone Production

PARANEOPLASTIC SYNDROME	ECTOPIC HORMONE	TYPICAL TUMOR TYPES[a]
Common		
Hypercalcemia of malignancy	Parathyroid hormone–related protein (PTHrP)	Squamous cell (head and neck, lung, skin), breast, genitourinary, gastrointestinal; osteolytic metastases
	1,25-Dihydroxyvitamin D	Lymphomas
	Parathyroid hormone (PTH) (rare)	Lung, ovary
	Prostaglandin E_2 (PGE_2) (rare)	Renal, lung
Syndrome of inappropriate antidiuretic hormone secretion (SIADH)	Vasopressin	Lung (squamous, small cell), gastrointestinal, genitourinary, ovary
Cushing's syndrome	Adrenocorticotropic hormone (ACTH)	Lung (small cell, bronchial carcinoid, adenocarcinoma, squamous), thymus, pancreatic islet, medullary thyroid carcinoma, pheochromocytoma
	Corticotropin-releasing hormone (CRH) (rare)	Pancreatic islet, carcinoid, lung, prostate
	Ectopic expression of gastric inhibitory peptide (GIP), luteinizing hormone (LH)/human chorionic gonadotropin (hCG), other G protein–coupled receptors (rare)	Macronodular adrenal hyperplasia
Less Common		
Non–islet cell hypoglycemia	Insulin-like growth factor type II (IGF-II)	Mesenchymal tumors, sarcomas, adrenal, hepatic, gastrointestinal, kidney, prostate
	Insulin (rare)	Cervix (small-cell carcinoma)
Male feminization	hCG[b]	Testis (embryonal, seminomas), germinomas, choriocarcinoma, lung, hepatic, pancreatic islet
Diarrhea or intestinal hypermotility	Calcitonin[c]	Lung, colon, breast, medullary thyroid carcinoma
	Vasoactive intestinal peptide (VIP)	Pancreas, pheochromocytoma, esophagus
Rare		
Oncogenic osteomalacia	Fibroblast growth factor 23 (FGF23) or phosphatonin	Hemangiopericytomas, osteoblastomas, fibromas, sarcomas, giant cell tumors, prostate, lung
Acromegaly	Growth hormone–releasing hormone (GHRH)	Pancreatic islet, bronchial, and other carcinoids
	Growth hormone (GH)	Lung, pancreatic islet
Hyperthyroidism	Thyroid-stimulating hormone (TSH)	Hydatidiform mole, embryonal tumors, struma ovarii
Hypertension	Renin	Juxtaglomerular tumors, kidney, lung, pancreas, ovary
Consumptive hypothyroidism	Type 3 deiodinase	Hepatic and other hemangiomas

[a]Only the most common tumor types are listed. For most ectopic hormone syndromes, an extensive list of tumors has been reported to produce one or more hormones. [b]hCG is produced eutopically by trophoblastic tumors. Certain tumors produce disproportionate amounts of the hCG α or hCG β subunit. High levels of hCG rarely cause hyperthyroidism because of weak binding to the TSH receptor. [c]Calcitonin is produced eutopically by medullary thyroid carcinoma and is used as a tumor marker.

Another relatively common cause of HHM is excess production of 1,25-dihydroxyvitamin D. Like granulomatous disorders associated with hypercalcemia, lymphomas can produce an enzyme that converts 25-hydroxyvitamin D to the more active 1,25-dihydroxyvitamin D, leading to enhanced gastrointestinal calcium absorption. Other causes of HHM include tumor-mediated production of osteolytic cytokines and inflammatory mediators.

Clinical Manifestations The typical presentation of HHM is a patient with a known malignancy who is found to be hypercalcemic on routine laboratory tests. Less often, hypercalcemia is the initial presenting feature of malignancy. Particularly when calcium levels are markedly increased (>3.5 mmol/L [>14 mg/dL]), patients may experience fatigue, mental status changes, polyuria, dehydration, or symptoms of nephrolithiasis. Hypercalcemia can shorten ST segments and QT intervals, as well as bundle branch blocks and bradyarrhythmias.

Diagnosis Features that favor HHM, as opposed to primary hyperparathyroidism, include known malignancy, recent onset of hypercalcemia, and very high serum calcium levels. Like hyperparathyroidism, hypercalcemia caused by PTHrP is accompanied by hypercalciuria and hypophosphatemia. Patients with HHM typically have metabolic alkalosis rather than hyperchloremic acidosis, as is seen in hyperparathyroidism. Measurement of PTH is useful to exclude primary hyperparathyroidism; the PTH level should be suppressed in HHM. An elevated PTHrP level confirms the diagnosis, and it is increased in ~80% of hypercalcemic patients with cancer. 1,25-Dihydroxyvitamin D levels may be increased in patients with lymphoma.

TREATMENT

Humoral Hypercalcemia of Malignancy

The management of HHM begins with removal of excess calcium in the diet, medications, or IV solutions. Saline rehydration (typically 200–500 mL/h) is used to dilute serum calcium and promote calciuresis; exercise caution in patients with cardiac, hepatic, or renal insufficiency. Forced diuresis with furosemide (20–80 mg IV in escalating doses) or other loop diuretics can enhance calcium excretion but provides relatively little value except in life-threatening hypercalcemia. When used, loop diuretics should be administered only after complete rehydration and with careful monitoring of fluid balance. Oral phosphorus (e.g., 250 mg Neutra-Phos 3–4 times daily) should be given until serum phosphorus is >1 mmol/L (>3 mg/dL). Bisphosphonates such as pamidronate (60–90 mg IV), zoledronate (4–8 mg IV), and etidronate (7.5 mg/kg per day PO for 3–7 consecutive days) can reduce serum calcium within 1–2 days and suppress calcium release for several weeks. Bisphosphonate infusions can be repeated, or oral bisphosphonates can be used for chronic treatment. Denosumab (120 mg SC weekly for 4 weeks and then monthly) can be used in patients who do not respond adequately to bisphosphonates. It acts as a decoy receptor for RANK ligand to mitigate stimulation of osteoclasts. Cinacalcet (30 mg PO bid to 90 mg PO qid) stimulates calcium-sensing receptors to suppress PTH secretion and is therefore applicable in parathyroid carcinoma and rare cases of ectopic PTH-producing tumors. Hypercalcemia associated with lymphomas, multiple myeloma, or leukemia may respond to glucocorticoid treatment (e.g., prednisone 40–100 mg PO in four divided doses). Dialysis should be considered in severe hypercalcemia when saline hydration and bisphosphonate treatments are not possible or are too slow in onset. Previously used agents such as calcitonin and mithramycin have little utility now that bisphosphonates and other agents are available.

ECTOPIC VASOPRESSIN: TUMOR-ASSOCIATED SYNDROME OF INAPPROPRIATE ANTIDIURETIC HORMONE

(See also Chap. 53)

Etiology Vasopressin is an antidiuretic hormone normally produced by the posterior pituitary gland. Ectopic vasopressin production by tumors is a common cause of the syndrome of inappropriate antidiuretic hormone (SIADH), occurring in at least half of patients with SCLC. SIADH also can be caused by a number of nonneoplastic conditions, including central nervous system (CNS) trauma, infections, and medications (Chap. 381). Compensatory responses to SIADH, such as decreased thirst, may mitigate the development of hyponatremia. However, with prolonged production of excessive vasopressin, the osmostat controlling thirst and hypothalamic vasopressin secretion may become reset. In addition, intake of free water, orally or intravenously, can quickly worsen hyponatremia because of reduced renal diuresis.

Tumors with neuroendocrine features, such as SCLC and carcinoids, are the most common sources of ectopic vasopressin production, but it also occurs in other forms of lung cancer and with CNS lesions, head and neck cancer, and genitourinary, gastrointestinal, and ovarian cancers. The mechanism of activation of the vasopressin gene in these tumors is unknown, but the frequent concomitant expression of the adjacent oxytocin gene suggests derepression of this locus.

Clinical Manifestations Most patients with ectopic vasopressin secretion are asymptomatic and are identified because of the presence of hyponatremia on routine chemistry testing. Symptoms may include weakness, lethargy, nausea, confusion, depressed mental status, and seizures. The severity of symptoms reflects the rapidity of onset as well as the severity of hyponatremia. Hyponatremia usually develops slowly but may be exacerbated by the administration of IV fluids or the institution of new medications.

Diagnosis The diagnostic features of ectopic vasopressin production are the same as those of other causes of SIADH (Chaps. 53 and 381). Hyponatremia and reduced serum osmolality occur in the setting of an inappropriately normal or increased urine osmolality. Urine sodium excretion is normal or increased unless volume depletion is present. Other causes of hyponatremia should be excluded, including renal, adrenal, or thyroid insufficiency. Physiologic sources of vasopressin stimulation (CNS lesions, pulmonary disease, nausea), adaptive circulatory mechanisms (hypotension, heart failure, hepatic cirrhosis), and medications, including many chemotherapeutic agents, also should be considered as possible causes of hyponatremia. Vasopressin measurements are not usually necessary to make the diagnosis.

TREATMENT

Ectopic Vasopressin: Tumor-Associated SIADH

Most patients with ectopic vasopressin production develop hyponatremia over several weeks or months. The disorder should be corrected gradually unless mental status is altered or there is risk of seizures. Rapid correction can cause brain dehydration and central pontine myelinolysis. Treatment of the underlying malignancy may reduce ectopic vasopressin production, but this response is slow if it occurs at all. Fluid restriction to less than urine output, plus insensible losses, is often sufficient to correct hyponatremia partially. However, strict monitoring of the amount and types of liquids consumed or administered intravenously is required for fluid restriction to be effective. Salt tablets and saline are not helpful unless volume depletion is also present. Demeclocycline (150–300 mg orally 3–4 times daily) can be used to inhibit vasopressin action on the renal distal tubule, but its onset of action is relatively slow (1–2 weeks). The vaptan class of drugs acts by inhibiting vasopressin receptors (V_{1A}, V_{1B}, V_2) in the renal collecting ducts. Conivaptan, a nonpeptide V_2-receptor antagonist, can be administered either PO (20–120 mg bid) or IV (10–40 mg) and is particularly effective when used in combination with fluid restriction in euvolemic hyponatremia. Tolvaptan (15 mg PO daily) is another vasopressin antagonist. The dose can be increased to 30–60 mg/d based on response. Severe hyponatremia (Na <115 meq/L) or mental status changes may require treatment with hypertonic (3%) or normal saline infusion together with furosemide to enhance free water clearance. The rate of sodium

correction should be slow (0.5–1 meq/L per hour) to prevent rapid fluid shifts and the possible development of central pontine myelinolysis.

CUSHING'S SYNDROME CAUSED BY ECTOPIC ACTH PRODUCTION

(See also **Chap. 386**)

Etiology Ectopic ACTH production accounts for 10–20% of cases of Cushing's syndrome. The syndrome is particularly common in neuroendocrine tumors. SCLC is the most common cause of ectopic ACTH, followed by bronchial and thymic carcinoids, islet cell tumors, other carcinoids, and pheochromocytomas. Ectopic ACTH production is caused by increased expression of the proopiomelanocortin (*POMC*) gene, which encodes ACTH, along with melanocyte-stimulating hormone (MSH), β lipotropin, and several other peptides. In many tumors, there is abundant but aberrant expression of the *POMC* gene from an internal promoter, proximal to the third exon, which encodes ACTH. However, because this product lacks the signal sequence necessary for protein processing, it is not secreted. Increased production of ACTH arises instead from less abundant, but unregulated, *POMC* expression from the same promoter site used in the pituitary. Because tumors lack many of the enzymes needed to process the POMC polypeptide, it is typically released as multiple large, biologically inactive fragments along with relatively small amounts of fully processed, active ACTH.

Rarely, corticotropin-releasing hormone (CRH) is produced by pancreatic islet cell tumors, SCLC, medullary thyroid cancer, carcinoids, or prostate cancer. When levels are high enough, CRH can cause pituitary corticotrope hyperplasia and Cushing's syndrome. Tumors that produce CRH sometimes also produce ACTH, raising the possibility of a paracrine mechanism for ACTH production.

A distinct mechanism for ACTH-independent Cushing's syndrome involves ectopic expression of various G protein–coupled receptors in adrenal nodules. Ectopic expression of the gastric inhibitory peptide (GIP) receptor is the best-characterized example of this mechanism. In this case, meals induce GIP secretion, which inappropriately stimulates adrenal growth and glucocorticoid production.

Clinical Manifestations The clinical features of hypercortisolemia are detected in only a fraction of patients with documented ectopic ACTH production. Patients with ectopic ACTH syndrome generally exhibit less marked weight gain and centripetal fat redistribution, probably because the exposure to excess glucocorticoids is relatively brief and because cachexia reduces the propensity for weight gain and fat deposition. The ectopic ACTH syndrome is associated with several clinical features that distinguish it from other causes of Cushing's syndrome (e.g., pituitary adenomas, adrenal adenomas, iatrogenic glucocorticoid excess). The metabolic manifestations of ectopic ACTH syndrome are dominated by fluid retention and hypertension, hypokalemia, metabolic alkalosis, glucose intolerance, and occasionally steroid psychosis. The very high ACTH levels often cause increased pigmentation, reflecting increased activity of MSH derived from the POMC precursor peptide. The extraordinarily high glucocorticoid levels in patients with ectopic sources of ACTH can lead to marked skin fragility and easy bruising. In addition, the high cortisol levels often overwhelm the renal 11β-hydroxysteroid dehydrogenase type II enzyme, which normally inactivates cortisol and prevents it from binding to renal mineralocorticoid receptors. Consequently, in addition to the excess mineralocorticoids produced by ACTH stimulation of the adrenal gland, high levels of cortisol exert activity through the mineralocorticoid receptor, leading to severe hypokalemia.

Diagnosis The diagnosis of ectopic ACTH syndrome is usually not difficult in the setting of a known malignancy. Urine-free cortisol levels fluctuate but are typically greater than two to four times normal, and the plasma ACTH level is usually >22 pmol/L (>100 pg/mL). A suppressed ACTH level excludes this diagnosis and indicates an ACTH-independent cause of Cushing's syndrome (e.g., adrenal or exogenous glucocorticoid). In contrast to pituitary sources of ACTH, most ectopic sources of ACTH do not respond to glucocorticoid suppression. Therefore, high-dose dexamethasone (8 mg PO) suppresses 8:00 A.M. serum cortisol (50% decrease from baseline) in ~80% of pituitary ACTH-producing adenomas but fails to suppress ectopic ACTH in ~90% of cases. Bronchial and other carcinoids are well-documented exceptions to these general guidelines, as these ectopic sources of ACTH may exhibit feedback regulation indistinguishable from pituitary adenomas, including suppression by high-dose dexamethasone, and ACTH responsiveness to adrenal blockade with metyrapone. If necessary, petrosal sinus catheterization can be used to evaluate a patient with ACTH-dependent Cushing's syndrome when the source of ACTH is unclear. After CRH stimulation, a 3:1 petrosal sinus:peripheral ACTH ratio strongly suggests a pituitary ACTH source. Imaging studies (computed tomography or magnetic resonance imaging) are also useful in the evaluation of suspected carcinoid lesions, allowing biopsy and characterization of hormone production using special stains. If available, positron emission tomography or octreotide scanning may identify some sources of ACTH production.

TREATMENT

Cushing's Syndrome Caused by Ectopic ACTH Production

The morbidity associated with the ectopic ACTH syndrome can be substantial. Patients may experience depression or personality changes because of extreme cortisol excess. Metabolic derangements, including diabetes mellitus and hypokalemia, can worsen fatigue. Poor wound healing and predisposition to infections can complicate the surgical management of tumors, and opportunistic infections caused by organisms such as *Pneumocystis carinii* and mycoses are often the cause of death in patients with ectopic ACTH production. These patients have increased risk of venous thromboembolism reflecting the combination of malignancy and altered coagulation factor profiles. Depending on prognosis and treatment plans for the underlying malignancy, measures to reduce cortisol levels are often indicated. Treatment of the underlying malignancy may reduce ACTH levels but is rarely sufficient to reduce cortisol levels to normal. Adrenalectomy is not practical for most of these patients but should be considered during surgery for the malignancy or if the underlying tumor is not resectable and the prognosis is otherwise favorable (e.g., carcinoid). Medical therapy with ketoconazole (300–600 mg PO bid), metyrapone (250–500 mg PO every 6 h), mitotane (3–6 g PO in four divided doses, tapered to maintain low cortisol production), etomidate (0.1–0.3 mg/kg/h IV), or other agents that block steroid synthesis or action is often the most practical strategy for managing the hypercortisolism associated with ectopic ACTH production. Glucocorticoid replacement should be provided to prevent adrenal insufficiency **(Chap. 386)**. Unfortunately, many patients eventually progress despite medical blockade. Mifepristone (200–1000 mg PO qd) inhibits both glucocorticoid and progesterone receptors, has rapid onset of action, and improves glucose intolerance and hypertension in a subset of patients. ACTH-neutralizing antibodies and ACTH receptor blockers are under investigation, as are selective inhibitors of the glucocorticoid receptor.

TUMOR-INDUCED HYPOGLYCEMIA CAUSED BY EXCESS PRODUCTION OF INSULIN-LIKE GROWTH FACTOR TYPE II

(See also **Chap. 406**) Mesenchymal tumors, hemangiopericytomas, hepatocellular tumors, adrenal carcinomas, and a variety of other large tumors have been reported to produce excessive amounts of insulin-like growth factor type II (IGF-II) precursor, which binds weakly to insulin receptors and more strongly to IGF-I receptors, leading to insulin-like actions. The gene encoding IGF-II resides on chromosome 11p15, a locus that is normally imprinted (that is, expression

is exclusively from a single parental allele). Biallelic expression of the IGF-II gene occurs in a subset of tumors, suggesting loss of methylation and loss of imprinting as a mechanism for gene induction. In addition to increased IGF-II production, IGF-II bioavailability is increased due to complex alterations in circulating binding proteins. Increased IGF-II suppresses growth hormone (GH) and insulin, resulting in reduced IGF binding protein 3 (IGFBP-3), IGF-I, and acid-labile subunit (ALS). The reduction in ALS and IGFBP-3, which normally sequester IGF-II, causes it to be displaced to a small circulating complex that has greater access to insulin target tissues. For this reason, circulating IGF-II levels may not be markedly increased despite causing hypoglycemia. In addition to IGF-II–mediated hypoglycemia, tumors may occupy enough of the liver to impair gluconeogenesis.

In most cases, a tumor causing hypoglycemia is clinically apparent (usually >10 cm in size), and hypoglycemia develops in association with fasting. As with other causes of hypoglycemia, patients may present with sweating, tremors, palpitations, confusion, seizures, or coma. The diagnosis is made by documenting low serum glucose and suppressed insulin levels in association with symptoms of hypoglycemia. Serum IGF-II levels may not be increased (IGF-II assays may not detect IGF-II precursors), but an elevated IGF-II/IGF-I ratio greater than 10:1 is suggestive. Increased IGF-II mRNA expression is found in most of these tumors. Any medications associated with hypoglycemia should be eliminated. Treatment of the underlying malignancy, if possible, may reduce the predisposition to hypoglycemia. Frequent meals and IV glucose, especially during sleep or fasting, are often necessary to prevent hypoglycemia. Glucagon and glucocorticoids have also been used to enhance glucose production. Antibodies that inhibit IGF-II action are under development.

HUMAN CHORIONIC GONADOTROPIN

hCG is composed of α and β subunits and can be produced as intact hormone, which is biologically active, or as uncombined biologically inert subunits. Ectopic production of intact hCG occurs most often in association with testicular embryonal tumors, germ cell tumors, extragonadal germinomas, lung cancer, hepatoma, and pancreatic islet tumors. Eutopic production of hCG occurs with trophoblastic malignancies. hCG α subunit production is particularly common in lung cancer and pancreatic islet cancer. In men, high hCG levels stimulate steroidogenesis and aromatase activity in testicular Leydig cells, resulting in increased estrogen production and the development of gynecomastia. Precocious puberty in boys or gynecomastia in men should prompt measurement of hCG and consideration of a testicular tumor or another source of ectopic hCG production. Most women are asymptomatic. hCG is easily measured. Treatment should be directed at the underlying malignancy.

ONCOGENIC OSTEOMALACIA

Hypophosphatemic oncogenic osteomalacia, also called tumor-induced osteomalacia (TIO), is caused by excessive production of fibroblast growth factor 23 (FGF23), previously referred to as phosphotonin. Oncogenic osteomalacia is characterized by markedly reduced serum phosphorus and renal phosphate wasting, leading to muscle weakness, bone pain, and osteomalacia. Serum calcium and PTH levels are normal. FGF23 inhibits the renal conversion of 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D, resulting in low levels of 1,25-dihydroxyvitamin D. Oncogenic osteomalacia is usually caused by benign mesenchymal tumors, such as hemangiopericytomas, fibromas, and giant cell tumors, often of the skeletal extremities or head. It has also been described in sarcomas and in patients with prostate or lung cancer. Resection of the tumor reverses the disorder, confirming its humoral basis. FGF23 levels are increased in some, but not all, patients with osteogenic osteomalacia. FGF23 forms a ternary complex with the klotho protein and renal FGF receptors to reduce renal phosphate reabsorption. Treatment involves removal of the tumor, if possible, and supplementation with phosphate and vitamin D. Octreotide treatment reduces phosphate wasting in some patients with tumors that express somatostatin receptor subtype 2. Octreotide scans may also be useful in detecting these tumors. The calcium-sensing receptor agonist, cinacalcet, has been effective in some patients, apparently by reducing PTH-mediated phosphaturia. FGF receptor inhibitors hold promise as future therapies targeted either to pathways that stimulate FGR23 production (e.g., FGFR1) or inhibit its action (e.g., FGF23 receptor).

CONSUMPTIVE HYPOTHYROIDISM

Newborns with hepatic hemangiomas can develop a rare form of hypothyroidism caused by overexpression of type 3 deiodinase (D3), an enzyme that degrades and inactivates thyroxine (T_4) and triiodothyronine (T_3). The very high expression of D3 and consumption of thyroid hormones apparently outstrip the thyroid gland's rate of hormone production. The disorder is characterized by low T_4, low T_3, high TSH, and markedly elevated reverse T_3 (rT_3), reflecting the degradation of T_4 to rT_3. In addition to treating the underlying hemangioma (rarely other tumor types), patients are treated with L-thyroxine replacement, titrated to normalize TSH. Steroids and propranolol may provide benefit, perhaps by inhibiting growth factor pathways thought to stimulate D3 production.

HEMATOLOGIC SYNDROMES

The elevation of granulocyte, platelet, and eosinophil counts in most patients with myeloproliferative disorders is caused by the proliferation of the myeloid elements due to the underlying disease rather than to a paraneoplastic syndrome. The paraneoplastic hematologic syndromes in patients with solid tumors are less well characterized than are the endocrine syndromes because the ectopic hormone(s) or cytokines responsible have not been identified in most of these tumors (Table 93-2). The extent of the paraneoplastic syndromes parallels the course of the cancer. With very rare exception, red cell, white cell or platelet numbers are self-limited and not associated with symptomatic abnormalities. In some circumstances, elevations in platelet counts can be a marker that influences prognosis. By far, the most consequential hematologic abnormality in cancer patients is hypercoagulability.

ERYTHROCYTOSIS

Ectopic production of erythropoietin by cancer cells causes most paraneoplastic erythrocytosis. The ectopically produced erythropoietin stimulates the production of red blood cells (RBCs) in the bone marrow and raises the hematocrit. Other lymphokines and hormones produced by cancer cells may stimulate erythropoietin release but have not been proved to cause erythrocytosis.

Most patients with erythrocytosis have an elevated hematocrit (>52% in men, >48% in women) that is detected on a routine blood

TABLE 93-2 Paraneoplastic Hematologic Syndromes

SYNDROME	PROTEINS	CANCERS TYPICALLY ASSOCIATED WITH SYNDROME
Erythrocytosis	Erythropoietin	Renal cancers, hepatocarcinoma, cerebellar hemangioblastomas
Granulocytosis	G-CSF, GM-CSF, IL-6	Lung cancer, gastrointestinal cancer, ovarian cancer, genitourinary cancer, Hodgkin's disease
Thrombocytosis	IL-6	Lung cancer, gastrointestinal cancer, breast cancer, ovarian cancer, lymphoma
Eosinophilia	IL-5	Lymphoma, leukemia, lung cancer
Thrombophlebitis	Unknown	Lung cancer, pancreatic cancer, gastrointestinal cancer, breast cancer, genitourinary cancer, ovarian cancer, prostate cancer, lymphoma

Abbreviations: G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; IL, interleukin.

count. Approximately 3% of patients with renal cell cancer, 10% of patients with hepatoma, and 15% of patients with cerebellar hemangioblastomas have erythrocytosis. In most cases, the erythrocytosis is asymptomatic.

Patients with erythrocytosis due to a renal cell cancer, hepatoma, or CNS cancer should have measurement of red cell mass. If the red cell mass is elevated, the serum erythropoietin level should be measured. Patients with a cancer that has been associated with erythrocytosis, elevated erythropoietin levels, and no other explanation for erythrocytosis (e.g., hemoglobinopathy that causes increased O_2 affinity; **Chaps. 63** and **98**) have the paraneoplastic syndrome.

TREATMENT

Erythrocytosis

Successful resection of the cancer usually resolves the erythrocytosis. If the tumor cannot be resected or treated effectively with radiation therapy or chemotherapy, phlebotomy may control any symptoms or risk related to erythrocytosis.

GRANULOCYTOSIS

Approximately 30% of patients with solid tumors have granulocytosis (granulocyte count >8000/μL). In about half of patients with granulocytosis and cancer, the granulocytosis has an identifiable nonparaneoplastic etiology (e.g., infection, tumor necrosis, glucocorticoid administration). The other patients have proteins in urine and serum that stimulate the growth of bone marrow cells. Tumors and tumor cell lines from patients with lung, ovarian, and bladder cancers have been documented to produce granulocyte colony-stimulating factor (G-CSF), granulocyte-macrophage colony-stimulating factor (GM-CSF), and/or interleukin 6 (IL-6). However, the etiology of granulocytosis has not been characterized in most patients.

Patients with granulocytosis are nearly all asymptomatic, and the differential white blood cell count does not have a shift to immature forms of neutrophils. Granulocytosis occurs in 40% of patients with lung and gastrointestinal cancers, 20% of patients with breast cancer, 30% of patients with brain tumors and ovarian cancers, 20% of patients with Hodgkin's disease, and 10% of patients with renal cell carcinoma. Patients with advanced-stage disease are more likely to have granulocytosis than are those with early-stage disease.

Paraneoplastic granulocytosis does not require treatment. The granulocytosis resolves when the underlying cancer is treated.

THROMBOCYTOSIS

Some 35% of patients with thrombocytosis (platelet count >400,000/μL) have an underlying diagnosis of cancer. IL-6, a candidate molecule for the etiology of paraneoplastic thrombocytosis, stimulates the production of platelets in vitro and in vivo. Some patients with cancer and thrombocytosis have elevated levels of IL-6 in plasma. Another candidate molecule is thrombopoietin, a peptide hormone that stimulates megakaryocyte proliferation and platelet production. The etiology of thrombocytosis has not been established in most cases.

Patients with thrombocytosis are nearly all asymptomatic. Thrombocytosis is not clearly linked to thrombosis in patients with cancer. Thrombocytosis is present in 40% of patients with lung and gastrointestinal cancers; 20% of patients with breast, endometrial, and ovarian cancers; and 10% of patients with lymphoma. Patients with thrombocytosis are more likely to have advanced-stage disease and have a poorer prognosis than do patients without thrombocytosis. In ovarian cancer, IL-6 has been shown to directly promote tumor growth. Paraneoplastic thrombocytosis does not require treatment other than treatment of the underlying tumor.

EOSINOPHILIA

Eosinophilia is present in ~1% of patients with cancer. Tumors and tumor cell lines from patients with lymphomas or leukemia may produce IL-5, which stimulates eosinophil growth. Activation of IL-5 transcription in lymphomas and leukemias may involve translocation of the long arm of chromosome 5, to which the genes for IL-5 and other cytokines map.

Patients with eosinophilia are typically asymptomatic. Eosinophilia is present in 10% of patients with lymphoma, 3% of patients with lung cancer, and occasional patients with cervical, gastrointestinal, renal, and breast cancer. Patients with markedly elevated eosinophil counts (>5000/μL) can develop shortness of breath and wheezing. A chest radiograph may reveal diffuse pulmonary infiltrates from eosinophil infiltration and activation in the lungs.

TREATMENT

Eosinophilia

Definitive treatment is directed at the underlying malignancy. Tumors should be resected or treated with radiation or chemotherapy. In most patients who develop shortness of breath related to eosinophilia, symptoms resolve with the use of oral or inhaled glucocorticoids. IL-5 antagonists exist but have not been evaluated in this clinical setting.

THROMBOPHLEBITIS AND DEEP VENOUS THROMBOSIS

Deep venous thrombosis and pulmonary embolism are the most common thrombotic conditions in patients with cancer. Migratory or recurrent thrombophlebitis may be the initial manifestation of cancer. Nearly 15% of patients who develop deep venous thrombosis or pulmonary embolism have a diagnosis of cancer **(Chap. 117)**. The coexistence of peripheral venous thrombosis with visceral carcinoma, particularly pancreatic cancer, is called *Trousseau's syndrome*.

Pathogenesis Patients with cancer are predisposed to thromboembolism because they are often at bed rest or immobilized, and tumors may obstruct or slow blood flow. Postoperative deep venous thrombosis is twice as common in cancer patients who undergo surgery. Chronic IV catheters also predispose to clotting. In addition, clotting may be promoted by release of procoagulants or cytokines from tumor cells or associated inflammatory cells or by platelet adhesion or aggregation. The specific molecules that promote thromboembolism have not been identified.

Chemotherapeutic agents, particularly those associated with endothelial damage, can induce venous thrombosis. The annual risk of venous thrombosis in patients with cancer receiving chemotherapy is about 11%, sixfold higher than the risk in the general population. Bleomycin, L-asparaginase, nitrogen mustard, thalidomide analogues, cisplatin-based regimens, and high doses of busulfan and carmustine are all associated with an increased risk.

In addition to cancer and its treatment causing secondary thrombosis, primary thrombophilic diseases may be associated with cancer. For example, the antiphospholipid antibody syndrome is associated with a wide range of pathologic manifestations **(Chap. 357)**. About 20% of patients with this syndrome have cancers. Among patients with cancer and antiphospholipid antibodies, 35–45% develop thrombosis.

Clinical Manifestations Patients with cancer who develop deep venous thrombosis usually develop swelling or pain in the leg, and physical examination reveals tenderness, warmth, and redness. Patients who present with pulmonary embolism develop dyspnea, chest pain, and syncope, and physical examination shows tachycardia, cyanosis, and hypotension. Some 5% of patients with no history of cancer who have a diagnosis of deep venous thrombosis or pulmonary embolism will have a diagnosis of cancer within 1 year. The most common cancers associated with thromboembolic episodes include lung, pancreatic, gastrointestinal, breast, ovarian, and genitourinary cancers; lymphomas; and brain tumors. Patients with cancer who undergo

surgical procedures requiring general anesthesia have a 20–30% risk of deep venous thrombosis.

Diagnosis The diagnosis of deep venous thrombosis in patients with cancer is made by impedance plethysmography or bilateral compression ultrasonography of the leg veins. Patients with a noncompressible venous segment have deep venous thrombosis. If compression ultrasonography is normal and there is a high clinical suspicion for deep venous thrombosis, venography should be done to look for a luminal filling defect. Elevation of D-dimer is not as predictive of deep venous thrombosis in patients with cancer as it is in patients without cancer; elevations are seen in people over age 65 years without concomitant evidence of thrombosis, probably as a consequence of increased thrombin deposition and turnover in aging.

Patients with symptoms and signs suggesting a pulmonary embolism should be evaluated with a chest radiograph, electrocardiogram, arterial blood gas analysis, and ventilation-perfusion scan. Patients with mismatched segmental perfusion defects have a pulmonary embolus. Patients with equivocal ventilation-perfusion findings should be evaluated as described above for deep venous thrombosis in their legs. If deep venous thrombosis is detected, they should be anticoagulated. If deep venous thrombosis is not detected, they should be considered for a pulmonary angiogram.

Patients without a diagnosis of cancer who present with an initial episode of thrombophlebitis or pulmonary embolus need no additional tests for cancer other than a careful history and physical examination. In light of the many possible primary sites, diagnostic testing in asymptomatic patients is wasteful. However, if the clot is refractory to standard treatment or is in an unusual site, or if the thrombophlebitis is migratory or recurrent, efforts to find an underlying cancer are indicated.

TREATMENT

Thrombophlebitis and Deep Venous Thrombosis

Patients with cancer and a diagnosis of deep venous thrombosis or pulmonary embolism should be treated initially with IV unfractionated heparin or low-molecular-weight heparin for at least 5 days, and warfarin should be started within 1 or 2 days. The warfarin dose should be adjusted so that the international normalized ratio (INR) is 2–3. Patients with proximal deep venous thrombosis and a relative contraindication to heparin anticoagulation (hemorrhagic brain metastases or pericardial effusion) should be considered for placement of a filter in the inferior vena cava (Greenfield filter) to prevent pulmonary embolism. Warfarin should be administered for 3–6 months. An alternative approach is to use low-molecular-weight heparin for 6 months. The new oral anticoagulants (factor Xa and thrombin inhibitors) are attractive because they do not require close monitoring of the prothrombin time and are not affected by dietary factors. Oral apixaban (10 mg bid for 7 days followed by 5 mg bid for 6 months) is noninferior to dalteparin in the treatment of cancer patients who develop deep vein thrombosis or pulmonary embolism. Patients with cancer who undergo a major surgical procedure should be considered for heparin prophylaxis or pneumatic boots. Breast cancer patients undergoing chemotherapy and patients with implanted catheters should be considered for prophylaxis. Guidelines recommend that hospitalized patients with cancer and patients receiving a thalidomide analogue receive prophylaxis with low-molecular-weight heparin or low-dose aspirin. Use of prophylaxis routinely during chemotherapy is controversial. Risk is affected by type of cancer, type of therapy, blood counts, and body mass index (all taken into account in the Khorana risk score; Table 93-3). Studies of Khorana high-risk patients with cancer using rivaroxaban and apixaban as clot prophylaxis have resulted in a 50% reduction in risk with a level of bleeding of about 5%. However, prophylaxis is not routinely recommended by the American Society of Clinical Oncology.

TABLE 93-3 Khorana Risk Score for Venous Thromboembolism in Cancer Patients

PATIENT CHARACTERISTICS		RISK SCORE POINTS
Site of cancer		
Very high risk (stomach, pancreas)		2
High risk (lung, lymphoma, gynecologic, genitourinary excluding prostate)		1
Prechemotherapy platelet count ≥350,000/μL		1
Hemoglobin level <10 g/dL or use of red cell growth factors		1
Prechemotherapy leukocyte count >11,000/μL		1
BMI ≥35 kg/m²		1
RISK SCORE (POINTS)	**RISK CATEGORY**	**RATES OF sVTE ACCORDING TO SCORES (%)**
0	Low	0.3–0.8
1–2	Intermediate	1.8–2.0
≥3	High	6.7–7.1

Abbreviations: BMI, body mass index; sVTE, symptomatic venous thromboembolism.

MISCELLANEOUS REMOTE EFFECTS OF CANCER

Patients with cancer can develop paraneoplastic autoimmune disorders (e.g., thrombocytopenia) and dysfunction of organs not directly invaded or involved with the cancer (rheumatologic and renal abnormalities are among the most frequent). The pathogenesis of these disorders is undefined, but often, the conditions reverse if the tumor is removed or successfully treated.

Cutaneous paraneoplastic syndromes are discussed in Chap. 58. Neurologic paraneoplastic syndromes are discussed in Chap. 94.

94 Paraneoplastic Neurologic Syndromes and Autoimmune Encephalitis

Josep Dalmau, Myrna R. Rosenfeld, Francesc Graus

Paraneoplastic neurologic disorders (PNDs) are cancer-related syndromes that can affect any part of the nervous system (Table 94-1). They are caused by mechanisms other than metastasis or by any of the complications of cancer such as coagulopathy, stroke, metabolic and nutritional conditions, infections, and side effects of cancer therapy. In 60% of patients, the neurologic symptoms precede the cancer diagnosis. Clinically disabling PNDs occur in 0.5–1% of all cancer patients, but they affect 2–3% of patients with neuroblastoma or small-cell lung cancer (SCLC) and 30–50% of patients with thymoma.

PATHOGENESIS

Most PNDs are mediated by immune responses triggered by neuronal proteins ectopically expressed by tumors (e.g., SCLC and other cancers) or as a result of altered immunologic responses caused by some types of tumors such as thymomas or lymphomas. In PNDs of the central nervous system (CNS), many antibody-associated immune responses have been identified (Table 94-2). These antibodies react with neurons and the patient's tumor, and their detection in serum or cerebrospinal fluid (CSF) usually predicts the presence of cancer. When the antigens are intracellular, most syndromes are associated with extensive infiltrates of CD4+ and CD8+ T cells, microglial activation, gliosis, and variable neuronal loss. The infiltrating T cells are often in close contact with neurons undergoing degeneration, suggesting a primary pathogenic role. T-cell–mediated cytotoxicity may contribute directly to cell death in these PNDs and probably underlies the resistance of many of these conditions to therapy.

In contrast to the predominant role of cytotoxic T-cell mechanisms in PND associated with antibodies against intracellular antigens, those associated with antibodies to antigens expressed on the neuronal cell surface of the CNS or at the neuromuscular junction are mediated by direct antibody effects on the target antigens and are more responsive to immunotherapy (Table 94-3, Fig. 94-1). These disorders occur with and without a cancer association and may affect children and young adults. Some disorders are triggered by viral encephalitis such as herpes simplex virus encephalitis or Japanese encephalitis, leading to autoimmune encephalitis.

In patients with cancer, the use of immune checkpoint inhibitors is associated in rare instances with immune-related adverse events accompanied by neuronal antibodies, which are indistinguishable from paraneoplastic neurologic syndromes.

Other PNDs are likely immune-mediated, although their antigens are unknown. The best example is opsoclonus-myoclonus syndrome associated with neuroblastoma or SCLC. For still other PNDs, the cause remains quite obscure. These include, among others, several neuropathies that occur in the terminal stages of cancer and a number of neuropathies associated with plasma cell dyscrasias or lymphoma without evidence of tumor infiltration or deposits of immunoglobulin, cryoglobulin, or amyloid.

TABLE 94-1 Paraneoplastic Syndromes of the Nervous System

CLASSIC SYNDROMES: USUALLY OCCUR WITH CANCER ASSOCIATION	NONCLASSIC SYNDROMES: MAY OCCUR WITH AND WITHOUT CANCER ASSOCIATION
Encephalomyelitis	Brainstem encephalitis
Limbic encephalitis	Stiff-person syndrome
Cerebellar degeneration (adults)	Progressive encephalomyelitis with rigidity and myoclonus
Opsoclonus-myoclonus	Necrotizing myelopathy
Subacute sensory neuronopathy	Motor neuron disease
Gastrointestinal paresis or pseudo-obstruction	Guillain-Barré syndrome
Dermatomyositis (adults)	Subacute and chronic mixed sensory-motor neuropathies
Lambert-Eaton myasthenic syndrome	Neuropathy associated with plasma cell dyscrasias and lymphoma
Cancer- or melanoma-associated retinopathy	Vasculitis of nerve
	Pure autonomic neuropathy
	Acute necrotizing myopathy
	Polymyositis
	Optic neuropathy
	BDUMP
	Peripheral nerve hyperexcitability (neuromyotonia)
	Myasthenia gravis

Abbreviation: BDUMP, bilateral diffuse uveal melanocytic proliferation.

TABLE 94-2 Antibodies to Intracellular Antigens, Syndromes, and Associated Cancers

ANTIBODY	ASSOCIATED NEUROLOGIC SYNDROME(S)	TUMORS
Anti-Hu (ANNA1)	Encephalomyelitis, subacute sensory neuronopathy	SCLC
Anti-Yo (PCA1)	Cerebellar degeneration	Ovary, breast
Anti-Ri (ANNA2)	Cerebellar degeneration, opsoclonus, brainstem encephalitis	Breast, gynecologic, SCLC
Anti-CRMP5 (CV2)	Encephalomyelitis, chorea, optic neuritis, uveitis, peripheral neuropathy	SCLC, thymoma, other
Anti-Ma proteins	Limbic, hypothalamic, brainstem encephalitis	Testicular (Ma2), other (Ma)
Anti-Kelch-like protein 11	Brainstem encephalitis, ataxia, hearing loss, diplopia	Seminoma, germ-cell tumor, teratoma
Anti-amphiphysin[a]	Stiff-person syndrome, encephalomyelitis	Breast, SCLC
Recoverin, bipolar cell antibodies, others[b]	Cancer-associated retinopathy (CAR), melanoma-associated retinopathy (MAR)	SCLC (CAR), melanoma (MAR)
Anti-GAD	Stiff-person, cerebellar syndromes, limbic encephalitis	Infrequent tumor association (thymoma and several cancers)

[a]Amphiphysin is likely exposed to the cell surface during synaptic vesicle endocytosis. [b]A variety of target antigens have been identified.

Abbreviations: CRMP, collapsin response-mediator protein; SCLC, small-cell lung cancer.

APPROACH TO THE PATIENT

Paraneoplastic Neurologic Disorders

Three key concepts are important for the diagnosis and management of PNDs. First, it is common for symptoms to appear before the presence of a tumor is known; second, the neurologic syndrome usually develops rapidly, producing severe deficits in a short period of time; and third, there is evidence that prompt tumor control improves the neurologic outcome. Therefore, the major concern of the physician is to recognize a disorder promptly as paraneoplastic and to identify and treat the tumor.

PND OF THE CENTRAL NERVOUS SYSTEM AND DORSAL ROOT GANGLIA

When symptoms involve brain, spinal cord, or dorsal root ganglia, the suspicion of PND is usually based on a combination of clinical, radiologic, and CSF findings. Presence of antineuronal antibodies

TABLE 94-3 Antibodies to Cell Surface or Synaptic Antigens, Syndromes, and Associated Tumors

ANTIBODY	NEUROLOGIC SYNDROME	TUMOR TYPE WHEN ASSOCIATED
Anti-NMDAR[a]	Anti-NMDAR encephalitis	Teratoma in young women (children and men rarely have tumors)
Anti-AMPAR[a]	Limbic encephalitis with relapses	SCLC, thymoma, breast, in ~70% of the patients
Anti-GluK2[a]	Encephalitis, cerebellar ataxia, cerebellitis	No tumor, rarely teratoma
Anti-$GABA_AR$[a]	Encephalitis with prominent seizures and status epilepticus	Thymoma in ~30% of the patients
Anti-$GABA_BR$[b]	Limbic encephalitis with early and prominent seizures	SCLC in ~50% of the patients
Glycine receptor[a]	PERM, stiff-person syndrome	Rarely, thymoma, lung, Hodgkin's
Anti-mGluR5[a]	Autoimmune encephalitis without distinctive features	Hodgkin's lymphoma, or no tumor
Anti-dopamine-2R[b]	Basal ganglia encephalitis	No cancer association
Anti-LGI1[a,c]	Limbic encephalitis, hyponatremia, faciobrachial dystonic seizures	Rarely thymoma
Anti-Caspr2[a,c]	Limbic encephalitis, ataxia, peripheral nerve hyperexcitability, neuropathy, Morvan's syndrome	~20% thymoma. In cases of Morvan syndrome: ~40% thymoma
Anti-DPPX[a]	Agitation, myoclonus, tremor, seizures, hyperekplexia, encephalomyelitis with rigidity	No cancer, but frequent diarrhea or cachexia suggesting paraneoplasia
Anti-neurexin 3α[b]	Autoimmune encephalitis without distinctive features	No cancer association
IgLON5[a]	NREM and REM sleep disorder, brainstem dysfunction, movement disorder, obstructive sleep apnea, stridor	No tumor association
Anti-mGluR1[a]	Cerebellar syndrome	Hodgkin's lymphoma, or no tumor
Anti-mGluR2	Cerebellar syndrome	Small-cell neuroendocrine tumor, rhabdomyosarcoma
Anti-Tr (DNER)	Cerebellar syndrome	Hodgkin's lymphoma, or no tumor
Anti-Sez6l2	Cerebellar ataxia, postural instability, frequent falls, dysarthria, extrapyramidal symptoms	No cancer association
Anti-MOG	ADEM, optic neuritis, myelitis, cortical encephalitis	No cancer association
Anti-AChR (muscle)[a]	Myasthenia gravis	Thymoma
Anti-AChR (neuronal)[a]	Autonomic ganglionopathy	SCLC
Anti-VGCC[a]	LEMS, cerebellar degeneration	SCLC

[a]A direct pathogenic role of these antibodies has been demonstrated in cultured neurons or animal models. [b]These antibodies are strongly suspected to be pathogenic. [c]Previously named voltage-gated potassium channel antibodies (VGKC); currently included under the term VGKC-complex proteins. Of note, the significance of antibodies to VGKC-complex proteins other than LGI1 and Caspr2 is uncertain (the antigens are unknown, and the response to immunotherapy is variable)

Abbreviations: AChR, acetylcholine receptor; ADEM, acute disseminated encephalomyelitis, AMPAR, α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid receptor; Caspr2, contactin-associated protein-like 2; DNER, delta/notch-like epidermal growth factor-related receptor; DPPX, dipeptidyl-peptidase-like protein-6; $GABA_BR$, γ-aminobutyric acid B receptor; GAD, glutamic acid decarboxylase; GluK2, glutamate receptor ionotropic kainate 2; mGluR, metabotropic glutamate receptor; LEMS, Lambert-Eaton myasthenic syndrome; LGI1, leucine-rich glioma-inactivated 1; MOG, myelin oligodendrocyte glycoprotein; NMDAR, *N*-methyl-D-aspartate receptor; NREM, non-rapid eye movement; PERM, progressive encephalomyelitis with rigidity and myoclonus; REM, rapid eye movement; SCLC, small-cell lung cancer; Sez6l2, Seizure-related 6 homolog like 2; VGCC, voltage-gated calcium channel.

(Tables 94-2 and 94-3) may help in the diagnosis, but only 60–70% of PNDs of the CNS and <20% of those involving the peripheral nervous system have neuronal or neuromuscular junction antibodies that can be used as diagnostic tests.

Magnetic resonance imaging (MRI) and CSF studies are important to rule out neurologic complications due to the direct spread of cancer, particularly metastatic and leptomeningeal disease. In most PNDs, the MRI findings are nonspecific. Paraneoplastic limbic encephalitis is usually associated with characteristic MRI abnormalities in the mesial temporal lobes (see below), but similar findings can occur with other disorders (e.g., nonparaneoplastic autoimmune limbic encephalitis and human herpesvirus type 6 [HHV-6] encephalitis) **(Fig. 94-2*A*)**. The CSF profile of patients with PND of the CNS or dorsal root ganglia typically consists of mild to moderate pleocytosis (<200 mononuclear cells, predominantly lymphocytes), an increase in the protein concentration, and a variable presence of oligoclonal bands. There are no specific electrophysiologic tests that are diagnostic of PND. Moreover, a biopsy of the affected tissue is often difficult to obtain, and although useful to rule out other disorders (e.g., metastasis), the pathologic findings are not specific for PND.

PND OF NERVE AND MUSCLE

If symptoms involve peripheral nerve, neuromuscular junction, or muscle, the diagnosis of a specific PND is usually established on clinical, electrophysiologic, and pathologic grounds. The clinical history, accompanying symptoms (e.g., anorexia, weight loss), and type of syndrome dictate the studies and degree of effort needed to demonstrate a neoplasm. For example, the frequent association of Lambert-Eaton myasthenic syndrome (LEMS) with SCLC should lead to a chest and abdomen computed tomography (CT) or body positron emission tomography (PET) scan and, if negative, periodic tumor screening for at least 3 years after the neurologic diagnosis. In contrast, the weak association of polymyositis with cancer calls into question the need for repeated cancer screenings in this situation. Serum and urine immunofixation studies should be considered in patients with peripheral neuropathy of unknown cause; detection of a monoclonal gammopathy suggests the need for additional studies to uncover a B-cell or plasma-cell malignancy. In paraneoplastic neuropathies, diagnostically useful antineuronal antibodies are limited to CRMP5 (CV2) and Hu (ANNA1).

For any type of PND, if antineuronal antibodies are negative, the diagnosis relies on the demonstration of cancer and the exclusion of other cancer-related or independent neurologic disorders. Combined CT and PET scans often uncover tumors undetected by other tests. For germ cell tumors of the testis and teratomas of the ovary, ultrasound (testicular, transvaginal, or pelvic) and MRI or CT of the abdomen and pelvis may reveal tumors undetectable by PET.

SPECIFIC PARANEOPLASTIC NEUROLOGIC SYNDROMES

■ PARANEOPLASTIC ENCEPHALOMYELITIS AND FOCAL ENCEPHALITIS WITH ANTIBODIES AGAINST INTRACELLULAR NEURONAL PROTEINS

The term *encephalomyelitis* describes an inflammatory process with multifocal involvement of the nervous system, including brain, brainstem, cerebellum, and spinal cord. It is often associated with dorsal root ganglia and autonomic dysfunction. For any given patient, the clinical manifestations are determined by the areas predominantly involved, but pathologic studies almost always reveal abnormalities beyond the symptomatic regions. Several clinicopathologic syndromes may occur alone or in combination: (1) *cortical encephalitis*, which may present as "epilepsia partialis continua"; (2) *limbic encephalitis*, characterized by confusion, depression, agitation, anxiety, severe deficit forming new memories ("short-term memory deficit"), and temporal lobe or generalized seizures (the MRI usually shows unilateral or bilateral medial temporal lobe abnormalities, best seen with T2 and fluid-attenuated

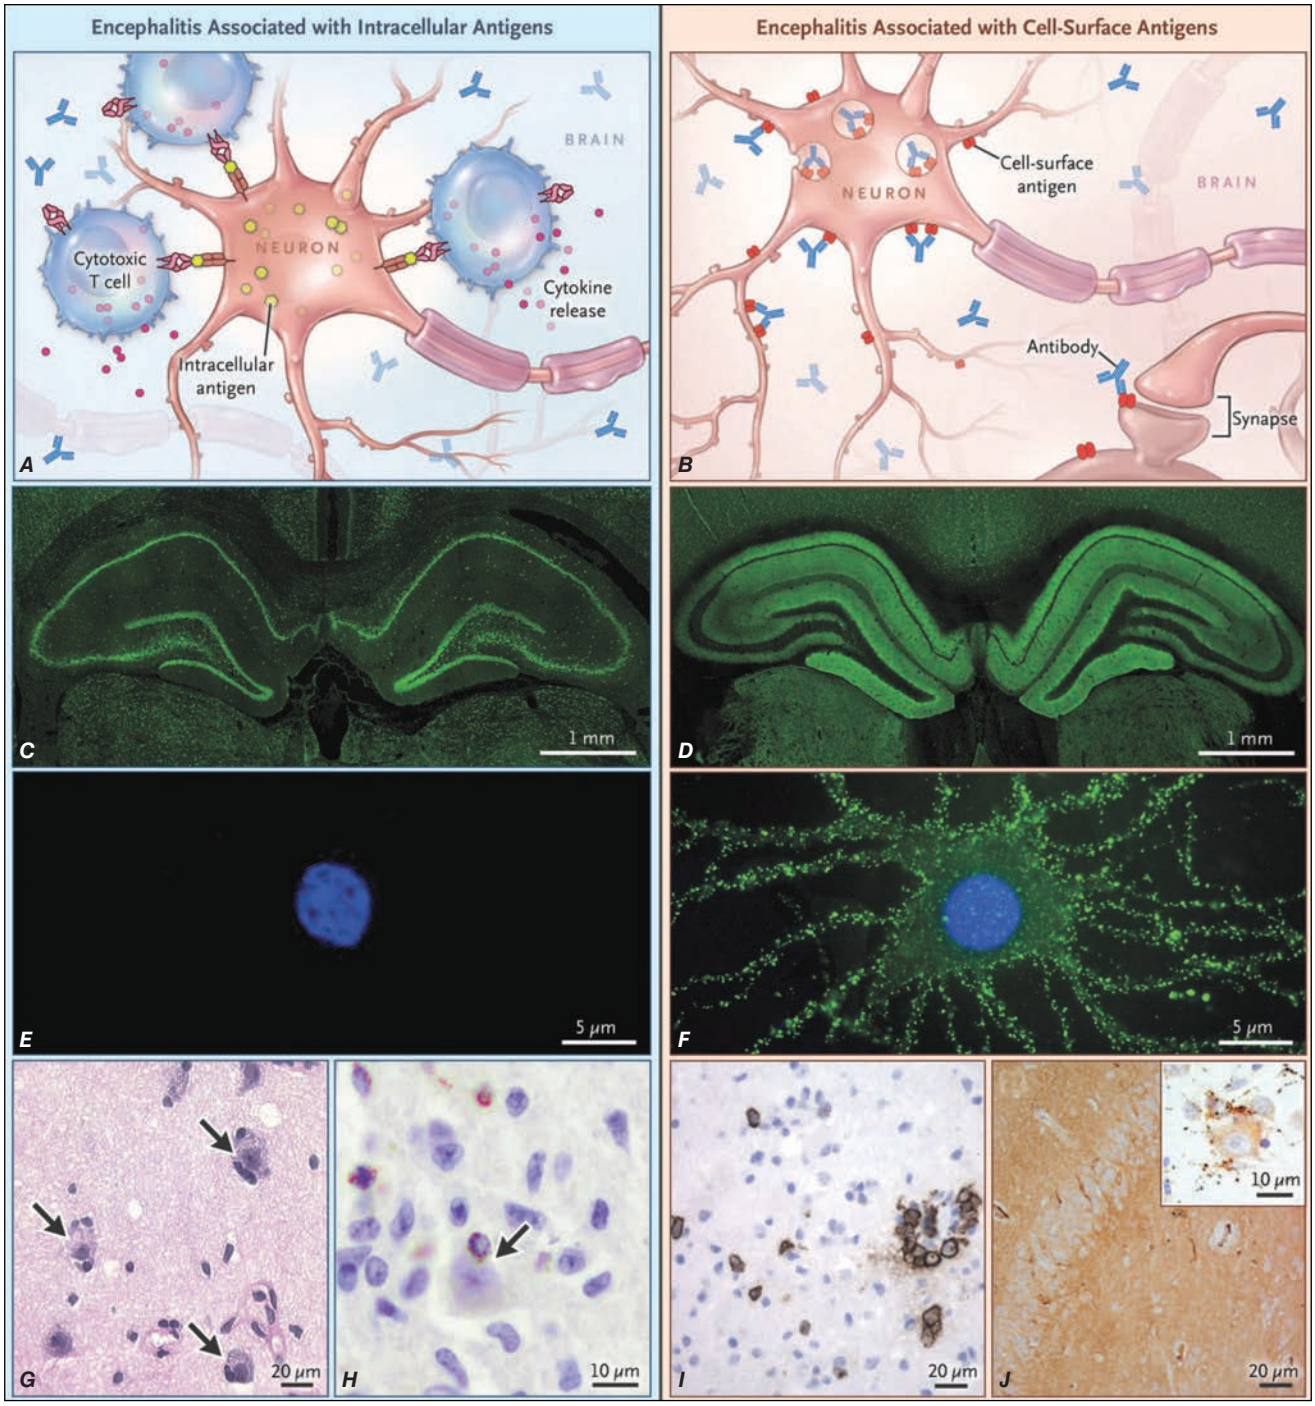

FIGURE 94-1 Antibody reactivity and pathologic findings in patients with antibodies against intracellular antigens compared with those of patients with antibodies against neuronal surface antigens. In encephalitis associated with antibodies against intracellular antigens, the antibodies cannot reach the intracellular epitopes and cytotoxic T-cell mechanisms are predominantly involved (***A***), whereas in encephalitis with antibodies against surface antigens, the antibodies have access to the epitopes and can potentially alter the structure and function of the antigen (***B***). The Hu antibodies (***C, E***) are shown here to exemplify the group of antibodies against intracellular antigens, and the NMDAR antibodies (***D, F***) are shown to exemplify the group of antibodies against cell-surface antigens. In rodent brain immunofluorescence with tissue permeabilized to allow entry of antibodies, the Hu antibodies produce a discrete pattern of cellular immunolabeling (***C***), whereas the NMDAR antibodies produce a pattern of neuropil-like immunolabeling (***D***). In contrast, with live cultured neurons, only the NMDAR antibodies have access to the target antigen showing intense immunolabeling (***F***), whereas the Hu antibodies cannot reach the intracellular antigen showing no immunolabeling (***E***). In autopsy studies, patients with encephalitis associated with antibodies to intracellular antigens (Hu or other) have extensive neuronal loss and inflammatory infiltrates (not shown); the T cells show direct contact with neurons (arrows in ***G***) likely contributing to neuronal degeneration via perforin and granzyme mechanisms (arrow in ***H***). In contrast, patients with antibodies against cell-surface antigens (NMDAR shown here, and probably applicable to other antigens) have moderate brain inflammatory infiltrates along with plasma cells (brown cells in ***I***), deposits of IgG (diffuse brown staining in ***J***), and microglial proliferation (inset in ***J***), without evidence of predominant T-cell–mediated neuronal loss (not shown). All human tissue sections (***G-J***) were obtained from hippocampus. *(From J Dalmau: Antibody mediated encephalitis. N Engl J Med 378:840, 2018. Copyright © 2018 Massachusetts Medical Society. Reprinted with permission.)*

inversion recovery [FLAIR] sequences); (3) *brainstem encephalitis*, resulting in eye movement disorders (nystagmus, opsoclonus, supranuclear or nuclear paresis), cranial nerve paresis, dysarthria, dysphagia, unsteady gait, and central autonomic dysfunction; (4) *cerebellar gait and limb ataxia*; (5) *myelitis*, which may cause lower or upper motor neuron symptoms, myoclonus, muscle rigidity, spasms, sensory deficits, and sphincter dysfunction; and (6) *autonomic dysfunction* as a result of involvement of the neuraxis at multiple levels, including hypothalamus, brainstem, and autonomic nerves (see Paraneoplastic Peripheral Neuropathies, below). Cardiac arrhythmias, postural

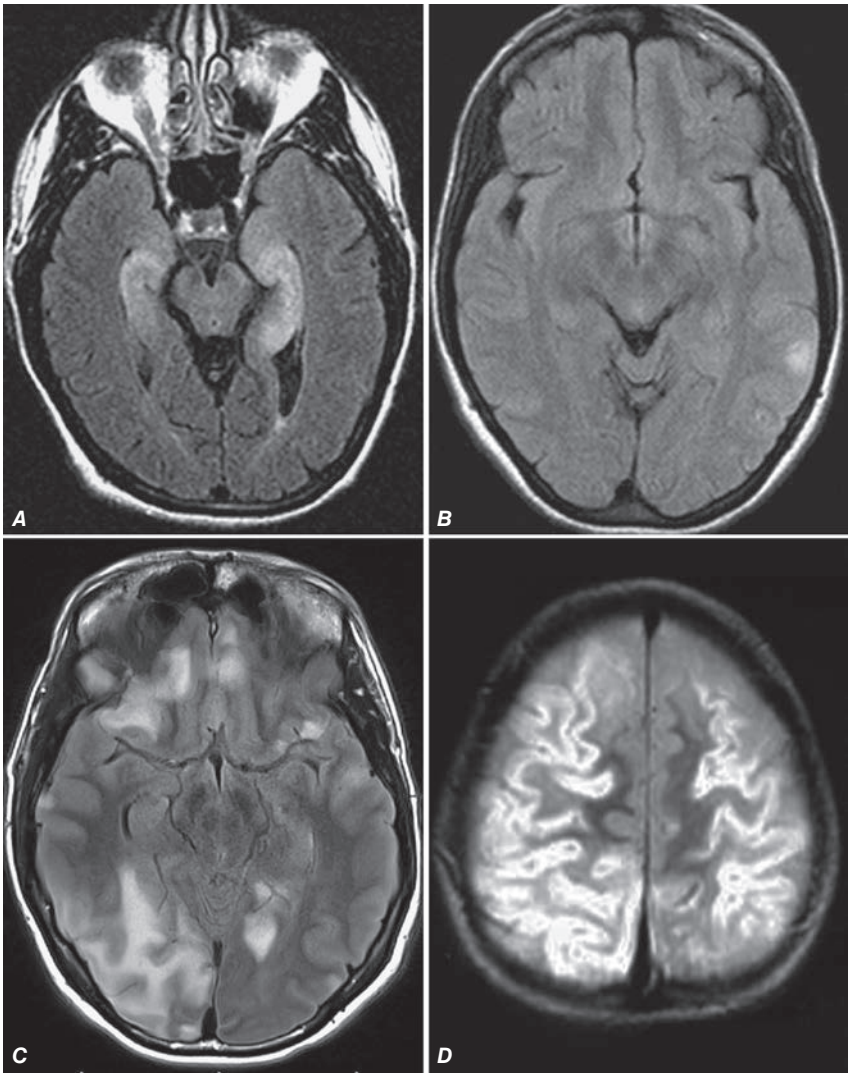

FIGURE 94-2 Brain MRI findings in paraneoplastic and autoimmune encephalitis. Representative MRI studies of patients with several types of autoimmune encephalitides. ***A.*** Limbic encephalitis (LE) may result from several different immune responses (Hu, Ma2, AMPAR, $GABA_BR$, LGI1, Caspr2) and typically manifests with unilateral or bilateral medial temporal lobe increased FLAIR signal. ***B.*** Anti-NMDAR encephalitis often occurs with normal MRI findings or mild FLAIR signal abnormalities. ***C.*** In contrast, anti-$GABA_AR$ encephalitis usually occurs with multiple cortical-subcortical increased FLAIR signal changes. ***D.*** Cortical encephalitis can occur in patients with myelin oligodendrocyte glycoprotein (MOG) antibodies, as shown in this T2-weighted MRI image from a 3-year-old boy who presented with extensive cortical abnormalities with mild enhancement (not shown here) suggesting cortical necrosis. *(Panels A-C from J Dalmau: Antibody mediated encephalitis. N Engl J Med 378:840, 2018. Copyright © 2018 Massachusetts Medical Society. Reprinted with permission. Lancet Neurol 19:234, 2020.)*

hypotension, and central hypoventilation can be the cause of death in patients with encephalomyelitis.

Paraneoplastic encephalomyelitis and focal encephalitis are usually associated with SCLC, but many other cancers have been implicated. Patients with SCLC and these syndromes usually have Hu antibodies in serum and CSF. CRMP5 antibodies occur less frequently; some of these patients may develop chorea, uveitis, or optic neuritis. Antibodies to Ma proteins are associated with limbic, hypothalamic, and brainstem encephalitis and occasionally with cerebellar symptoms; some patients develop hypersomnia, cataplexy, and severe hypokinesia. MRI abnormalities are frequent, including those described with limbic encephalitis and variable involvement of the hypothalamus, basal ganglia, or upper brainstem. Kelch-like protein 11 antibodies are predominantly associated with brainstem encephalitis and seminomas, germ cell tumors, and teratomas. Amphiphysin antibodies usually are associated with paraneoplastic stiff-person syndrome, but in some patients, they can occur with paraneoplastic encephalomyelitis or isolated myelitis. The oncologic associations of these antibodies are shown in Table 94-2.

Most types of paraneoplastic encephalitis and encephalomyelitis in which the antigens are intracellular respond poorly to treatment. Stabilization of symptoms or partial neurologic improvement may occur, particularly if there is a satisfactory response of the tumor to treatment. Controlled trials of therapy are lacking, but many reports and the opinion of experts suggest that therapies aimed to remove the antibodies against intracellular antigens, such as intravenous immunoglobulin (IVIg) or plasma exchange, usually fail. The main concern should be to treat the tumor and consider immunotherapies aimed at cytotoxic T-cell responses. Approximately 30% of patients with anti-Ma2-associated encephalitis respond to treatment of the tumor (usually a germ cell neoplasm of the testis) and immunotherapy.

ENCEPHALITIDES WITH ANTIBODIES TO CELL-SURFACE OR SYNAPTIC PROTEINS (TABLE 94-3)

These disorders are important for four reasons: (1) they can occur with and without tumor association; less frequently, they develop after a viral encephalitis (herpes simplex or Japanese encephalitis); (2) some syndromes predominate in young individuals and children; (3) despite the severity of the symptoms, patients usually respond to treatment of the tumor, if found, and immunotherapy (e.g., glucocorticoids, IVIg, plasma exchange, rituximab, or cyclophosphamide); and (4) for many of these disorders, the antibody pathogenicity has been demonstrated in models using cultures of neurons or passive transfer of patients' antibodies to animals (Fig. 94-3).

Encephalitis with N*-methyl-*D*-aspartate (NMDA) receptor antibodies* usually occurs in young women and children, but men and older patients of both sexes can be affected. The disorder has a characteristic pattern of symptom progression that often includes a prodrome resembling a viral process, followed in a few days by the onset of severe psychiatric symptoms, sleep dysfunction (usually insomnia), reduced verbal output, memory loss, seizures, decreased level of consciousness, abnormal movements (orofacial, limb, and trunk dyskinesias, dystonic postures), autonomic instability, and frequent hypoventilation. Monosymptomatic episodes, such as pure psychosis, occur in about 5% of patients. Clinical relapses occur in 12–24% of patients (12% during the first 2 years after initial presentation). Most patients have intrathecal synthesis of antibodies, likely by infiltrating plasma cells in brain and meninges (Fig. 94-1*I*). In about 65% of patients, the brain MRI is normal; in the other 35%, it shows FLAIR abnormalities that can affect cortical and subcortical regions, usually mild and transient, and rarely the presence of contrast enhancement (Fig. 94-2*B*). The syndrome may be misdiagnosed as a viral or idiopathic encephalitis, neuroleptic malignant syndrome, or encephalitis lethargica, and some patients are initially evaluated by psychiatrists with the suspicion of acute psychosis as the presentation of a primary psychiatric disease. The detection of an associated teratoma is dependent on age and gender: 46% of female patients 12 years or older have uni- or bilateral ovarian teratomas, whereas <7% of girls younger than 12 have a teratoma (Fig. 94-4*A*). In young male patients, the detection of a tumor is rare. Patients older than 45 years are more frequently male; about 20% of these patients have tumors (e.g., cancer of the breast, ovary, or lung). Prompt diagnosis and treatment with immunotherapy (and tumor removal when it applies) improve outcome. Overall, about 85–90% of patients have substantial neurologic improvement or full recovery.

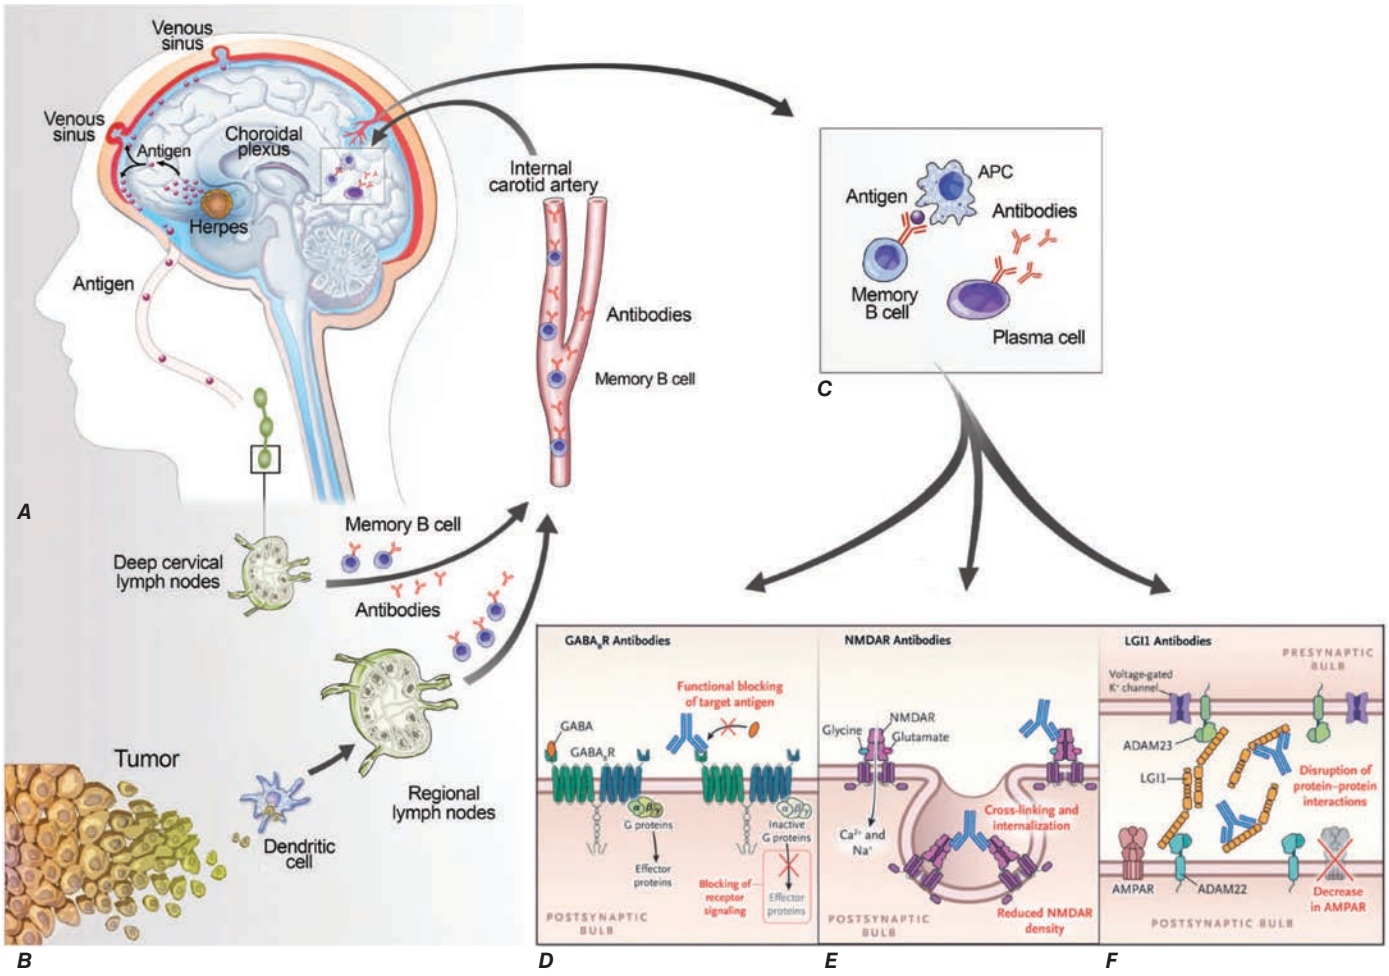

FIGURE 94-3 Proposed mechanisms of disease and functional interactions of autoantibodies with neuronal proteins. The graph shows a multistep process that results in antibody-mediated neuronal dysfunction; some of the steps have been demonstrated in reported studies, whereas others are based on proposed hypotheses. Two well-known triggers of autoimmune encephalitides are represented: herpes simplex encephalitis (***A***) and systemic tumors (***B***); the genetic susceptibility of some autoimmune encephalitides and unknown immunologic triggers are not depicted. It is postulated that antigens released by viral-induced neuronal destruction or apoptotic tumor cells are loaded into antigen-presenting cells (APCs; dendritic cells) and transported to regional lymph nodes. In the lymph nodes, naïve B cells exposed to the processed antigens, with cooperation of CD4+ T cells, become antigen-experienced and differentiate into antibody-producing plasma cells. After entering the brain, memory B cells undergo restimulation, antigen-driven affinity maturation, clonal expansion, and differentiation into antibody-producing plasma cells (***C***). The contribution of systemically produced antibodies to the pool of antibodies present in the brain is unclear and may depend on systemic antibody titers and integrity of the blood-brain barrier. Based on experimental models with cultured neurons, the presence of antibodies in the brain may lead to neuronal dysfunction by different mechanisms, including functional blocking of the target antigen (GABA$_B$R antibodies; ***D***), receptor crosslinking and internalization (NMDAR antibodies; ***E***), and disruption of protein-protein interaction, leading to downstream effects on receptors (LGI1 leading to a decrease of Kv1 potassium channels and AMPAR; ***F***). These mechanisms are influenced by the type of antibodies; for example, whereas IgG1 antibodies frequently crosslink and internalize the target antigen, IgG4 antibodies are less effective at crosslinking the target and more often alter protein-protein interactions. *(Panels D-F J Dalmau: Antibody mediated encephalitis. N Engl J Med 378:840, 2018. Copyright © 2018 Massachusetts Medical Society. Reprinted with permission.)*

Deficits of attention, memory, and executive functions may recover slowly over many months, sometimes a few years.

Approximately 25% of patients with herpes simplex encephalitis develop a form of autoimmune encephalitis that usually is associated with abnormal movements (choreoathetosis after herpes simplex encephalitis) in children and with cognitive and psychiatric symptoms in adults. This disorder develops a few weeks after the viral infection has resolved, is associated with new synthesis of antibodies against the NMDA receptor and other neuronal cell surface proteins, and is usually less responsive to immunotherapy than anti-NMDA receptor encephalitis (idiopathic or teratoma-associated).

Encephalitis with α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) receptor antibodies affects middle-aged women, who develop acute limbic dysfunction or, less frequently, prominent psychiatric symptoms; 70% of patients have an underlying tumor in the lung, breast, or thymus **(Fig. 94-4*B*)**. In about 50% of cases, the brain MRI shows typical features of limbic encephalitis (similar to Fig. 94-2*A*). Neurologic relapses may occur; these also respond to immunotherapy and are not necessarily associated with tumor recurrence.

Encephalitis with GluK2 antibodies can affect children and adults and is associated with rapidly progressive encephalopathy with cerebellar ataxia or cerebellitis. Symptoms of encephalopathy may include impairment of memory and level of consciousness and motor alterations such as dyskinesias, choreoathetosis, bradykinesia, and spastic paraparesis. Some patients develop intracranial hypertension. In one patient, the symptoms were associated with teratoma.

Encephalitis with γ-aminobutyric acid type A ($GABA_A$) receptor antibodies may affect children and adults and is associated with prominent seizures and status epilepticus often requiring a pharmacologically induced coma. In approximately 80% of patients, the brain MRI shows multifocal, asynchronous, cortical-subcortical T2/FLAIR abnormalities predominantly involving temporal and frontal lobes, but also basal ganglia and other regions **(Fig. 94-2*C*)**. Most patients do not have an underlying tumor, but some, usually of Japanese ethnicity, may have thymoma.

Encephalitis with $GABA_B$ receptor antibodies is usually associated with limbic encephalitis and seizures. In >50% of cases, the MRI shows increased medial temporal lobe FLAIR changes characteristic of limbic encephalitis (similar to Fig. 94-2*A*). In rare instances, patients

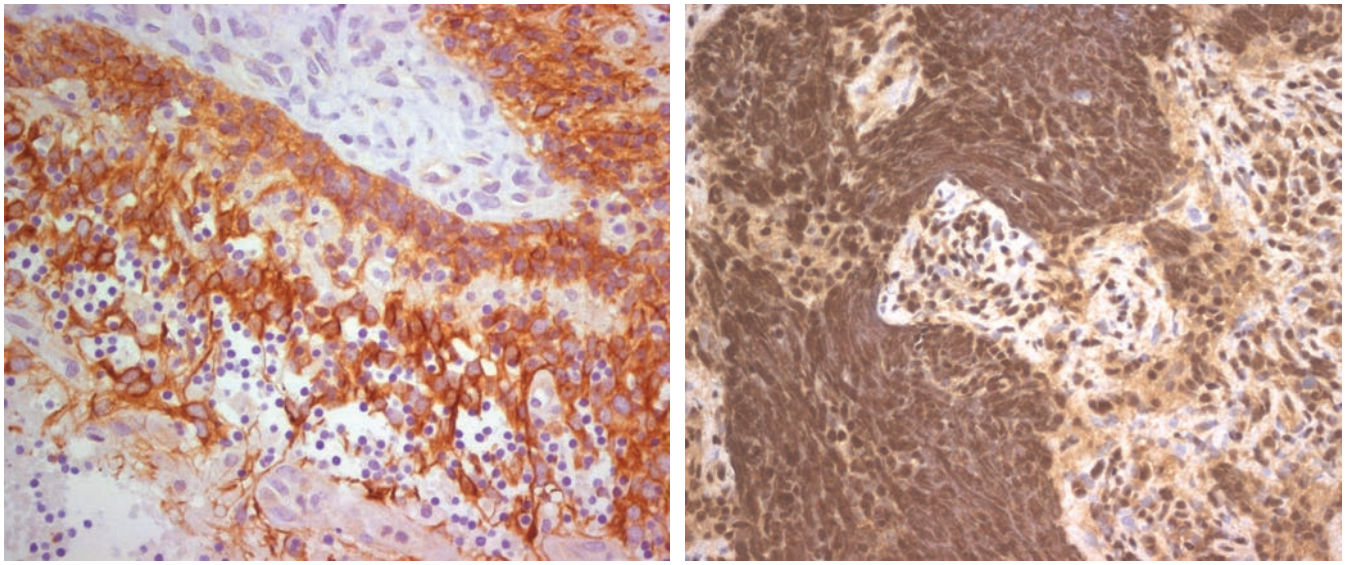

FIGURE 94-4 Immunopathological studies in tumors of patients with autoimmune encephalitis. ***A.*** Neurons and neuronal processes (brown cells; stained with MAP2) in the teratoma of a patient with anti-NMDA receptor encephalitis; these neurons express NMDA receptors (not shown). ***B.*** Lung cancer from a patient with anti–α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) receptor encephalitis showing expression of AMPA receptors by the neoplastic cells (brown cells). *(Panel B from M Lai et al: AMPA receptor antibodies in limbic encephalitis alter synaptic receptor location. Ann Neurol 65:424, 2009.)*

develop cerebellar symptoms and opsoclonus. Fifty percent of patients have SCLC or a neuroendocrine tumor of the lung. Patients may have additional antibodies to glutamic acid decarboxylase (GAD), which are of unclear significance. Other antibodies to nonneuronal proteins are often found in these patients as well as in patients with AMPA receptor antibodies, indicating a general tendency to autoimmunity.

Encephalitis with glycine receptor (GlyR) antibodies usually manifests with a syndrome characterized by progressive encephalomyelitis with rigidity and myoclonus (PERM) or stiff-person spectrum of symptoms. The disease usually occurs in adults and rarely in children. About 20% of adult patients have a concurrent underlying tumor (thymoma, B-cell lymphoma, breast or lung cancer) or past history of cancer (thymoma, breast, Hodgkin lymphoma, melanoma).

Encephalitis with metabotropic glutamate receptor 5 (mGluR5) antibodies is characterized by nonspecific clinical features of encephalitis (confusion, agitation, memory loss, delusions, paranoid ideation, hallucinations, psychosis, or seizures) without distinctive MRI changes and frequent association with Hodgkin's lymphoma (Ophelia syndrome). The encephalitis is highly responsive to immunotherapy and treatment of the tumor.

Encephalitis with antibodies against dopamine-2 receptor has been reported in children with basal ganglia encephalitis manifesting with abnormal movements (coarse tremor, parkinsonism, chorea, oculogyric crises) along with psychiatric features, lethargy, drowsiness, brainstem dysfunction, or ataxia. The disorder is extremely rare and is not associated with cancer.

Encephalitis with leucine-rich glioma-inactivated 1 (LGI1) antibodies predominates in patients older than 50 years (65% male) and frequently presents with short-term memory loss and seizures (limbic encephalopathy), along with hyponatremia and sleep dysfunction. The MRI often shows increased FLAIR signal in one or both medial temporal lobes. In about 40% of patients, these symptoms are preceded by faciobrachial dystonic seizures, which consist of sudden, short-lasting, mainly distal muscle contractions involving the arm, face, or leg. These are unilateral but can independently affect both sides and occur multiple times during the day or night. About 15% of patients present with rapidly progressive cognitive decline, resembling a rapidly progressive dementia. Less than 5% of patients have thymoma. An association with the human leukocyte antigen (HLA) haplotypes DRB1*07:01, DQB1*02:02, DQA1*02:01, and DRB4 has been identified in nonparaneoplastic cases. All symptoms, including faciobrachial dystonic seizures, respond to immunotherapy, although about two-thirds of patients are left with memory or cognitive deficits.

Encephalitis with contactin-associated protein-like 2 (Caspr2) antibodies predominates in patients older than 50 years and is associated with a form of encephalitis with three or more of the following core symptoms: encephalopathy, cerebellar symptoms, peripheral nervous system hyperexcitability, dysautonomia, insomnia, neuropathic pain, and weight loss. Patients with Morvan's syndrome, which includes clinical features of encephalitis (confusion, hallucinations, prominent sleep dysfunction, or "agrypnia excitata"), autonomic alterations, and peripheral nerve hyperexcitability or neuromyotonia, usually have Caspr2 antibodies. About 20% of patients with Caspr2 antibody–associated syndromes have thymoma; this percentage is higher (~40%) in patients with Morvan's syndrome. An association of Caspr2 antibody–associated syndromes with HLA DRB1*11.01 has been reported.

Encephalitis with dipeptidyl-peptidase-like protein-6 (DPPX) antibodies is usually preceded or develops concurrently with diarrhea, other gastrointestinal symptoms, and substantial loss of weight that often suggest the presence of a gastrointestinal disease. Neurologic symptoms include agitation, hallucinations, paranoid delusions, and features of CNS hyperexcitability such as tremor, myoclonus, nystagmus, seizures, or hyperekplexia. Some patients develop a clinical picture similar to progressive encephalomyelitis with rigidity and myoclonus. The few patients reported with an associated tumor all had B-cell neoplasms.

Encephalitis with antibodies against neurexin 3 alpha does not have distinctive clinical features; the experience is limited, and the disorder does not appear to be associated with cancer.

Anti-IgLON5 disease is a chronic or subacute encephalopathy that characteristically is associated with rapid eye movement (REM) and non-REM (NREM) parasomnia that may be preceded or accompanied by bulbar symptoms, gait abnormalities, movement disorders (chorea, distal myoclonus, tremor, dystonia, or spasms), oculomotor dysfunction, and, in less than half of cases, cognitive decline. The median age of the patients is in the early 60s, and men and women are equally affected. The sleep disorder is characterized by abnormal sleep initiation with undifferentiated NREM sleep associated with frequent vocalizations and quasi-purposeful movements. Examination of the CSF and MRI is unrevealing or demonstrates minor changes of unclear clinical relevance. It is not associated with cancer but shows a strong association with HLA-DRB1*10:01 and HLA-DQB1*05:01. The response to immunotherapy is poor. Neuropathologic studies often show a neuronal tauopathy predominantly involving the hypothalamus and tegmentum of the brainstem.

With the exception of patients with anti-IgLON5 disease, who rarely respond to treatment, most patients with autoimmune or

paraneoplastic encephalopathies associated with antibodies against cell-surface or synaptic proteins respond to immunotherapy and treatment of the tumor (if appropriate). Although there are no specific standardized treatment protocols, the most frequent approach consists of progressive escalation of immunotherapy using first a combination of glucocorticoids, IVIg, and plasma exchange, and then, if there is no response, rituximab or cyclophosphamide.

Encephalitis with myelin oligodendrocyte glycoprotein (MOG) antibodies can present with a clinical picture suggestive of autoimmune encephalitis related to neuronal antibodies. Most patients with MOG antibody–associated syndromes are children and young adults who present with optic neuritis, myelitis, or acute disseminated encephalomyelitis (ADEM). About 85% of patients with these syndromes respond to immunotherapy, although relapses occur in about 30% of cases. Besides these syndromes, there is a small group of adults and children that present with unilateral or bilateral cortical encephalitis, and their response to treatment is variable. In children, two phenotypes of poor prognosis include ADEM-like relapses progressing to leukodystrophy-like features and extensive cortical encephalitis evolving to atrophy **(Fig. 94-2*D*)**. In general, MOG antibody syndromes are not associated with tumors.

PARANEOPLASTIC CEREBELLAR DEGENERATION

This disorder is often preceded by a prodrome that may include dizziness, oscillopsia, blurry or double vision, nausea, and vomiting. A few days or weeks later, patients develop dysarthria, gait and limb ataxia, and variable dysphagia. The examination usually shows downbeating nystagmus and, rarely, opsoclonus. Brainstem dysfunction, upgoing toes, or a mild neuropathy may occur. Early in the course, MRI studies are usually normal; later, the MRI reveals cerebellar atrophy. The disorder results from extensive degeneration of Purkinje cells, with variable involvement of other cerebellar cortical neurons, deep cerebellar nuclei, and spinocerebellar tracts. The tumors more frequently involved are SCLC, cancer of the breast and ovary, and Hodgkin's lymphoma.

Anti-Yo (PCA1) antibodies in patients with breast or gynecologic cancers typically are associated with prominent or pure cerebellar degeneration. A variable degree of cerebellar dysfunction can be associated with virtually any of the antibodies and PND of the CNS shown in Table 94-2. A number of single case reports have described neurologic improvement after tumor removal, plasma exchange, IVIg, cyclophosphamide, rituximab, or glucocorticoids. However, most patients with paraneoplastic cerebellar degeneration and any of the antibodies shown in Table 94-2 do not improve with treatment.

A cerebellar syndrome can also occur with antibodies against cell-surface or synaptic proteins, including P/Q-type voltage-gated calcium channels (VGCC), Tr (DNER), mGluR2, or Sez6l2 (Table 94-3). The frequency and type of tumor association vary with the type of antibody. The cerebellar syndrome of patients with mGluR1 antibodies is highly responsive to treatment of the tumor and immunotherapy, whereas the syndrome of patients with Tr or VGCC antibodies is less treatment responsive. The experience with mGluR2 and Sez6l2 is limited to a few patients, but mGluR2 antibody–associated cerebellar symptoms seem to be highly responsive to treatment. Patients with GluK2 antibodies can present with cerebellitis and posterior fossa edema with compression of the 4th ventricle; the syndrome is potentially treatable with immunotherapy.

PARANEOPLASTIC OPSOCLONUS-MYOCLONUS SYNDROME

Opsoclonus is a disorder of eye movement characterized by involuntary, chaotic saccades that occur in all directions of gaze; it is frequently associated with myoclonus and ataxia. Opsoclonus-myoclonus may be cancer-related or idiopathic. When the cause is paraneoplastic, the tumors involved are usually cancer of the lung and breast in adults, neuroblastoma in children, and ovarian teratoma in adolescents and young women. The pathologic substrate of opsoclonus-myoclonus is unclear, but studies suggest that disinhibition of the fastigial nucleus of the cerebellum is involved. Most patients do not have antineuronal antibodies. A small subset of patients with ataxia, opsoclonus, and other eye-movement disorders develop Ri antibodies; these patients may also develop muscle rigidity, laryngeal spasms, and autonomic dysfunction. The tumors most frequently involved in anti-Ri-associated syndromes are breast, ovarian, and lung cancers. If the tumor is not successfully treated, the syndrome in adults often progresses to encephalopathy, coma, and death. In addition to treating the tumor, symptoms may respond to immunotherapy (glucocorticoids, plasma exchange, and/or IVIg).

At least 50% of children with opsoclonus-myoclonus have an underlying neuroblastoma. Hypotonia, ataxia, behavioral changes, and irritability are frequent accompanying symptoms. Neurologic symptoms often improve with treatment of the tumor and glucocorticoids, adrenocorticotropic hormone (ACTH), plasma exchange, IVIg, rituximab, or cyclophosphamide. Many patients are left with psychomotor retardation and behavioral and sleep problems.

PARANEOPLASTIC SYNDROMES OF THE SPINAL CORD

The number of reports of paraneoplastic spinal cord syndromes, such as *subacute motor neuronopathy* and *acute necrotizing myelopathy*, has decreased in recent years. This may represent a true decrease in incidence, due to improved and prompt oncologic interventions, or the identification of nonparaneoplastic etiologies. Some patients with cancer or lymphoma develop *upper* or *lower motor neuron dysfunction* or both, resembling amyotrophic lateral sclerosis. It is unclear whether these disorders have a paraneoplastic etiology or simply coincide with the presence of cancer.

Paraneoplastic myelitis may present with upper or lower motor neuron symptoms, segmental myoclonus, sensory deficits, sphincter dysfunction, and neurogenic pruritus and can be the first manifestation of encephalomyelitis. The spine MRI usually shows longitudinally extensive, symmetric tract or gray matter abnormalities in the spinal cord. It is mainly associated with breast and lung carcinomas and with CRMP5 or amphiphysin antibodies. The prognosis is poor. *Neuromyelitis optica (NMO) with aquaporin 4 antibodies* may occur in rare instances as a paraneoplastic manifestation of a cancer. NMO is discussed in detail in **Chap. 445**.

PARANEOPLASTIC STIFF-PERSON SYNDROME

This disorder is characterized by progressive muscle rigidity, stiffness, and painful spasms triggered by auditory, sensory, or emotional stimuli. Rigidity mainly involves the lower trunk and legs, but it can affect the upper extremities and neck. Sometimes, only one extremity is affected (*stiff-limb syndrome*). Symptoms improve with sleep and general anesthetics. Electrophysiologic studies demonstrate continuous motor unit activity. The associated antibodies target proteins (GAD, amphiphysin) involved in the function of inhibitory synapses using γ-aminobutyric acid (GABA) or glycine as neurotransmitters. The presence of amphiphysin antibodies usually indicates a paraneoplastic etiology related to SCLC and breast cancer. By contrast, GAD antibodies may occur in some cancer patients but are much more frequently present in the nonparaneoplastic disorder. GlyR antibodies may occur in some patients with stiff-person syndrome; these antibodies are more frequently detectable in patients with PERM **(Fig. 94-5)**.

Optimal treatment of stiff-person syndrome requires therapy of the underlying tumor, glucocorticoids, and symptomatic use of drugs that enhance GABA-ergic transmission (diazepam, baclofen, sodium valproate, tiagabine, vigabatrin). IVIg and plasma exchange are transiently effective in some patients, and there are reports of responses to rituximab in patients who did not respond to other treatments.

PARANEOPLASTIC SENSORY NEURONOPATHY OR DORSAL ROOT GANGLIONOPATHY

This syndrome is characterized by sensory deficits that may be symmetric or asymmetric, painful dysesthesias, radicular pain, and decreased or absent reflexes. All modalities of sensation and any part of the body including face and trunk can be involved. Special senses such as taste and hearing can also be affected. Electrophysiologic studies show decreased or absent sensory nerve potentials with normal or

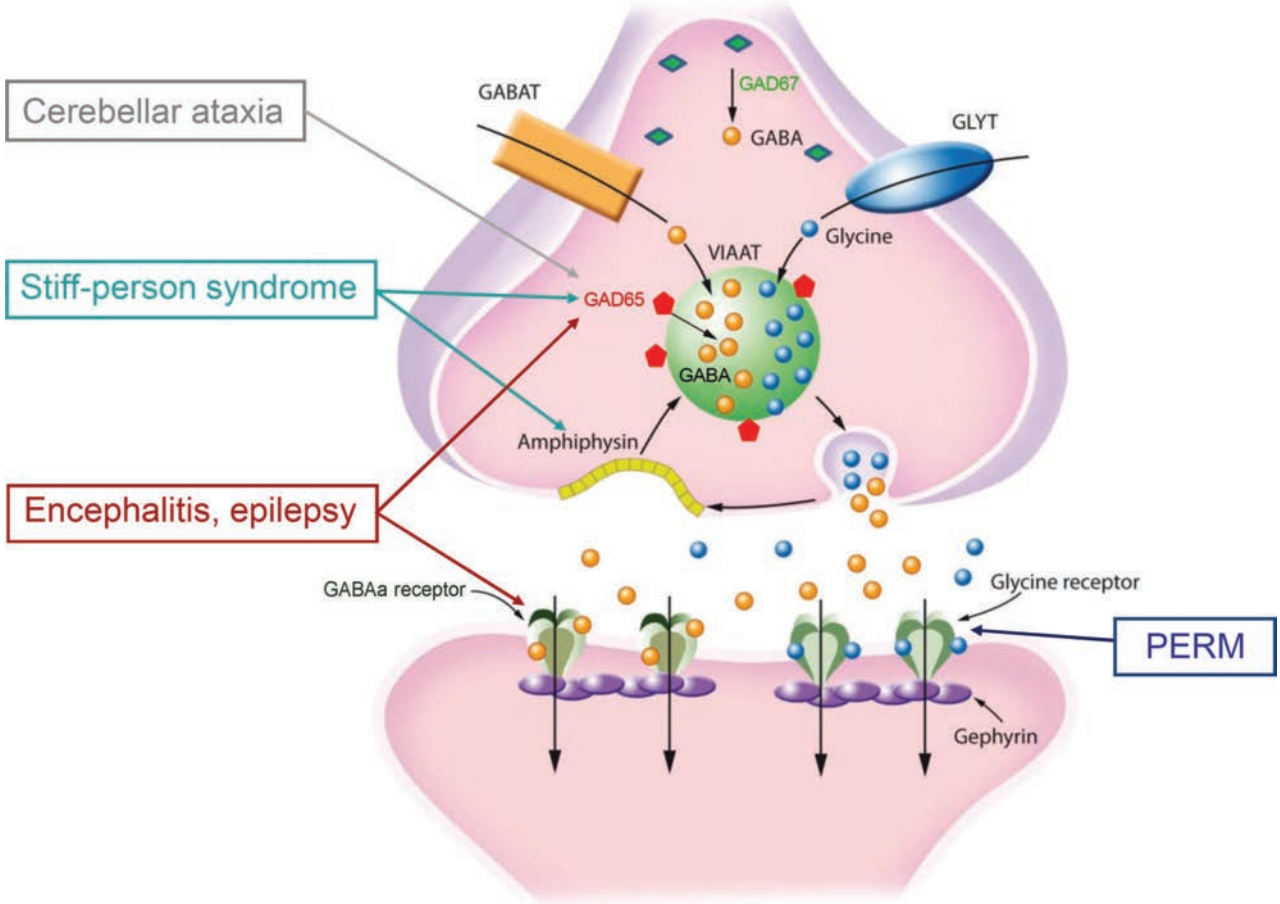

FIGURE 94-5 Schematic representation of an inhibitory synapse showing the main autoimmune targets (GAD, amphiphysin, GABA receptor, and glycine receptor) and the corresponding neurologic disorders. GAD antibodies predominantly occur in stiff-person syndrome (SPS), cerebellar ataxia, and epilepsy, sometimes in the setting of encephalitis. Amphiphysin antibodies are markers of paraneoplastic SPS and breast cancer, GlyR antibodies often associate with progressive encephalomyelitis with rigidity and myoclonus (PERM), and $GABA_A$ receptor antibodies occur in a form of autoimmune encephalitis that is frequently associated with refractory seizures and status epilepticus. *(Modified from F Graus et al: Nat Rev Neurol 16:353, 2020.)*

near-normal motor conduction velocities. Symptoms result from an inflammatory, likely immune-mediated, process that targets the dorsal root ganglia, causing neuronal loss and secondary degeneration of the posterior columns of the spinal cord. The dorsal and, less frequently, the anterior nerve roots and peripheral nerves may also be involved. This disorder often precedes or is associated with encephalomyelitis and autonomic dysfunction and has the same immunologic and oncologic associations (Hu antibodies, SCLC).

As with anti-Hu-associated encephalomyelitis, the therapeutic approach focuses on prompt treatment of the tumor and cytotoxic T-cell–mediated mechanisms. Glucocorticoids occasionally produce clinical stabilization or improvement. The benefit of IVIg and plasma exchange is not proven.

PARANEOPLASTIC PERIPHERAL NEUROPATHIES

These disorders may develop any time during the course of the neoplastic disease. Neuropathies occurring at late stages of cancer or lymphoma usually cause mild to moderate sensorimotor deficits due to axonal degeneration of unclear etiology. These neuropathies are often masked by concurrent neurotoxicity from chemotherapy and other cancer therapies. In contrast, the neuropathies that develop in the early stages of cancer frequently show a rapid progression, sometimes with a relapsing and remitting course, and evidence of inflammatory infiltrates and axonal loss or demyelination. If demyelinating features predominate **(Chaps. 446** and **447)**, IVIg, plasma exchange, or glucocorticoids may improve symptoms. Occasionally, CRMP5 antibodies are present; detection of anti-Hu suggests concurrent dorsal root ganglionitis.

Guillain-Barré syndrome **(Chap. 447)** and *brachial plexitis* **(Chap. 446)** have occasionally been reported in patients with Hodgkin's lymphoma, but there is no clear evidence of a paraneoplastic association.

Diseases associated with monoclonal gammopathies such as multiple myeloma, osteosclerotic myeloma, cryoglobulinemia, amyloidosis, Waldenström's macroglobulinemia, or POEMS (polyneuropathy, organomegaly, endocrinopathy, M-protein spike, and skin manifestations) syndrome, among others, may cause neuropathy by a variety of mechanisms, including compression of roots and plexuses by metastasis to vertebral bodies and pelvis, by deposits of amyloid in peripheral nerves, or through a direct interaction of the abnormal immunoglobulin with peripheral nerve antigens. In other patients, the mechanisms underlying the neuropathy remain unknown and paraneoplastic immune-mediated mechanisms have not been ruled out. Neuropathies more often occur with IgM gammopathies followed by IgG and IgA. The phenotype of the neuropathy and likelihood of improvement with successful treatment of the gammopathy are dependent on the underlying hematologic disorder **(Chap. 447)**.

Vasculitis of the nerve and muscle causes a painful symmetric or asymmetric distal axonal sensorimotor neuropathy with variable proximal weakness. It predominantly affects elderly men and is associated with an elevated erythrocyte sedimentation rate and increased CSF protein concentration. SCLC and lymphoma are the primary tumors involved. Glucocorticoids and cyclophosphamide often result in neurologic improvement.

Peripheral nerve hyperexcitability (*neuromyotonia,* or *Isaacs' syndrome*) is characterized by spontaneous and continuous muscle fiber activity of peripheral nerve origin. Clinical features include cramps, muscle twitching (fasciculations or myokymia), stiffness, delayed muscle relaxation (pseudomyotonia), and spontaneous or evoked

carpal or pedal spasms. The involved muscles may be hypertrophic, and some patients develop paresthesias and hyperhidrosis. The electromyogram (EMG) shows fibrillations; fasciculations; and doublet, triplet, or multiplet single-unit (myokymic) discharges that have a high intraburst frequency. Some patients have Caspr2 antibodies usually in the context of Morvan's syndrome, but most patients with isolated neuromyotonia are antibody negative. The disorder often occurs without cancer; if paraneoplastic, benign and malignant thymomas and SCLC are the usual tumors. Phenytoin, carbamazepine, and plasma exchange improve symptoms.

Paraneoplastic autonomic neuropathy usually develops as a component of other disorders, such as LEMS and encephalomyelitis. It may rarely occur as a pure or predominantly autonomic neuropathy with cholinergic or adrenergic dysfunction at the pre- or postganglionic levels. Patients can develop several life-threatening complications, such as gastrointestinal paresis with pseudo-obstruction, cardiac dysrhythmias, and postural hypotension. Other clinical features include abnormal pupillary responses, dry mouth, anhidrosis, erectile dysfunction, and problems in sphincter control. The disorder occurs in association with several tumors, including SCLC, cancer of the pancreas or testis, carcinoid tumors, and lymphoma. Because autonomic symptoms can be the presenting feature of encephalomyelitis, serum Hu and CRMP5 antibodies should be sought. Antibodies to ganglionic (α3-type) neuronal acetylcholine receptors are the cause of autoimmune autonomic ganglionopathy, a disorder that frequently occurs without cancer association **(Chap. 440)**.

LAMBERT-EATON MYASTHENIC SYNDROME

LEMS is discussed in **Chap. 448**.

MYASTHENIA GRAVIS

Myasthenia gravis is discussed in **Chap. 448**.

POLYMYOSITIS-DERMATOMYOSITIS

Polymyositis and dermatomyositis are discussed in detail in **Chap. 365**.

IMMUNE-MEDIATED NECROTIZING MYOPATHY

Patients with this syndrome develop myalgias and rapid progression of weakness involving the extremities, neck, pharyngeal, respiratory, and sometimes cardiac muscles. Serum muscle enzymes are elevated, and muscle biopsy shows extensive necrosis with minimal or absent inflammation and sometimes deposits of complement. The disorder may occur without cancer association (sometimes as a result of statin exposure, connective tissue disease, or HIV) or with cancer association. Patients with antibodies against 3-hydroxy-3-methylglutaryl-coenzyme A reductase (HMGCR) and seronegative patients are more likely to have an underlying cancer than those with antibodies against signal recognition particle. No specific type of cancer has been found to be predominant. Successful treatment of the tumor and aggressive immunotherapy (steroids, IVIg, and steroid-sparing immunosuppressants) may lead to complete or substantial recovery. Immune-mediated necrotizing myopathy is discussed in **Chap. 365**.

PARANEOPLASTIC VISUAL SYNDROMES

This group of disorders involves the retina and, less frequently, the uvea and optic nerves. The term *cancer-associated retinopathy* is used to describe paraneoplastic cone and rod dysfunction characterized by photosensitivity, progressive loss of vision and color perception, central or ring scotomas, night blindness, and attenuation of photopic and scotopic responses in the electroretinogram (ERG). The most commonly associated tumor is SCLC. Melanoma-associated retinopathy affects patients with metastatic cutaneous melanoma. Patients develop acute onset of night blindness and shimmering, flickering, or pulsating photopsias that often progress to visual loss. The ERG shows reduced b-waves with normal dark adapted a-waves. Paraneoplastic optic neuritis and uveitis can develop in association with encephalomyelitis. Patients with paraneoplastic uveitis and optic neuritis may harbor CRMP5 antibodies.

Some paraneoplastic retinopathies are associated with serum antibodies that specifically react with the subset of retinal cells undergoing degeneration, supporting an immune-mediated pathogenesis (Table 94-2). Paraneoplastic retinopathies rarely show substantial improvement after treatment of the tumor and immunotherapy; however, stabilization of symptoms and partial responses to a variety of immunotherapies (glucocorticoids, plasma exchange, IVIg, rituximab, or alemtuzumab) have been reported.

95 Cancer Survivorship and the Long-Term Impact of Cancer and Its Treatment

Mark Roschewski, Dan L. Longo

The impact of cancer extends well past initial diagnosis. Patients are significantly affected by cancer and treatment-related toxicities often extending beyond the initial treatment period. Adult survivors of childhood, adolescent, and young adult cancer face special health consequences of cancer treatment related to premature physiologic aging and frailty. More than 40% of these patients will experience a severe, disabling, or life-threatening condition or die of a chronic condition. Long-term effects include toxicities that emerge during therapy and continue beyond treatment, while late effects include toxicities that may not emerge for months or years after treatment. Significant improvements in cancer treatments have enabled more people to survive once-deadly diseases, leading to more cancer survivors subjected to the potential long-term impact of cancer treatment (**Table 95-1** lists potential long-term and late effects of cancer therapy by organ system). The direct causality of emerging treatments may not be immediately evident, and pharmacovigilance remains critical after treatments first become approved.

TABLE 95-1 Organ Systems at Risk for Long-Term and Late Effects of Cancer Treatment

ORGAN SYSTEM	LONG-TERM EFFECTS	LATE EFFECTS
Cardiovascular	Congestive heart failure Arrhythmias Pericardial disease Myocarditis Hypertension	Congestive heart failure Arrhythmias Coronary artery disease Peripheral vascular disease Cardiac valvular disease
Pulmonary	Pneumonitis	Pulmonary fibrosis Radiation recall pneumonitis
Immunologic	Opportunistic infections Autoimmune disease	Second malignancies Myelodysplasia Recurrent infections Autoimmune disease
Endocrine	Fractures Hypopituitarism Avascular necrosis Diabetes insipidus	Gonadal dysfunction/infertility Premature ovarian insufficiency Sarcopenia Diabetes Osteoporosis Thyroid disorders
Neurologic	Peripheral sensorimotor neuropathy Myelopathy Hearing loss	Cognitive impairment
Gastrointestinal	Malabsorption Colitis Chronic liver disease	Chronic diarrhea Small bowel obstruction Gastrointestinal stricture
Genitourinary	Chronic renal failure	Hemorrhagic cystitis Ureteral stricture
Psychological	Anxiety Depression	Mood disorders Posttraumatic stress disorder Sexual dysfunction Substance abuse disorders Financial hardship Psychosocial dysfunction

In the United States, the number of cancer survivors may increase from 17 million to nearly 26 million by the year 2040, and the number of patients who survive at least 5 years after initial diagnosis is expected to increase by 35% over the next decade. Improvements in cancer treatments for children and adolescents have led to modern 5-year survival rates of approximately 80% or greater. Despite the magnitude of the growing problem, the core issues related to cancer survivorship remain understudied and the research is often concentrated in highly prevalent cancers. Most studies are observational and descriptive with fewer studies focused on the prevention and treatment of complications. Cancer survivorship remains an area that is ripe for further discovery; a deeper understanding of the biological basis and/or the influence of genetics on host susceptibility and the long-term effects of cancer therapy is needed.

Our primary understanding of the long-term impact of cancer treatment originated from survivors of childhood malignancies who are often cured after treatment with a combination of chemotherapy, radiation, and surgery. Treatment paradigms for cancer continuously evolve, however, and newer treatments including targeted agents and immunotherapy have introduced unique long-term effects, particularly when these agents are administered indefinitely (**Table 95-2** lists the potential long-term effects of specific cancer treatments). Improvements in the tolerability of cancer therapy and in supportive care have allowed a greater number of patients with comorbid conditions and advanced age to receive treatment, which has increased the rate of chronic morbidity. Approximately 60% of current cancer survivors are older than age 65. Indeed, the cause-specific mortality following initial treatment of Hodgkin lymphoma includes nearly 40% of deaths attributed to nonlymphoma causes. Indeed, more patients diagnosed with Hodgkin lymphoma die from treatment-related late toxicity than from Hodgkin lymphoma. Individuals aged 60–74 have a disproportionate excess of deaths related to heart disease, lung disease, infections, and adverse effects of drugs. The complexities of cancer survivorship and the importance of longitudinal care of cancer patients are recognized as vital components to comprehensive cancer care, and model systems have been specifically developed for this purpose. Still, the primary goal of cancer therapy remains long-term disease control, and the treating physician must maintain proper perspective when considering these relative risks. The fear of long-term complications should not prevent the application of effective cancer treatment, particularly when delivered with curative intent. In a sense, managing long-term effects is a privilege only afforded those fortunate enough to overcome the initial threat to life represented by the cancer diagnosis.

CARDIOVASCULAR DYSFUNCTION

The excess risks of cardiovascular disease after anthracycline chemotherapy and radiation that involves the mediastinum are well characterized and include arrhythmias, cardiac ischemia, congestive heart failure (CHF), pericardial disease, myocarditis, and peripheral vascular disease. It is estimated that one in eight childhood cancer survivors will experience a life-threatening cardiovascular event within 30 years after initial exposure, and cardiovascular disease is the most common cause of noncancer death in this population. Newer targeted agents and immunotherapy have introduced additional cardiovascular risks that extend into older populations as well. A new discipline of cardio-oncology has been developed to better characterize individuals at high risk for treatment-related cardiac toxicities, develop surveillance strategies, and improve the management of long-term effects.

Radiation therapy that includes the heart can cause interstitial myocardial fibrosis, acute and chronic pericarditis, valvular disease, and accelerated premature atherosclerotic coronary artery disease. Repeated or high (>6000 cGy) radiation doses are associated with greater risk, as is concomitant cardiotoxic cancer chemotherapy exposure. Symptoms of acute pericarditis peak about 9 months after treatment and include dyspnea, chest pain, and fever. Chronic constrictive pericarditis may develop 5–10 years following radiation therapy. Cardiac valvular disease includes aortic insufficiency from fibrosis or papillary muscle dysfunction resulting in mitral regurgitation. Extensive radiation fields are associated with accelerated coronary artery disease and peripheral vascular disease and a markedly increased risk of fatal myocardial infarction or thromboembolic stroke. Three-dimensional conformal techniques and newer particles including proton beams may more precisely target the tumor and spare normal tissue, but these are not widely available and the degree to which they will decrease long-term cardiovascular effects is unknown. In recognition of the risks of radiation, careful planning procedures are performed before treatment designed to limit the field of radiation to the greatest extent possible.

The myocardial toxicity of anthracyclines is dose-dependent and is associated with the pathognomonic finding of myofibrillar dropout on endomyocardial biopsy. Anthracycline cardiotoxicity occurs through a root mechanism of chemical free radical damage. Fe^{3+}-doxorubicin complexes damage DNA, nuclear and cytoplasmic membranes, and mitochondria. These cardiotoxic effects may also be mediated by topoisomerase IIB. Approximately 5% of patients receiving >450–550 mg/m^2 total dose of doxorubicin will develop CHF, but it can also develop at substantially lower doses in some patients. Anthracycline-related CHF is often irreversible and carries a high mortality rate, making prevention crucial. Genome-wide association studies have identified multiple genetic polymorphisms associated with a higher risk of cardiotoxicity, but our ability to risk-stratify is limited. The risk of cardiac failure appears to be related to the route of administration, and regimens that use continuous infusion of doxorubicin or liposomally encapsulated doxorubicin are associated with less cardiotoxicity. Baseline assessment of cardiac function with multigated acquisition scan (MUGA) or

TABLE 95-2 Long-Term Effects of Cancer Treatment by Type of Therapy

THERAPY TYPE	LONG-TERM EFFECT
Radiation	Second malignancies
	Coronary artery disease
	Pericardial disease
	Peripheral vascular disease
	Cardiac valvular disease
	Neurocognitive impairment
	Hypopituitarism and infertility
	Hypothyroidism and reduced bone density
	Gastrointestinal stricture
	Hepatic venoocclusive disease
Chemotherapy and Hormonal Agents	
Anthrayclines, trastuzumab, cyclophosphamide	Congestive heart failure
Bleomycin, oxaliplatin, 5-fluorouracil	Pulmonary fibrosis
Nitrosoureas, methotrexate, fludarabine, brentuximab	Pneumonitis
Alkylating agents, anthracyclines, tamoxifen, bendamustine, platinum agents	Second malignancies/myelodysplasia
Bendamustine, alkylating agents, anthracyclines	Immune dysfunction and recurrent infections
Alkylating agents	Infertility
Cyclophosphamide, Ifosfamide	Hemorrhagic cystitis
Platinum agents	Renal tubular dysfunction
Vinca alkaloids, taxanes, platinum agents	Neuropathy
Cytarabine	Ataxia
Aromatase inhibitors	Vasomotor symptoms
Antiandrogens	Sexual dysfunction
Immunotherapy Agents	
Immune checkpoint inhibitors	Autoimmune conditions/autoimmune hepatitis
Immune checkpoint inhibitors	Pericarditis and fulminant myocarditis
CAR-T therapy	Congestive heart failure
CAR-T therapy	Arrhythmias
CAR-T therapy, bi-specific monoclonal antibodies, immune checkpoint inhibitors	Peripheral neuropathy
CAR-T therapy, bi-specific monoclonal antibodies	B-cell aplasia
Targeted Agents	
Immunomodulatory agents	Second cancers/leukemia
Proteasome inhibitors	Peripheral neuropathy
Anti-CD20 agents, immunomodulatory agents	Neutropenia
BTK inhibitors, ALK inhibitors	Atrial and ventricular arrhythmias
PI3K inhibitors, CDK inhibitors	Hepatitis, colitis
Gemtuzumab	Sinusoidal obstruction syndrome
EGFR inhibitors, anti-VEGF agents, BCR-ABL inhibtors, MEK inhibitors, proteasome inhibitors	Congestive heart failure
BCR-ABL inhibitors	Pleural effusions, pancreatitis
BCR-ABL inhibitors, PI3K inhibitors, BTK inhibitors, immunomodulatory agents, EGFR inhibitors	Chronic diarrhea
BCR-ABL inhibitors	Impaired growth and stature
Anti-VEGF agents, BCR-ABL inhibitors	Thyroid dysfunction
PI3K inhibitors, mTOR inhibitors, BRAF inhibitors	Hyperglycemia
FLT3 inhibitors, anti-VEGF agents, PI3K inhibitors	Systemic hypertension
Anti-VEGF agents, BCR-ABL inhibitors	Pulmonary hypertension

Abbreviation: CAR-T, chimeric antigen receptor T cell.

transthoracic echocardiograms is commonly performed, and a patient who develops symptoms suggestive of CHF should be tested immediately while therapy is held. Periodic surveillance testing during therapy is often done in asymptomatic patients with preexisting risk factors.

Trastuzumab is a monoclonal antibody targeting human epidermal growth factor receptor 2 (HER2) that is also associated with CHF. It is used in combination with chemotherapy as both adjuvant therapy and as treatment of metastatic breast cancer, and it is sometimes combined with anthracyclines, which is believed to result in additive or possibly synergistic toxicity. In contrast to anthracyclines, cardiotoxicity is not dose related, is usually reversible, is not associated with pathologic changes on cardiac myofibrils, and has a different biochemical mechanism inhibiting intrinsic cardiac repair mechanisms. Monitoring for cardiac toxicity is typically performed every three or four doses using functional cardiac testing, and treatment is interrupted when ejection fractions significantly decline from baseline. Other potentially

cardiotoxic chemotherapy agents include phosphoramide mustards (cyclophosphamide) at high doses and ifosfamide.

Small-molecule inhibitors, including tyrosine kinase inhibitors, are novel classes of molecularly targeted anticancer agents that have become routinely applicable across a variety of malignancies. Although the overall tolerability of these drugs is often better than chemotherapy, they are frequently administered indefinitely, which introduces new notions of cumulative long-term effects. These agents also carry risks of cardiovascular toxicities including CHF, atrial and ventricular arrhythmias, prolongation of the QT interval, and pulmonary and systemic hypertension. New anticancer agents often become available for use on accelerated approvals before a full understanding of the long-term toxicity profile is known. Two illustrative examples of this are lapatinib and ponatinib, which both had their approvals updated with black box cardiovascular toxicity warnings a median of 4 years after initial drug approval. Other small-molecule inhibitors that have been associated with CHF include bosutinib, dasatinib, nilotinib, pazopanib, axitinib, trametinib, sunitinib, carfilzomib, and sorafenib. Systemic hypertension is commonly associated with agents targeting vascular endothelial growth factor or its receptors (e.g., bevacizumab, cabozantinib, lenvatinib, nintedanib), ponatinib (an Abl inhibitor), and trametinib (a MEK inhibitor), whereas dasatinib (an Abl inhibitor) has a well-documented association with pulmonary hypertension. Ibrutinib (a BTK inhibitor) has been associated with atrial fibrillation as well as ventricular arrythmias. As more of these small-molecule inhibitors become approved for use and their indications broaden, additional monitoring for long-term and late effects should be incorporated into the routine surveillance of oncologists, cardiologists, and primary care providers.

Immunotherapy agents have also emerged as effective anticancer therapies that have substantially improved clinical outcomes in a variety of cancers. Immune checkpoint inhibitors have been associated with a number of important cardiovascular toxicities including pericardial disease, vasculitis, and fulminant myocarditis. The mechanism of these toxicities is T cell mediated, and the toxicities often respond to early institution of glucocorticoids, but they can be severe or fatal if not recognized promptly. Combinations of multiple immune checkpoint inhibitors increase the risk of these immune-related toxicities, and no clear pattern of which patients are most susceptible has emerged. Chimeric antigen receptor T-cell (CAR-T) therapies are associated with cytokine release syndromes (CRS), which can be severe and associated with arrhythmias or decompensated heart failure. Interleukin 6 receptor blockers may decrease these risks, and supportive care guidelines recommend early institution of these agents in severe CRS.

The management of treatment-associated cardiovascular disease is essentially the same as for cardiac disease unrelated to cancer treatment. Discontinuation of the offending agent is the first step. Diuretics, fluid and sodium restriction, and antiarrhythmic agents are often useful for acute symptoms. Afterload reduction with angiotensin-converting enzyme inhibitors or β-adrenergic blockers may improve systolic function over time, and digitalis may improve symptoms. Routine screening for asymptomatic systolic dysfunction is currently recommended for survivors at high risk for cardiomyopathy including those with an anthracycline exposure ≥250 mg/m^2, ≥35 Gy of chest radiation, or combined therapy with both anthracyclines and radiation. Echocardiography is the recommended screening modality, and surveillance should begin no later than 2 years after exposure and should be repeated a minimum of every 5 years thereafter.

PULMONARY DYSFUNCTION

Radiation-induced lung injury presents in early phases as acute pneumonitis at 4 weeks following treatment, but it can evolve into pulmonary fibrosis in late phases. Risk factors for radiation pneumonitis include advanced age, smoking, poor performance status, preexisting compromised pulmonary function, and radiation volume and dose. It occurs most commonly in patients with lung cancer, mediastinal lymphoma, and breast cancer, and the incidence is decreasing due to advances in radiation delivery techniques. The dose "threshold" is thought to be in the range of 5–20 Gy. Hypoxemia and dyspnea on exertion are characteristic, and the severity of symptoms may be out of proportion to the lung volume irradiated. Fine, high-pitched "Velcro rales" may be an accompanying physical finding, and fever, cough, and pleuritic chest pain are common symptoms. The diffusion capacity of the lungs for carbon dioxide (D_{LCO}) is the most sensitive measure of pulmonary functional impairment, and ground-glass infiltrates often correspond with relatively sharp edges to the irradiated volume, although the pneumonitis may progress beyond the field and even occasionally involve the contralateral unirradiated lung. The mechanism of lung injury is a direct effect of radiation that leads to increased capillary permeability and pulmonary edema. Damage to type I and II pneumocytes leads to surfactant loss and the transudation of serum proteins into the alveoli. Cytokines including tumor necrosis factor α are released from the damaged lung cells and attract inflammatory cells to the alveoli and interstitial space. The late phases of injury are caused by reactive oxygen species that stimulate collagen production and lead to fibrosis but do not occur in all cases. Transforming growth factor β (TGF-β) is particularly important in stimulating collagen synthesis and may represent a therapeutic target to prevent pulmonary fibrosis.

Bleomycin generates activated free radical oxygen species and causes pneumonitis associated with a radiographic or interstitial ground-glass appearance diffusely throughout both lungs, often worse in the lower lobes. A nonproductive cough with or without fever may be an early sign. This toxicity is dose-related and dose-limiting. The D_{LCO} is a sensitive measure of toxicity and recovery, and a baseline value is generally obtained for future comparison before administering bleomycin therapy. Doses are reduced or stopped if the baseline D_{LCO} falls 25% or more. Additive or synergistic risk factors include age, prior lung disease, and concomitant use of other chemotherapy, lung irradiation, and high concentrations of inspired oxygen. Other chemotherapeutic agents notable for pulmonary toxicity include mitomycin, nitrosoureas, doxorubicin with radiation, gemcitabine combined with weekly docetaxel, methotrexate, and fludarabine. High-dose alkylating agents, cyclophosphamide, ifosfamide, and melphalan are frequently used in the hematopoietic stem cell transplant setting, often with whole-body radiation. This therapy may result in severe pulmonary fibrosis and/or pulmonary venoocclusive disease.

Radiation-induced lung injury and chemotherapy-induced pneumonitis are generally glucocorticoid responsive, except in the case of nitrosoureas. Prednisone 1 mg/kg is often used to control acute symptoms and prevent pulmonary dysfunction with a slow taper over 12 weeks. Prolonged glucocorticoid therapy requires gastrointestinal protection with proton pump inhibitors, management of hyperglycemia, heightened infection management, and prevention or treatment of steroid-induced osteoporosis. Antibiotics, bronchodilators, oxygen in only lowest necessary doses, and diuretics may all play an important role in management of pneumonitis, and consultation with a pulmonologist should be routinely undertaken. Relapses can occur after an initial response to glucocorticoids and may respond to agents such as azathioprine or cyclosporine. Amifostine is a free radical scavenger and radioprotective agent that reduces the rate of pneumonitis, but it is associated with severe nausea and hypotension that limit its use. No effective therapy exists for pulmonary fibrosis, and the treatment is primarily supportive with supplemental oxygen. Targeted anti-inflammatory agents are being tested to reduce the incidence of pulmonary fibrosis, but they remain experimental.

Pulmonary toxicity resulting from targeted anticancer agents including small-molecule inhibitors and immunotherapy agents is uncommon but can be potentially life-threatening and often lead to drug discontinuation. Noninfectious pneumonitis is associated with cough, dyspnea, and infiltrates on chest imaging and has been reported to be associated with sunitinib, sorafenib, epidermal growth factor receptor (EGFR) inhibitors (cetuximab, afatinib), crizotinib (ALK inhibitor), phosphoinositide 3-kinase (PI3K) inhibitors (idelalisib, copanlisib), and mammalian target of rapamycin (mTOR) inhibitors (everolimus, temsirolimus). The antibody-drug conjugate brentuximab vedotin may also cause severe pulmonary toxicity when used in combination with other chemotherapy agents, particularly bleomycin. The onset of drug-induced pneumonitis can be rapid, and prompt use

of glucocorticoids is important once infectious causes are excluded. Severe pneumonitis is typically a reason to discontinue the offending drug permanently.

IMMUNE SYSTEM DYSFUNCTION

A significant risk of most anticancer treatment is hematologic toxicity with cumulative effects on the host immune system leading to a higher risk of second malignancies and impaired long-term immune health. Second malignancies in cancer survivors are a major cause of death, and survivors of childhood cancers have a twofold increased risk of solid tumors beyond the age of 40 years compared to the general population. The induction of second malignancies is governed by the complex interplay of age, sex, environmental exposures, genetic susceptibility, and specific cancer treatments. Often, the events that led to the primary cancer remain, and a risk of a second malignancy persists. Patients with a history of lung cancer remain at increased risk of other cancers that are associated with tobacco use including esophageal, head and neck, kidney, and bladder cancers. Patients with breast cancer are at increased risk of breast cancer in the opposite breast. Patients with Hodgkin lymphoma are at risk for other B-cell non-Hodgkin lymphomas. Genetic cancer syndromes (e.g., multiple endocrine neoplasia or Li-Fraumeni, Lynch's, Cowden's, and Gardner's syndromes) are examples of genetically based second malignancies of specific types. Cancer treatment itself does not appear to be responsible for the risk of these secondary malignancies. Genetic disorders that result in DNA repair deficiencies including ataxia-telangiectasia, Bloom's syndrome, and Fanconi's anemia greatly increase the lifetime risk of cancers as well as the risks associated with DNA-damaging agents. Importantly, the risk of treatment-related second malignancies is at least additive and often synergistic with combined chemotherapy and radiation therapy, and hence for such combined-therapy treatment approaches, it is important to establish the necessity of each component in the treatment program. These patients require indefinite surveillance and prophylactic surgery in some cases.

Patients receiving radiation have an increasing and lifelong risk of second malignancies that is 1–2% in the second decade following treatment but increases to >25% after 25 years. The risk of second malignancies from radiation is dose-dependent and often occurs within or near the treatment field. Common radiation-related solid tumors include central nervous system (CNS), breast, lung, thyroid, skin, and bone cancers and sarcomas, which are often aggressive and have a poor prognosis. An example of an organ-, age-, and sex-dependent radiation-induced secondary malignancy is breast cancer, in which the risk is small with radiation in women aged older than 30 years but increases about twentyfold over baseline in women aged younger than 30 years. A 25-year-old woman treated with mantle radiation for Hodgkin lymphoma has a 29% actuarial risk of developing breast cancer by age 55.

Chemotherapy is significantly associated with two fatal second malignancies: acute leukemia and myelodysplastic syndromes. Two types of secondary leukemia have been described; in patients treated with chronic alkylating agents (especially combined with radiation therapy), acute myeloid leukemia is associated with deletions in chromosome 5 or 7 and complex karyotypes and often is preceded by myelodysplasia. The lifetime risk is about 1–5%, is increased by radiation therapy, and increases with age. The incidence of these leukemias peaks at 5–8 years, with risk returning close to baseline at 10 years. The other type of acute myeloid leukemia is related to therapy with topoisomerase inhibitors, is associated with chromosome 11q23 translocations, has an incidence of <1%, generally occurs 1.5–3 years after treatment, and is rarely preceded by myelodysplasia. Both of these acute myeloid leukemias are largely refractory to treatment and have a high mortality. The development of myelodysplastic syndromes is increased following chemotherapy, and these cases are often associated with leukemic progression and a dismal prognosis. A fraction of the population develops clonal hematopoiesis not related to prior cancer treatment, and the percentage increases with age. In such patients, the hematopoietic stem cells carry mutations that are associated with myeloid malignancy despite normal blood counts. It is thought that the presence of these genetic lesions may predispose patients to develop myeloid malignancies, but evidence is greater that clonal hematopoiesis increases the risk of lymphoma and atherosclerotic heart disease.

Other cytotoxic agents are associated with long-term alterations in immunity beyond the initial treatment period and neutrophil recovery. Bendamustine has significant effects on both B-cell and T-cell subpopulations that can persist for years, and long-term studies of lymphoma patients treated with bendamustine-based regimens show higher rates of death from second malignancies compared to other chemotherapy regimens. Purine analogues like cladribine and pentostatin also produce long-term T-cell suppression. The risk of solid tumors is also increased after chemotherapy, and alkylating agents increase the risk of thyroid, lung, breast, and bladder cancers and sarcomas. Cyclophosphamide increases the risk of both sarcoma and breast cancer in a dose-dependent manner. Other chemotherapy agents, including procarbazine and platinum agents, have been associated with gastrointestinal malignancies. Treatment of breast cancer with tamoxifen for 5 years or longer is associated with a 1–2% risk of endometrial cancer. Surveillance is generally effective at finding these cancers at an early stage. The risk of mortality from tamoxifen-induced endometrial cancer is low compared to the benefit of tamoxifen as adjuvant therapy for breast cancer. Treatment of multiple myeloma with the immunomodulatory agent lenalidomide is associated with a significantly increased risk of second hematologic malignancies including lymphomas and leukemias. These risks are highest after prior use of the alkylating agent melphalan.

Given the high risk of second malignancies in cancer survivors, patients need indefinite surveillance. Guidelines for breast cancer surveillance in survivors exposed to chest radiation recommend that patients be screened with mammograms and/or breast MRI beginning at age 25 years or 8 years after treatment, whichever occurs later. Any organ in the treatment field is susceptible to developing a cancer; e.g., radiation to the chest may increase the risk of gastric or esophageal cancer. Patients exposed to abdominal or pelvic radiation should have annual colonoscopies starting at age 35 years or 10 years after exposure. For patients treated with neck radiation, no formal surveillance is recommended, but fine-needle aspiration should be performed on any palpable thyroid nodules and thyroid-stimulating hormone (TSH) levels should be monitored periodically.

Combination chemotherapy is also associated with impaired immune health and increases the risk of opportunistic infections, autoimmune complications, and impaired host protection from infections. Survivors of lymphoma have elevated risks of developing autoimmune hemolytic anemia, viral or fungal pneumonias, meningitis, or other infections, and these risks remain high decades after treatment. Agents or treatment regimens that result in significant T-cell depletion, including antithymocyte globulin or antibodies targeting cell surface proteins on T cells, increase the risk of Epstein-Barr virus–associated B-cell lymphoproliferative disorders. Discontinuing immunosuppressive therapy, if possible, is often associated with complete disease regression. Anti-CD20 monoclonal antibodies, CAR-T therapy, bi-specific monoclonal antibodies targeting both B cells and T cells, and immune checkpoint inhibitors have all been associated with long-term B-cell aplasia that often requires intravenous immunoglobulin replacement and persistent vigilance for recurrent sinopulmonary infections. Rituximab and immunomodulatory agents have both been associated with late-onset neutropenia that can occur months after exposure to the drug and often requires growth factor support. Given these risks of impaired immune system function, all cancer survivors should undergo annual influenza vaccination and should be considered for pneumococcal vaccination depending on age and immune health status.

REPRODUCTIVE AND ENDOCRINE DYSFUNCTION

Endocrine complications are prevalent in childhood cancer survivors. Nearly half of all survivors will have at least one hormonal disorder in their lifetime, and these most commonly present as late effects. Radiation to the head, neck, or pelvis is associated with the greatest risk of endocrine dysfunction. Testicles and ovaries in prepubertal patients are sensitive to radiation damage in a dose-related fashion;

spermatogenesis is affected by low doses of radiation, and complete azoospermia occurs at 600–700 cGy. Leydig cell dysfunction, in contrast, occurs at <2000 cGy, and hence, endocrine function is lost at much higher radiation doses than spermatogenesis. Erectile dysfunction occurs in up to 80% of men treated with external-beam radiation therapy for prostate cancer. Sildenafil may be useful in reversing erectile dysfunction. Ovarian function damage with radiation is age-related and occurs at doses of 150–500 cGy. Hormone replacement therapy is often contraindicated (as in estrogen receptor–positive breast cancer). Attention must be paid to maintenance of bone mass with calcium and vitamin D supplements and oral bisphosphonates, and bone mass should be monitored using bone density determinations. Paroxetine, clonidine, pregabalin, and other drugs may be useful in symptomatically controlling hot flashes. Long-term survivors of childhood cancer who have received cranial radiation may have altered leptin biology and growth hormone deficiency, leading to obesity and reduced strength, exercise tolerance, and bone density. Radiation therapy to the neck may lead to hypothyroidism, Graves' disease, thyroiditis, and thyroid malignancies. TSH is followed routinely in such patients to prevent hypothyroidism and to suppress persistently elevated levels of TSH, which may cause or drive thyroid cancer. Cranial radiation may also be associated with an array of endocrine abnormalities with disruption of normal pituitary-hypothalamic axis function, and a high index of suspicion needs to be maintained to identify and treat this toxicity. Efforts to eliminate unnecessary radiation such as prophylactic CNS irradiation may decrease some of the late endocrine effects. Patients who have received abdominal radiation should receive annual screens for obesity and diabetes mellitus with heigh and weight measurements along with a hemoglobin A_{1C} at least every 2 years.

Alkylating agents are the chemotherapy agents associated with the highest rates of male and female infertility, which is directly dependent on age, dose, and duration of treatment. The age at treatment is an important determinant of fertility outcome, with prepubertal patients having the highest tolerance. Ovarian failure is age related, and females who resume menses after treatment are still at increased risk for premature menopause. Males generally have reversible azoospermia during lower intensity alkylator chemotherapy, and long-term infertility is associated with doses of cyclophosphamide >9 g/m^2 and with high-intensity therapy, such as that used in hematopoietic stem cell transplantation. All patients should be counseled on the potential impact on future reproduction, and timely referral for established interventions such as sperm cryopreservation, oocyte preservation, and embryo preservation should be offered when feasible and appropriate. Assisted reproductive technologies can be helpful to couples with chemotherapy-induced infertility.

Combination chemotherapy can impair bone health, and older patients may be more susceptible to these effects. Due to the combined risk of age-related osteoporosis and the effect of therapy, the risk of fractures in patients over the age of 70 years may be as high as 5–10% within a few years of finishing therapy. The risk of low bone mineral density is highest in certain high-risk groups including survivors of pediatric acute lymphoblastic leukemia and CNS tumors and those who have undergone hematopoietic stem cell transplant.

Immune checkpoint inhibitors that target CTLA-4 and PD-1 have led to serious chronic toxicities including the breaking of self-tolerance and the autoimmune destruction of certain endocrine organs, particularly the thyroid and adenohypophysis (anterior pituitary). Hypophysitis is more commonly reported in association with CTLA-4 inhibitors, whereas thyroid dysfunction is more common with PD-1 inhibitors. Most immune-related toxicities occur within 8–12 weeks of starting treatment, but they can occur at any time during treatment or even after therapy has stopped. Patients with autoimmune thyroiditis or hypophysitis require lifelong hormone replacement, and early recognition is important.

Tyrosine kinase inhibitors such as imatinib have been associated with growth deceleration in children, particularly when treatment is initiated before puberty. The mechanism is postulated to be related to disruptions in growth hormone signaling or inhibition of the insulin-like growth factor 1 (IGFR-1) receptor. Other BCR-ABL inhibitors, including nilotinib and dasatinib, have been associated with both hyper- and hypothyroidism. Endocrine effects that have been reported to be associated with other tyrosine kinase inhibitors include alterations in bone remodeling, reduced calcium and vitamin D levels, thyroid dysfunction, gonadal dysfunction, adrenal dysfunction, altered glucose metabolism, and secondary hyperparathyroidism. Thyroid function tests should be monitored periodically while patients are on these targeted agents, and replacement hormones and/or vitamins should be prescribed as necessary.

NEUROLOGIC DYSFUNCTION

Neurologic dysfunction from cancer treatment is increasing in both incidence and severity as a result of improved supportive care that enables more aggressive regimens, an expanded number of older patients receiving treatment, extended durations of therapy, and longer periods of cancer survivorship. Direct effects on myelin, glial cells, and neurons have all been implicated, with alterations in cellular cytoskeleton, axonal transport, and cellular metabolism as potential mechanisms. Telomere shortening that occurs with normal aging may be accelerated by radiation. Survivors of CNS tumors are at the greatest risk of late-onset neurocognitive impairment that includes impaired intelligence and slower processing speeds along with deficits in executive function, memory, and attention. These toxicities are reported after treatment with both radiation and chemotherapy in childhood survivors.

Acute radiation CNS toxicity occurs within weeks and is characterized by nausea, drowsiness, hypersomnia, and ataxia, which typically recover over time. Early delayed toxicity occurring weeks to 3 months following therapy is associated with similar symptoms as acute toxicity and is pathologically associated with reversible demyelination. Chronic, late radiation injury occurs 9 months to up to 10 years following therapy, and dysfunction increases over time. Radiation-associated spinal cord injury (myelopathy) is highly dose-dependent and rarely occurs with modern radiation therapy. An early, self-limited form involving electric sensations down the spine on neck flexion (Lhermitte's sign) is seen 6–12 weeks after treatment and generally resolves over weeks. Peripheral nerve toxicity is quite rare owing to relative radiation resistance. Diffuse radiation injury is associated with global CNS neurologic dysfunction and diffuse white matter changes on computed tomography (CT) or MRI. Pathologically, small vessel changes are prominent and focal necrosis is common. Necrotizing encephalopathy is the most severe form of radiation injury and almost always is associated with concurrent use of chemotherapy, notably methotrexate. Prophylactic cranial irradiation in both childhood and adult leukemias/lymphomas has largely been abandoned due to the acute and long-term effects of therapy. Glucocorticoids may be symptomatically useful for acute toxicities but do not alter the course. Psychostimulants such as methylphenidate may improve attention and executive functioning in childhood survivors.

In children and adolescent cancers, younger age, higher cranial irradiation dose, larger brain volumes irradiated, and longer treatment times are associated with worse neurocognitive outcomes. In adult cancers, patients over the age of 60 who receive whole-brain radiation therapy are at high risk for neurocognitive impairment after therapy. Genetic polymorphisms may be associated with an increased risk of neurocognitive problems, and emerging evidence suggests polymorphisms in the folate pathway, oxidative stress genes, and enzymes that regulate both catecholamines and deamination of amines are associated with individual risk.

Vinca alkaloids produce a characteristic "stocking-glove" neuropathy with numbness and tingling advancing to loss of motor function, which is highly dose related. Distal sensorimotor polyneuropathy prominently involves loss of deep tendon reflexes with initially loss of pain and temperature sensation, followed by proprioceptive and vibratory loss. This requires careful patient history and physical examination by experienced oncologists to decide when the drug must be stopped or reduced to prevent permanent damage. Milder toxicity often slowly completely resolves after treatment discontinuation. Vinca alkaloids may sometimes be associated with jaw claudication,

hoarseness, autonomic neuropathy, ileus, cranial nerve palsies, and, in severe cases, encephalopathy, seizures, and coma. Cisplatin is associated with sensorimotor neuropathy and hearing loss, especially at doses >400 mg/m^2, requiring audiometry in patients with preexisting hearing compromise. Carboplatin is often substituted in such cases given its lesser effect on hearing. Many of the agents that target kinase enzymes in tumor cells and 5-fluorouracil congeners produce dysesthesias and painful hands and feet known as hand-foot syndrome or palmar-plantar erythrodysesthesia. Symptoms usually abate when the agent is stopped. Methotrexate alone may cause acute leukoencephalopathy characterized by somnolence and confusion that is often reversible. Acute toxicity is dose-related, especially at doses >3 g/m^2, with younger patients being at greater risk. Subacute methotrexate toxicity occurs weeks after therapy and is often ameliorated with glucocorticoid therapy. Chronic methotrexate toxicity (leukoencephalopathy) develops months or years after treatment and is characterized clinically as progressive loss of cognitive function and focal neurologic signs, which are irreversible, promoted by synchronous or metachronous radiation therapy, and more pronounced at a younger age. Neurocognitive decline following chemotherapy alone occurs notably in breast cancer patients receiving adjuvant chemotherapy with anthracyclines, taxanes, or cyclophosphamide; this has been referred to as "chemo brain." It is clinically associated with impaired memory, learning, attention, and speed of information processing. There is no clear mechanistic explanation for its cause and no clearly effective therapy, although regular exercise is associated with improved symptoms. Most symptoms improve within a year of therapy, but symptoms can persist in 10–20% of patients for extended periods of time.

Newer molecularly targeted agents and immunotherapy have also been associated with neurologic dysfunction and may exacerbate persistent neuropathy from prior therapy. Proteasome inhibitors are associated with neuropathic pain and motor neuropathy that can occur immediately or be delayed in onset. The proposed mechanism is through enhanced oxidative stress on neural cells. Subcutaneous administration of these agents is associated with less peripheral neuropathy than intravenous infusions. Immunotherapy agents such as CAR-T therapies and bi-specific monoclonal antibodies targeting both T cells and B cells are associated with significant acute neurotoxicity including confusion, encephalopathy, seizures, and cerebellar symptoms. These symptoms are hypothesized to be related to the CRS associated with these therapies and often are time limited. However, a minority of patients treated with these agents will have persistent central and neurologic dysfunction for which management is mainly supportive. Glucocorticoids may be useful in the short term, but treatment with interleukin 6 receptor antagonists that are effective for decreasing the severity of CRS is largely ineffective at preventing neurologic toxicities. Progressive multifocal leukoencephalopathy (PML) is a rare but serious brain infection that is caused by the JC virus and has been reported as a rare complication of treatment with rituximab, ibrutinib, and PI3K inhibitors. The inflammatory response to the virus presents as unifocal or multifocal hyperintense lesions involving the subcortical white matter that are best seen on T2/fluid-attenuated inversion recovery (FLAIR) images on MRI. Treatment is supportive and includes removal of the offending agent. Other targeted agents that may be associated with neurologic dysfunction when given for extended durations of treatment include dasatinib, thalidomide, and lenalidomide.

Antibody-drug conjugates (ADCs) are novel therapies in which a monoclonal antibody targeted to a tumor antigen is attached to a potent anticancer agent via a chemical linker. Often, these agents are associated with significant central and peripheral neurotoxicity, as has been described with agents such as brentuximab vedotin and pertuzumab. These neuropathies often emerge during treatment similar to those seen with chemotherapy and are dose-dependent. Early recognition of treatment-emergent neuropathy induced by ADCs mandates dose interruption or modification to less frequent dosing schedules in order for patients to remain on therapy. Immune checkpoint inhibitors have been associated with autoimmune complications and unique neurologic manifestations such as optic neuritis that may be reversible after glucocorticoids.

HEPATIC AND GASTROINTESTINAL DYSFUNCTION

Long-term hepatic damage from standard chemotherapy regimens is rare. Long-term methotrexate or high-dose chemotherapy alone or with radiation therapy, for example, in preparative regimens for bone marrow transplantation, may result in venoocclusive disease of the liver. This potentially lethal complication classically presents with anicteric ascites, elevated alkaline phosphatase, and hepatosplenomegaly. Pathologically, there is venous congestion, epithelial cell proliferation, and hepatocyte atrophy progressing to frank fibrosis. Frequent monitoring of liver function tests during any chemotherapy is necessary to avoid both idiosyncratic and expected toxicities. Certain nucleoside drugs have been associated with hepatic dysfunction; however, this complication is rare in oncology. Hepatic radiation damage depends on dose, volume, fractionation, preexisting liver disease, and synchronous or metachronous chemotherapy. In general, radiation doses to the liver >1500 cGy can produce hepatic dysfunction with a steep dose-injury curve. Radiation-induced liver disease closely mimics hepatic venoocclusive disease.

Novel targeted agents including immunotherapy agents have introduced a number of gastrointestinal toxicities that can occur late in the course of treatment including hepatitis, colitis, malabsorption, and chronic diarrhea. Early signs of serious liver injury should lead to discontinuation of the offending agent as the effect does not appear to be dose-related and dose reductions do not reliably reduce further liver injury. The mechanisms for colitis or hepatitis associated with these targeted agents are not completely understood but are hypothesized to be T cell–mediated, and the risk is highest when used in targeted agent combinations. Diarrhea with or without severe colitis can be associated with virtually all targeted agents including PI3K inhibitors, BCR-ABL inhibitors, BTK inhibitors, EGFR inhibitors, MEK inhibitors, CDK inhibitors, and immunomodulatory agents. Even if the diarrhea is not severe, the impact associated with indefinite treatment greatly interferes with the quality of life and often leads to discontinuation of targeted therapy if not managed effectively. Immunomodulatory agents including lenalidomide are associated with late onset of diarrhea that is caused by bile acid malabsorption and often responds to bile acid sequestrants. Immune checkpoint inhibitors are associated with colitis and hepatitis that may be responsive to prompt initiation of glucocorticoids that may require a long taper for resolution.

RENAL AND BLADDER DYSFUNCTION

Cisplatin produces reversible decrements in renal function but may also produce severe irreversible toxicity in the presence of renal disease and may predispose to accentuated damage with subsequent renal insults. Cyclophosphamide and ifosfamide are prodrugs primarily activated in the liver with cleavage products (acrolein) that can produce hemorrhagic cystitis. This can be prevented with the free radical scavenger MESNA (mercaptoethane sulfonate), which is required for ifosfamide administration. Hemorrhagic cystitis caused by these agents may predispose to bladder cancer.

Targeted agents generally do not carry significant acute nephrotoxic risks, but a number of agents, including PI3K inhibitors, anti-VEGF agents, and FLT3 inhibitors, are associated with systemic hypertension, which can lead to late effects or a progressive decline in renal function. Renal dysfunction following immunotherapy is uncommon, but acute interstitial nephritis can occur. Similar to other immune-related toxicities, this acute toxicity requires prompt use of glucocorticoids to avoid long-term effects on renal function.

PSYCHOLOGICAL DYSFUNCTION AND SOCIOECONOMIC IMPACT OF SURVIVORSHIP

The diagnosis and treatment of cancer can introduce long-term and late psychological effects that continue throughout life. Cancer survivors are at increased risk for anxiety, depression, attention problems, and posttraumatic stress syndromes. Many cancer patients experience intrusive or debilitating concerns about cancer recurrence following

successful therapy. In addition, these patients may experience socioeconomic stressors that affect employment, insurance, relationships and lead to financial and/or sexual difficulties. Survivors of childhood cancers are less likely to graduate from college or gain full-time employment than their peers and are more likely to engage in risky health behaviors such as substance abuse and excessive alcohol use. The long-term psychosocial effects of treatment are greatest in patients who undergo CNS-directed therapies including radiation and intensive combination chemotherapy regimens. Oncologists should ask about and address these issues explicitly with patients and provide appropriate counseling or support systems. The overall risk of suicidal ideation and suicide is low but is greater in cancer patients and survivors than age-matched controls. Tailored cognitive-behavioral therapy may improve the anxiety and posttraumatic stress associated with cancer survivorship.

CANCER SURVIVORSHIP CARE PLANS

Survivorship starts at the time of diagnosis and continues indefinitely. Many guidelines recommend that every patient be provided with a survivorship care plan unique to their situation, but the evidence that these improve health outcomes is limited and sufficient resources to implement recommendations are often lacking. Focused surveillance plans for late effects are critical for early detection and implementation of interventions but also must include risk stratification to avoid unnecessary surveillance testing that wastes resources and leads to overdiagnosis and/or psychological distress. Survivorship care has traditionally been performed by oncologists, but the scope of the problem mandates that primary care physicians, midlevel providers, and preventive medicine specialists be trained in the follow-up of treated cancer patients in remission. All former cancer patients should undergo surveillance for recurrence and second malignancies and be monitored for long-term effects of treatment; however, as a practical matter, nearly all recurrences are detected because of symptoms. Health promotion and disease prevention with age- and sex-specific routine screening tests (e.g., colonoscopy, Pap smears, mammography, human papillomavirus vaccination, dual-energy x-ray absorptiometry scans) should be a focus of survivorship care along with psychosocial well-being. Annual mammography should start no later than 10 years after breast radiation. Patients receiving radiation fields encompassing thyroid tissue should have regular thyroid examinations and TSH testing. Localized pain or palpable abnormality in a previously radiated field should prompt radiographic evaluation. Patients treated with alkylating agents or topoisomerase inhibitors should have a complete blood count every 6–12 months, and cytopenias, abnormal cells on peripheral smear, or macrocytosis should be evaluated with bone marrow biopsy and aspirate and include cytogenetics, flow cytometry, or fluorescence in situ hybridization (FISH) studies as appropriate.

As the population of cancer survivors increases and patients live longer, cancer survivorship has become increasingly important, and the Institute of Medicine and National Research Council have published a monograph entitled *From Cancer Patient to Cancer Survivor: Lost in Transition.* The monograph proposes a plan that would inform clinicians caring for cancer survivors of the complete details of patients' previous treatments, complications thereof, signs and symptoms of late effects, and recommended screening and follow-up procedures.

OUTLOOK

Survivorship care is one of the most challenging problems facing oncologists today. The challenge is to develop cancer treatments that utilize the most effective combination of surgery, chemotherapy, radiation, targeted agents, or immunotherapy that is required to cure disease or effect long-term disease control with the least amount of toxicity. As cancer treatments continue to improve, the need for cancer care increases due to more cancer survivors with increasing life expectancy. Clearly, much work remains to elucidate the pathophysiology of cancer treatment–related effects and identification of patient characteristics associated with an increased vulnerability to adverse effects. Clinical management strategies focused on the clinical management of acute toxicities and prevention of long-term effects after therapy are necessary. Finally, research initiatives should recognize that as treatment paradigms continue to evolve, the nature and biologic basis for toxicities will change. Advances in genomic medicine may add depth to our understanding of toxicities and allow for more personalized surveillance strategies. Longitudinal monitoring of the health of cancer survivors is required since the incidence of late effects of treatment does not appear to plateau over time.

Section 2 Hematopoietic Disorders

96 Hematopoietic Stem Cells

David T. Scadden, Dan L. Longo

All of the cell types in the peripheral blood and some cells in every tissue of the body are derived from hematopoietic (*hemo*: blood; *poiesis*: creation) stem cells. If the hematopoietic stem cell is damaged and can no longer function (e.g., due to a nuclear accident), a person would survive 2–4 weeks in the absence of extraordinary support measures. With the clinical use of hematopoietic stem cells, tens of thousands of lives are saved each year **(Chap. 114)**. Stem cells produce hundreds of billions of blood cells daily from a stem cell pool that is estimated to be only 100,000. How stem cells do this, how they persist for many decades despite the production demands, and how they may be better used in clinical care are important issues in medicine.

The study of blood cell production has become a paradigm for how other tissues may be organized and regulated. Basic research in hematopoiesis includes defining stepwise molecular changes accompanying functional changes in maturing cells, aggregating cells into functional subgroups, and demonstrating hematopoietic stem cell

regulation by a specialized microenvironment; these concepts are worked out in hematology and offer models for other tissues. Moreover, these concepts may not be restricted to normal tissue function but extend to malignancy. Stem cells are rare cells among a heterogeneous population of cell types, and their behavior is assessed mainly in experimental animal models involving reconstitution of hematopoiesis. Thus, much of what we know about stem cells is imprecise and based on inferences from genetically manipulated animals.

CARDINAL FUNCTIONS OF HEMATOPOIETIC STEM CELLS

All stem cell types have two cardinal functions: self-renewal and differentiation **(Fig. 96-1)**. Stem cells exist to generate, maintain, and repair tissues. They function successfully if they can replace a wide variety of shorter-lived mature cells over prolonged periods. The process of self-renewal (see below) assures that a stem cell population can be sustained over time. Without self-renewal, the stem cell pool would become exhausted and tissue maintenance would not be possible. The process of differentiation leads to production of the effectors of tissue function: mature cells. Without proper differentiation, the integrity of tissue function would be compromised and organ failure or neoplasia would ensue.

In the blood, mature cells have variable average life spans, ranging from hours for mature neutrophils to a few months for red blood cells to many years for memory lymphocytes. However, the stem cell pool is the central, durable source of all blood and immune cells, maintaining a capacity to produce a broad range of cells from a single cell source, yet keeping itself vigorous over decades of life. As an individual stem cell divides, it has the capacity to accomplish one of three division outcomes: two stem cells, two cells destined for differentiation, or one stem cell and one differentiating cell. The former two outcomes are the result of symmetric cell division, whereas the latter indicates a different outcome for the two daughter cells—an event termed asymmetric cell division. The relative balance for these types of outcomes may change during development and under particular kinds of demands on the stem cell pool.

DEVELOPMENTAL BIOLOGY OF HEMATOPOIETIC STEM CELLS

During development, blood cells are produced at different sites. Initially, the yolk sac provides oxygen-carrying red blood cells and many of the macrophage-like cells that are resident in tissues: cells like microglia in the brain. The placenta and several sites of intraembryonic blood cell production then become involved in sequential order. These move from the genital ridge at a site where the aorta, gonadal tissue, and mesonephros are emerging to the fetal liver and then, in the second trimester, to the bone marrow and spleen. As the location of stem cells changes, the cells they produce also change. The yolk sac provides red cells expressing embryonic hemoglobins and tissue-resident macrophages. Intraembryonic sites of hematopoiesis generate stem cells, red cells, platelets, and the circulating cells of innate immunity. The production of the cells of adaptive immunity occurs then as well but becomes robust as the thymus forms and the bone marrow is colonized in the second trimester. Stem cell proliferation remains high, even in the bone marrow, until shortly after birth, when it appears to dramatically decline. The cells in the bone marrow are thought to arrive by the bloodborne transit of cells from the fetal liver after calcification of the long bones has begun. The presence of stem cells in the circulation is not unique to a time window in development, however, as hematopoietic stem cells circulate throughout life. The time that stem cells spend freely circulating appears to be brief (measured in minutes in the mouse), but the stem cells that do circulate are functional and can be used for transplantation. The number of stem cells that circulate can be increased in a number of ways to facilitate harvest and transfer to the same or a different host.

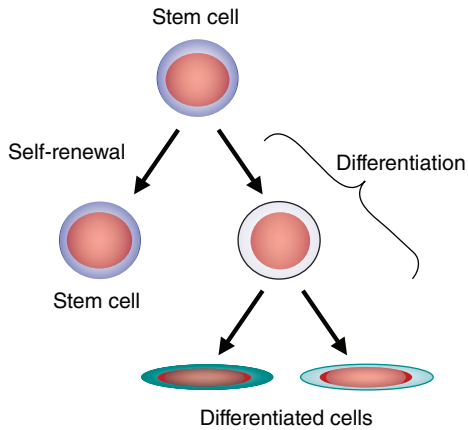

FIGURE 96-1 Signature characteristics of the stem cell. Stem cells have two essential features: the capacity to differentiate into a variety of mature cell types and the capacity for self-renewal. Intrinsic factors associated with self-renewal include expression of *Bmi-1, Gfi-1, PTEN, STAT5, Tel/Atv6, p21, p18, MCL-1, Mel-18, RAE28,* and *HoxB4.* Extrinsic signals for self-renewal include Notch, Wnt, SHH, angiogenin, and Tie2/Ang-1. Based mainly on murine studies, hematopoietic stem cells express the following cell surface molecules: CD34, Thy-1 (CD90), c-Kit receptor (CD117), CD133, CD164, and c-Mpl (CD110, also known as the thrombopoietin receptor).

MOBILITY OF HEMATOPOIETIC STEM CELLS

Cells entering and exiting the bone marrow do so through a series of molecular interactions. Circulating stem cells (through CD162 and CD44) engage the lectins (carbohydrate binding proteins) P- and E-selectin on the endothelial surface to slow the movement of the cells to a rolling phenotype. Stem cell integrins are then activated and accomplish firm adhesion between the stem cell and vessel wall, with a particularly important role for stem cell VCAM-1 engaging endothelial VLA-4. The chemokine CXCL12 (SDF1) interacting with stem cell CXCR4 receptors and ionic calcium interacting with the calcium-sensing receptor appear to be important in the process of stem cells getting from the circulation to where they engraft in the bone marrow. This is particularly true in the developmental move from fetal liver to bone marrow.

In the adult, the role for CXCR4 is in retention of stem cells in the bone marrow as well as getting them there. Interrupting that retention process through specific molecular blockers of the CXCR4/CXCL12 interaction, cleavage of CXCL12, or downregulation of the CXCR4 receptor can result in the release of stem cells into the circulation. This process is an increasingly important aspect of recovering stem cells for therapeutic use as it has permitted the harvesting process to be done by leukapheresis rather than bone marrow punctures in the operating room. Granulocyte colony-stimulating factor and plerixafor, a macrocyclic compound that can block CXCR4, are both used clinically to mobilize marrow hematopoietic stem cells for transplant. Refining our knowledge of how stem cells get into and out of the bone marrow may improve our ability to obtain stem cells and make them more efficient at finding their way to the specific sites for blood cell production, the so-called stem cell niche.

HEMATOPOIETIC STEM CELL MICROENVIRONMENT

The concept of a specialized microenvironment, or stem cell niche, was first proposed to explain why cells derived from the bone marrow of one animal could be used in transplantation and again be found in the bone marrow of the recipient. This niche is more than just a housing site for stem cells, however. It is an anatomic location where regulatory signals are provided that allow the stem cells to thrive, to expand if needed, and to provide varying amounts of descendant daughter cells. In addition, unregulated growth of stem cells may be problematic based on their undifferentiated state and self-renewal capacity. Thus, the niche must also regulate the number of stem cells produced. In this manner, the niche has the dual function of serving as a site of nurture but imposing limits for stem cells: in effect, acting as both a nutritive and constraining home.

The niche for blood stem cells changes with each of the sites of blood production during development, but for most of human life, it

is located in the bone marrow. Within the bone marrow, the perivascular space particularly in regions of trabecular bone serves as a niche. The mesenchymal and endothelial cells of the marrow microvessels produce kit ligand and CXCL12, both known to be important for hematopoietic stem cells. Other cell types, such as sympathetic neurons, nonmyelinating Schwann cells, macrophages, megakaryocytes, osteoclasts, and osteoblasts, have been shown to regulate stem cells, some by direct and others by indirect effects. Extracellular matrix proteins like osteopontin and heparan sulfates also affect stem cell function. The endosteal region appears to be particularly important for transplanted cells, in part because many of the mesenchymal cells and sinusoidal blood vessels of the central marrow are disrupted by the conditioning regimens used to prepare a patient for transplantation. The functioning of the niche as a supportive context for stem cells is of obvious importance for maintaining hematopoiesis and in transplantation. An active area of study involves determining whether the niche is altered in disease as experimental models have shown that mutations in niche cells can lead to myeloid malignancies. It logically follows that targeting of niche functions is a potential therapeutic strategy for both malignant and normal hematopoiesis.

EXCESS CAPACITY OF HEMATOPOIETIC STEM CELLS

In the absence of disease, one never runs out of hematopoietic stem cells. Indeed, serial transplantation studies in mice suggest that sufficient stem cells are present to reconstitute several animals in succession, with each animal having normal blood cell production. The fact that allogeneic stem cell transplant recipients also never run out of blood cells in their life span, which can extend for decades, argues that even the limiting numbers of stem cells provided to them are sufficient. How stem cells respond to different conditions to increase or decrease their mature cell production remains poorly understood. Clearly, negative feedback mechanisms affect the level of production of most of the cells, leading to the normal tightly regulated blood cell counts. However, many of the regulatory mechanisms that govern production of more mature progenitor cells do not apply or apply differently to stem cells. Similarly, most of the molecules shown to be able to change the size of the stem cell pool have little effect on more mature blood cells. For example, the growth factor erythropoietin, which stimulates red blood cell production from precursor cells, has no effect on stem cells. Similarly, granulocyte colony-stimulating factor drives the rapid proliferation of granulocyte precursors but has little or no effect on the cell cycling of stem cells. Rather, it changes the location of stem cells by indirect means, altering molecules such as CXCL12 that tether stem cells to their niche. Molecules shown to be important for altering the proliferation, self-renewal, or survival of stem cells, such as cyclin-dependent kinase inhibitors, transcription factors like Bmi-1, microRNA-processing enzymes like Dicer, or even metabolic regulators like pyruvate kinase isoforms, have little or different effects on progenitor cells. Hematopoietic stem cells have governing mechanisms that are distinct from the cells they generate.

HEMATOPOIETIC STEM CELL DIFFERENTIATION

Hematopoietic stem cells sit at the base of a branching hierarchy of cells culminating in the many mature cell types that compose the blood and immune system **(Fig. 96-2)**. The maturation steps leading to terminally differentiated and functional blood cells take place both as a consequence of intrinsic changes in gene expression and niche-directed and cytokine-directed changes in the cells. Our knowledge of the details remains incomplete. As stem cells mature to progenitors, precursors, and, finally, mature effector cells, they undergo a series of functional changes. These include the obvious acquisition of functions defining mature blood cells, such as phagocytic capacity or hemoglobin synthesis. They also include the progressive loss of plasticity (i.e., the ability to become other cell types). For example, the myeloid progenitor can make all cells in the myeloid series but none in the lymphoid series. As common myeloid progenitors mature, they become precursors for either monocytes and granulocytes or erythrocytes and megakaryocytes, but not both. Some amount of reversibility of this process may exist early in the differentiation cascade, but that is lost beyond a distinct stage in normal physiologic conditions. With genetic interventions, however, blood cells, like other somatic cells, can be reprogrammed to become a variety of cell types.

As cells differentiate, they may also lose proliferative capacity **(Fig. 96-3)**. Mature granulocytes are incapable of proliferation and only increase in number by increased production from precursors. The exceptions to the rule are some tissue-resident macrophages, which appear capable of proliferation, and lymphoid cells. Lymphoid cells retain the capacity to proliferate but have linked their proliferation to the recognition of particular proteins or peptides by specific antigen receptors on their surface. Like many tissues with short-lived mature cells such as the skin and intestine, blood cell proliferation is largely accomplished by a more immature progenitor population. In general, cells within the highly proliferative progenitor cell compartment are also relatively short-lived, making their way through the differentiation process in a defined molecular program involving the sequential activation of particular sets of genes. For any particular cell type, the differentiation program is difficult to speed up. The time it takes for hematopoietic progenitors to become mature cells is ~10–14 days in humans, evident clinically by the interval between cytotoxic chemotherapy and blood count recovery in patients.

Although hematopoietic stem cells are generally thought to have the capacity to form all cells of the blood, it is becoming clear that individual stem cells may not be equal in their differentiation potential. That is, some stem cells are "biased" to become mature cells of a particular type. In addition, the general concept of cells having a binary choice of lymphoid or myeloid differentiation is not entirely accurate. A cell population with limited megakaryocytic and erythroid or myeloid (monocyte and granulocyte) and lymphoid potential is now added to the commitment steps stem cells may undergo.

SELF-RENEWAL

The hematopoietic stem cell must balance its three potential fates: apoptosis, self-renewal, and differentiation. The proliferation of cells is generally not associated with the ability to undergo a self-renewing division except among memory T and B cells and among stem cells. Self-renewal capacity has generally been regarded as giving way to differentiation as the only option after cell division when cells leave the stem cell compartment, unless they become memory lymphocytes. However, emerging data suggest that some myeloid committed progenitors may also have self-renewing potential in vivo, providing long-term production of cells. Stem cells all have self-renewing capacity by definition, and they have an additional feature characterizing their proliferation machinery. Stem cells in many mature adult tissues are heterogeneous with some being deeply quiescent, serving as a deep reserve, whereas others are more proliferative and replenish the short-lived progenitor population. In the hematopoietic system, stem cells are generally cytokine-resistant, remaining dormant even when cytokines drive bone marrow progenitors to proliferation rates measured in hours. Stem cells, in contrast, are thought to divide at far longer intervals, measured in months to years, for the most quiescent cells. This quiescence is difficult to overcome in vitro, limiting the ability to effectively expand human hematopoietic stem cells. The process may be controlled by particularly high levels of cyclin-dependent kinase inhibitors like p57 or CDKN1c that restrict entry of stem cells into the cell cycle, blocking the G_1-S transition. Exogenous signals from the niche also appear to enforce quiescence, including angiogenin, interleukin 18, and perhaps angiopoietin 1.

The regulation of stem cell proliferation also appears to change with age. Both cell intrinsic features like the cyclin-dependent kinase inhibitor p16INK4a and bone marrow microenvironment features like declining sympathetic innervation are implicated in age-related stem cell changes. Either lowering expression of p16INK4a or stimulating beta-3 adrenergic receptors in older animals improves stem cell cycling and capacity to reconstitute hematopoiesis in adoptive hosts, making them similar to younger animals. Mature cell numbers are unaffected. Therefore, molecular events governing the specific functions of stem cells are being gradually made clear and offer the potential of new

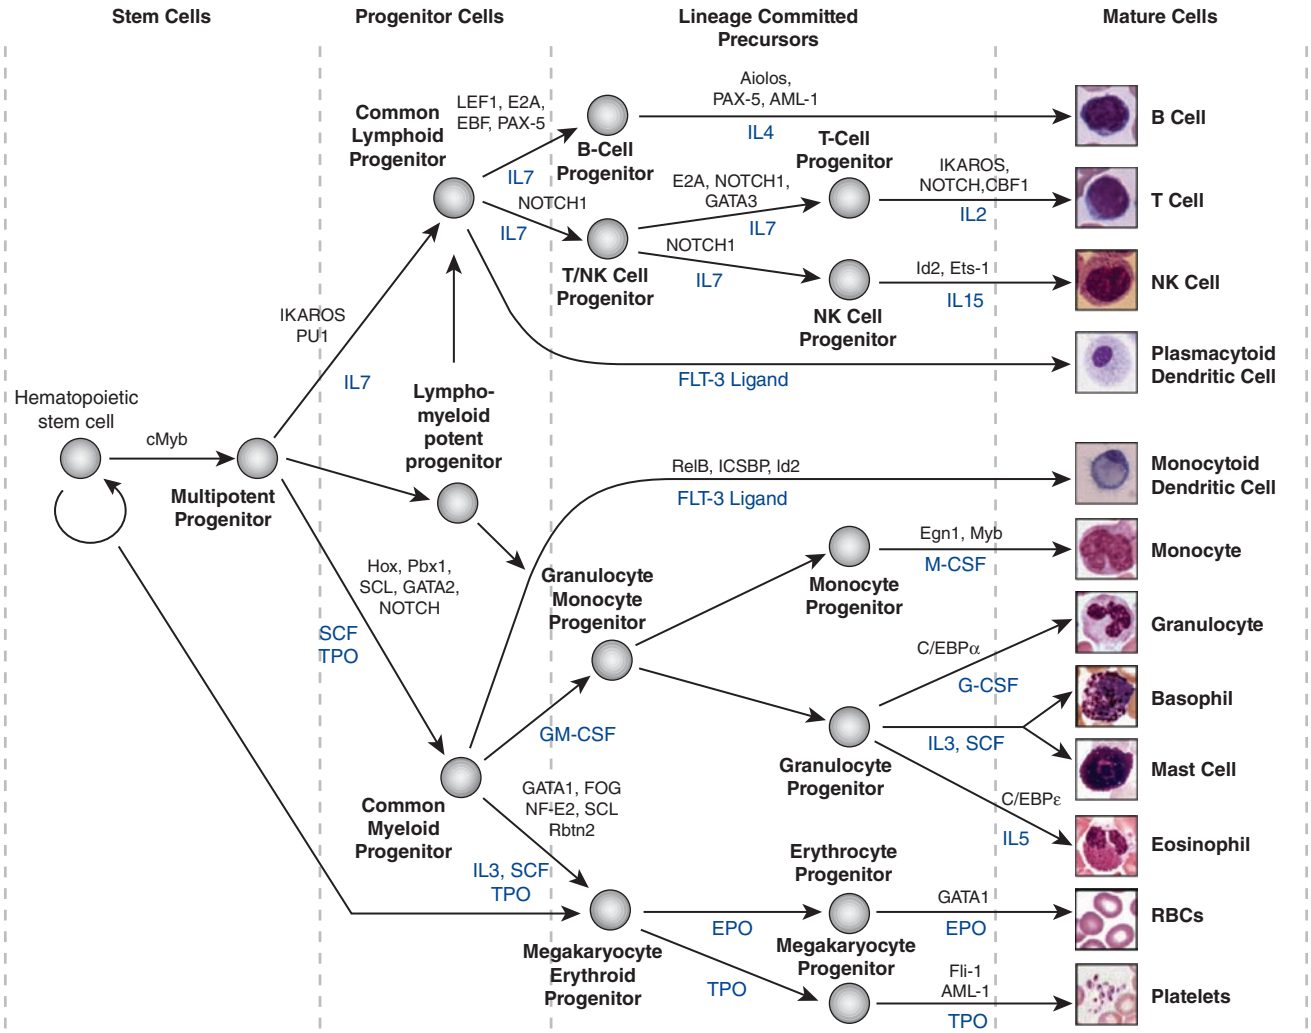

FIGURE 96-2 Hierarchy of hematopoietic differentiation. *Stem cells* are multipotent cells that are the source of all descendant cells and have the capacity to provide either long-term (measured in years) or short-term (measured in months) cell production. *Progenitor cells* have a more limited spectrum of cells they can produce and are generally a shorter-lived, highly proliferative population also known as transient amplifying cells. *Precursor cells* are cells committed to a single blood cell lineage but with a continued ability to proliferate; they do not have all the features of a fully mature cell. *Mature cells* are the terminally differentiated product of the differentiation process and are the effector cells of specific activities of the blood and immune system. Progress through the pathways is mediated by alterations in gene expression. The regulation of the differentiation by soluble factors and cell-cell communications within the bone marrow niche are still being defined. The transcription factors that characterize particular cell transitions are illustrated on the *arrows*; the soluble factors that contribute to the differentiation process are in *blue*. This picture is a simplification of the process. Active research is revealing multiple discrete cell types in the maturation of B cells and T cells and has identified cells that are biased toward one lineage or another (rather than uncommitted) in their differentiation. EPO, erythropoietin; RBC, red blood cell; SCF, stem cell factor; TPO, thrombopoietin.

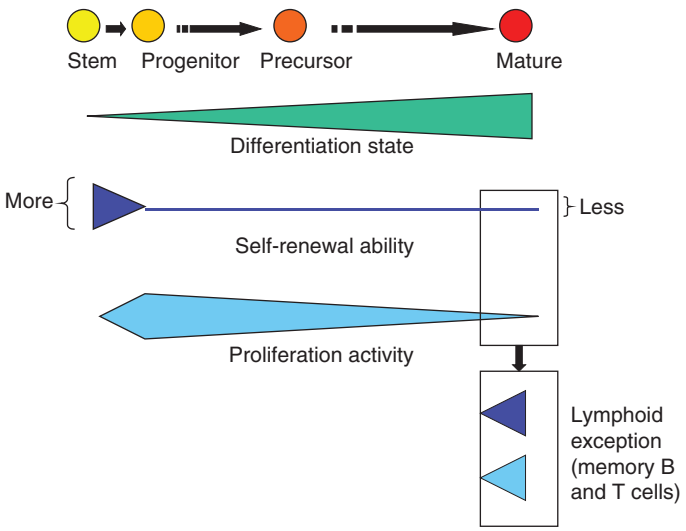

FIGURE 96-3 Relative function of cells in the hematopoietic hierarchy. The boxes represent distinct functional features of cells in the myeloid (*upper box*) versus lymphoid (*lower box*) lineages.

therapeutic approaches to changing stem cell functions. One critical stem cell function that remains poorly defined is the molecular regulation of self-renewal.

For medicine, self-renewal is perhaps the most important function of stem cells because it is critical in regulating the number of stem cells. Stem cell number is a key limiting parameter for both autologous and allogeneic stem cell transplantation. Were we to have the ability to use fewer stem cells or expand limited numbers of stem cells ex vivo, it might be possible to reduce the morbidity and expense of stem cell harvests, enable use of other stem cell sources, and improve the potential for gene-modified stem cell transplant. For example, umbilical cord blood is a rich source of stem cells but generally has an inadequate number of stem cells for use in transplantation in adults. These cells have two advantages over other stem cell sources: there is a lower incidence of graft-versus-host disease, and cord blood banks have representation of populations underrepresented in adult donor registries. Hematopoietic reconstitution from cord blood is slow, however, in part due to cell number. Expansion might improve this; however, advances in haploidentical donor cell transplantation have reduced cord blood use.

Gene-modified stem cells are increasingly being tested and have been found to offer great promise for genetic blood diseases like congenital immunodeficiencies and hemoglobinopathies such as sickle cell

disease. However, the complexity and cost of modifying enough stem cells for transplantation is problematic. Expanding a small number of gene-modified stem cells may mitigate that issue. Therefore, understanding self-renewal offers the potential to facilitate development of an important new area of stem cell–based medicine. Some limited understanding of self-renewal exists and, intriguingly, implicates gene products that are associated with the chromatin state, a high-order organization of chromosomal DNA that influences transcription. These include members of the polycomb family, a group of zinc finger–containing transcriptional regulators that interact with the chromatin structure, contributing to the accessibility of groups of genes for transcription. One member, Bmi-1, is important in enabling hematopoietic stem cell self-renewal through modification of cell cycle regulators such as the cyclin-dependent kinase inhibitors. In the absence of Bmi-1 or of the transcriptional regulator, Gfi-1, hematopoietic stem cells decline in number and function. In contrast, dysregulation of Bmi-1 has been associated with leukemia; it may promote leukemic stem cell self-renewal when it is overexpressed. The same is true for the polycomb gene, *Asxl1*, that is commonly mutated in myelodysplasia and leukemia. Other transcription regulators have also been associated with self-renewal, particularly homeobox, or "hox," genes. These transcription factors are named for their ability to govern large numbers of genes, including those determining body patterning in invertebrates. HoxB4 is capable of inducing extensive self-renewal of stem cells through its DNA-binding motif. Other members of the hox family of genes have been noted to affect normal stem cells, but they are also associated with leukemia. Epigenetic modifiers such as the DNA methyl transferase DNMT3a or the dioxygenase involved in DNA demethylation, Tet2, also play a role in stem cell regulation. Like *Asxl1*, mutations of these genes are associated with clonal outgrowth of stem cells bearing the mutations. These mutations are not sufficient for malignancy, but they enable clones bearing them to gain dominance and predispose cells to malignant transformation. They are often referred to as "founder mutations" because myelodysplastic and leukemic cells appear to evolve from them by DNA sequencing analysis.

CANCER IS SIMILAR TO AN ORGAN WITH SELF-RENEWING CAPACITY

The relationship of stem cells to cancer is an important dimension of adult stem cell biology. Cancer may share principles of organization with normal tissues. Cancer cells are heterogeneous even within a given patient and may have a hierarchical organization of cells with a base of stem-like cells capable of the signature stem cell features: self-renewal and differentiation. These stem-like cells might be the basis for perpetuation of the tumor and represent a slowly dividing, rare population with distinct regulatory mechanisms, including a relationship with a specialized microenvironment. A subpopulation of self-renewing cells has been defined for some, but not all, cancers. These include myeloid leukemias where founder mutations appear to enable clones of cells to expand. With additional mutations, these can serve as the initiating or stem cells of a cancer, and eliminating them may be necessary for curing the patient. Understanding the hierarchical cell organization within cancers and whether eliminating cancer stem cell equivalents can improve cure rates is an area of active investigation.

Does the concept of cancer stem cells provide insight into the cellular origin of cancer? The fact that some cells within a cancer have stem cell–like properties does not necessarily mean that the cancer arose in the stem cell itself. Rather, more mature cells could have acquired the self-renewal characteristics of stem cells. Any single genetic event is unlikely to be sufficient to enable full transformation of a normal cell to a frankly malignant one. Rather, cancer is a multistep process, and for the multiple steps to accumulate, the cell of origin must be able to persist for prolonged periods. It must also be able to generate large numbers of daughter cells. The normal stem cell has these properties and, by virtue of its having intrinsic self-renewal capability, may be more readily converted to a malignant phenotype. This hypothesis has been tested experimentally in the hematopoietic system. Taking advantage of the cell-surface markers that distinguish hematopoietic cells of varying maturity, stem cells, progenitors, precursors, and mature cells can be isolated. Powerful transforming gene constructs were placed in these cells, and it was found that the cell with the greatest potential to produce a malignancy was dependent on the transforming gene. In some cases, it was the stem cell, but in others, the progenitor cell functioned to initiate and perpetuate the cancer. This shows that cells can acquire stem cell–like properties in malignancy.

WHAT ELSE CAN HEMATOPOIETIC STEM CELLS DO?

Some experimental data have suggested that hematopoietic stem cells or other bone marrow cells are capable of playing a role in healing the vascular and tissue damage associated with stroke and myocardial infarction. These data are controversial, and the applicability of a stem cell approach to nonhematopoietic conditions remains experimental. However, reprogramming technology offers the potential for using readily obtained hematopoietic cells as a source for cells with other capabilities. Active areas of investigation are to use reprogrammed cells to generate mature lymphoid cells for immuno-oncology applications or red cells and platelets to overcome dependency on blood donors.

STEM CELLS AS TARGETS OF GENE THERAPY

Tools to alter gene sequence, expression, and regulation are becoming increasingly feasible. The hematopoietic stem cell is a target for a wide range of interventions. Lentiviral, retroviral, and adenoviral vectors are being used to replace defective genes (e.g., in primary immunodeficiency diseases). Antisense technology is being applied to block gene expression (e.g., blocking the Bcl11a repression of fetal globin expression in sickle cell disease and thalassemia). CRISPR/Cas technology is being applied to repair abnormal gene sequences. Precision genetic manipulations are expanding, and the hematopoietic system is central to it.

In sum, the stem cell has tremendous healing capacity and is essential for life. However, if dysregulated, it can threaten the life it maintains. Understanding how stem cells function, the signals that modify their behavior, and the tissue niches that modulate stem cell responses to injury and disease is critical for more effectively developing stem cell–based medicines.

97 Iron Deficiency and Other Hypoproliferative Anemias

John W. Adamson

Anemias associated with normocytic and normochromic red cells and an inappropriately low reticulocyte response (reticulocyte index <2–2.5) are *hypoproliferative anemias*. This category includes early iron deficiency (before hypochromic microcytic red cells develop), acute and chronic inflammation (including many malignancies), renal disease, hypometabolic states such as protein malnutrition and endocrine

TABLE 97-1 Body Iron Distribution		
	IRON CONTENT, mg	
	ADULT MALE, 80 kg	ADULT FEMALE, 60 kg
Hemoglobin	2500	1700
Myoglobin/enzymes	500	300
Transferrin iron	3	3
Iron stores	600–1000	0–300

deficiencies, and anemias from marrow damage. Marrow damage states are discussed in Chap. 102.

Hypoproliferative anemias are the most common anemias, and in the clinic, iron deficiency anemia is the most common of these followed by the anemia of inflammation. The anemia of inflammation, similar to iron deficiency, is related in part to abnormal iron metabolism. The anemias associated with renal disease, inflammation, cancer, and hypometabolic states are characterized by a suboptimal erythropoietin response to the anemia.

IRON METABOLISM

Iron is a critical element in the function of all cells, although the amount of iron required by individual tissues varies during development. At the same time, the body must protect itself from free iron, which is highly toxic in that it participates in chemical reactions that generate free radicals such as singlet O_2 or OH^-. Consequently, elaborate mechanisms have evolved that allow iron to be made available for physiologic functions while at the same time conserving this element and handling it in such a way that toxicity is avoided.

The major role of iron in mammals is to carry O_2 as part of hemoglobin. O_2 is also bound by myoglobin in muscle. Iron is a critical element in iron-containing enzymes, including the cytochrome system in mitochondria. Iron distribution in the body is shown in Table 97-1. Without iron, cells lose their capacity for electron transport and energy metabolism. In erythroid cells, hemoglobin synthesis is impaired, resulting in anemia and reduced O_2 delivery to tissue.

THE IRON CYCLE IN HUMANS

Figure 97-1 outlines the major pathways of internal iron exchange in humans. Iron absorbed from the diet or released from stores circulates in the plasma bound to *transferrin*, the iron transport protein. Transferrin is a bilobed glycoprotein with two iron-binding sites. Transferrin that carries iron exists in two forms—*monoferric* (one iron atom) or *diferric* (two iron atoms). The turnover (half-clearance time) of transferrin-bound iron is very rapid—typically 60–90 min. Because almost all of the iron transported by transferrin is delivered to the erythroid marrow, the clearance time of transferrin-bound iron from the circulation is affected most by the plasma iron level and the erythroid marrow activity. When erythropoiesis is markedly stimulated, the pool of erythroid cells requiring iron increases, and the clearance time of iron from the circulation decreases. The half-clearance time of iron in the presence of iron deficiency is as short as 10–15 min. With suppression of erythropoiesis, the plasma iron level typically increases, and the half-clearance time may be prolonged to several hours. Normally, the iron bound to transferrin turns over 6–8 times per day. Assuming a normal plasma iron level of 80–100 μg/dL, the amount of iron passing through the transferrin pool is 20–24 mg/day.

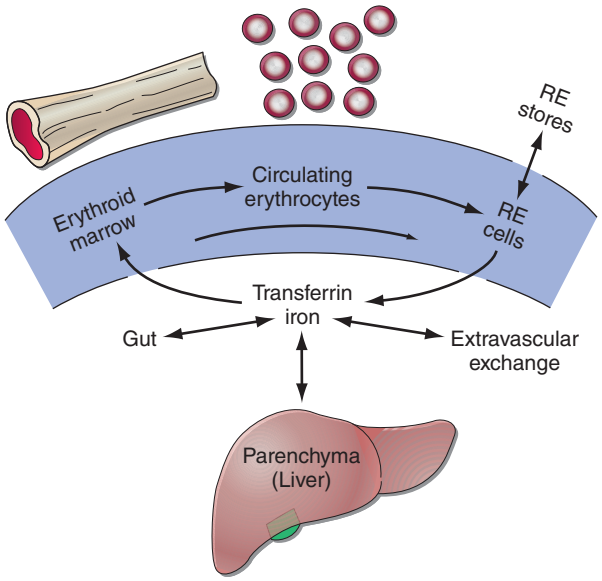

FIGURE 97-1 Internal iron exchange. Normally 80% of iron passing through the plasma transferrin pool is recycled from senescent red cells. Absorption of ~1 mg/d is required from the diet in men, and 1.4 mg/d in women to maintain homeostasis. As long as transferrin saturation is maintained between 20 and 60% and erythropoiesis is not increased, use of iron stores is not required. However, in the event of blood loss, dietary iron deficiency, or inadequate iron absorption, up to 40 mg/d of iron can be mobilized from stores. RE, reticuloendothelial.

The iron-transferrin complex circulates in the plasma until it interacts with specific *transferrin receptors* on the surface of marrow erythroid cells. Diferric transferrin has the highest affinity for transferrin receptors; apotransferrin (not carrying iron) has very little affinity. Although transferrin receptors are found on cells in many tissues within the body—and all cells at some time during development will display transferrin receptors—the cell having the greatest number of receptors (300,000–400,000/cell) is the developing erythroblast.

Once the iron-bearing transferrin interacts with its receptor, the complex is internalized via clathrin-coated pits and transported to an acidic endosome, where the iron is released at the low pH. The iron is then made available for heme synthesis while the transferrin-receptor complex is recycled to the surface of the cell, where the bulk of the transferrin is released back into circulation and the transferrin receptor re-anchors into the cell membrane. At this point, a certain amount of the transferrin receptor protein may be released into circulation and can be measured as soluble transferrin receptor protein. Within the erythroid cell, iron in excess of the amount needed for hemoglobin synthesis binds to a storage protein, *apoferritin*, forming *ferritin*. This mechanism of iron exchange also takes place in other cells of the body expressing transferrin receptors, especially liver parenchymal cells where the iron can be incorporated into heme-containing enzymes or stored. The iron incorporated into hemoglobin subsequently enters the circulation as new red cells are released from the bone marrow. The iron is then part of the red cell mass and will not become available for reutilization until the red cell dies.

In a normal individual, the average red cell life span is 120 days. Thus, 0.8–1% of red cells are replaced each day. At the end of its life span, the red cell is recognized as senescent by the cells of the *reticuloendothelial (RE) system*, and the red cell undergoes phagocytosis. Once within the RE cell, the ingested hemoglobin is broken down, the globin and other proteins are returned to the amino acid pool, and the iron is shuttled back to the surface of the RE cell, where it is presented to circulating transferrin via the iron export channel, ferroportin. It is the efficient and highly conserved recycling of iron from senescent red cells that supports steady-state (and even accelerated) erythropoiesis.

Because each milliliter of red cells contains 1 mg of elemental iron, the amount of iron needed to replace those red cells lost through senescence amounts to 20 mg/d (assuming an adult with a red cell mass of 2 L). Any additional iron required for daily red cell production comes from the diet. Normally, an adult male will need to absorb at least 1 mg of elemental iron daily to meet needs, while females in the childbearing years will need to absorb an average of 1.4 mg/d. However, to achieve a maximum proliferative erythroid marrow response to anemia, additional iron must be available. With markedly stimulated erythropoiesis, demands for iron are increased by as much as six- to eightfold. With extravascular hemolytic anemia, the rate of red cell destruction is increased, but the iron recovered from the red cells is efficiently reutilized for hemoglobin synthesis. In contrast, with intravascular hemolysis or blood loss anemia, the rate of red cell production is limited by the amount of iron that can be mobilized from stores. Typically, the rate of mobilization under these circumstances will not

support red cell production more than 2.5 times normal. If the delivery of iron to the stimulated marrow is suboptimal, the marrow's proliferative response is blunted, and hemoglobin synthesis is impaired. The result is a hypoproliferative marrow accompanied by microcytic, hypochromic anemia.

Whereas blood loss or hemolysis places a demand on the iron supply, inflammatory conditions interfere with iron release from stores and can result in a rapid decrease in the serum iron (see below).

NUTRITIONAL IRON BALANCE

The balance of iron in humans is tightly controlled and designed to conserve iron for reutilization. There is no regulated excretory pathway for iron, and the only mechanisms by which iron is lost are blood loss (via gastrointestinal bleeding, menses, or other forms of bleeding) and the loss of epithelial cells from the skin, gut, and genitourinary tract. Normally, the only route by which iron comes into the body is via absorption from food or from medicinal iron taken orally. Iron may also enter the body through red cell transfusions or injection of iron complexes. The margin between the amount of iron available for absorption and the requirement for iron in growing infants and the adult female is narrow; this accounts for the great prevalence of iron deficiency worldwide—currently estimated at more than one billion people.

The amount of iron required from the diet to replace losses averages ~10% of body iron content a year in men and 15% in women of childbearing age. Dietary iron content is closely related to total caloric intake (~6 mg of elemental iron per 1000 calories). Iron bioavailability is affected by the nature of the foodstuff, with heme iron (e.g., red meat) being most readily absorbed. In the United States, the average iron intake in an adult male is 15 mg/d with 6% absorption; for the average female, the intake is 11 mg/d with 12% absorption. An individual with iron deficiency can increase iron absorption to ~20% of the iron present in a meat-containing diet but only 5–10% of the iron in a vegetarian diet. As a result, one-third of the female population in the United States has virtually no iron stores. Vegetarians are at an additional disadvantage because certain foodstuffs that include phytates and phosphates reduce iron absorption by ~50%. When ionizable iron salts are given together with food, the amount of iron absorbed is reduced. When the percentage of iron absorbed from individual food items is compared with the percentage for an equivalent amount of ferrous salt, iron in vegetables is only about one-twentieth as available, egg iron one-eighth, liver iron one-half, and heme iron one-half to two-thirds.

Infants, children, and adolescents may be unable to maintain normal iron balance because of the demands of body growth and lower dietary intake of iron. During the last two trimesters of pregnancy, daily iron requirements increase to 5–6 mg, and iron supplements are strongly recommended for pregnant women in developed countries.

Iron absorption takes place largely in the duodenum and proximal small intestine and is a carefully regulated process. For absorption, iron must be taken up by the luminal cell. That process is facilitated by the acidic contents of the stomach, which maintains the iron in solution. At the brush border of the absorptive cell, the ferric iron is converted to the ferrous form by a ferrireductase. Transport across the membrane is accomplished by divalent metal transporter type 1 (DMT-1, also known as natural resistance macrophage-associated protein type 2 [Nramp 2] or DCT-1). DMT-1 is a general cation transporter. Once inside the gut cell, iron may be stored as ferritin or transported through the cell to be released at the basolateral surface to plasma transferrin through the membrane-embedded iron exporter, ferroportin. The function of ferroportin is negatively regulated by hepcidin, the principal iron regulatory hormone. In the process of release, iron interacts with another ferroxidase, hephaestin, which oxidizes the iron to the ferric form for transferrin binding. Hephaestin is similar to ceruloplasmin, the copper-carrying protein.

Iron absorption is influenced by a number of physiologic states. Erythroid hyperplasia stimulates iron absorption even in the face of normal or increased iron stores, and hepcidin levels are inappropriately low. Thus, patients with anemias associated with high levels of ineffective erythropoiesis absorb excess amounts of dietary iron. The molecular mechanism underlying this is the production of erythroferrone (ERFE) by developing erythroblasts. ERFE suppresses hepcidin production, and over time, this may lead to iron overload and tissue damage. In iron deficiency, hepcidin levels are also low and iron is much more efficiently absorbed; the contrary is true in states of secondary iron overload. The normal individual can reduce iron absorption in situations of excessive intake or medicinal iron intake; however, while the percentage of iron absorbed goes down, the absolute amount goes up. This accounts for the acute iron toxicity occasionally seen when children ingest large numbers of iron tablets. Under these circumstances, the amount of iron absorbed exceeds the transferrin binding capacity of the plasma, resulting in free iron that affects critical organs such as cardiac muscle cells.

IRON-DEFICIENCY ANEMIA

Iron deficiency is one of the most prevalent forms of malnutrition. Globally, 50% of anemia is attributable to iron deficiency and accounts for approximately nearly a million deaths annually worldwide. Africa and parts of Asia bear 71% of the global mortality burden; North America represents only 1.4% of the total morbidity and mortality associated with iron deficiency.

STAGES OF IRON DEFICIENCY

The progression to iron deficiency can be divided into three stages (Fig. 97-2). The first stage is *negative iron balance*, in which the demands for (or losses of) iron exceed the body's ability to absorb iron from the diet. This stage results from a number of physiologic mechanisms, including blood loss, pregnancy (in which the demands for red cell production by the fetus outstrip the mother's ability to provide iron), rapid growth spurts in the adolescent, or inadequate dietary iron intake. Blood loss in excess of 10–20 mL of red cells per day is greater than the amount of iron that the gut can absorb from a normal diet. Under these circumstances, the iron deficit must be made up by mobilization of iron from RE storage sites. During this period, iron stores—reflected by the serum ferritin level or the appearance of stainable iron on bone marrow aspirations—decrease. As long as iron stores are present and can be mobilized, the serum iron, total iron-binding

	Normal	Negative iron balance	Iron-deficient erythropoiesis	Iron-deficiency anemia
Marrow iron stores	1-3+	0-1+	0	0
Serum ferritin (μg/L)	50-200	<20	<15	<15
TIBC (μg/dL)	300-360	>360	>380	>400
SI (μg/dL)	50-150	NL	<50	<30
Saturation (%)	30-50	NL	<20	<10
Marrow sideroblasts (%)	40-60	NL	<10	<10
RBC protoporphyrin (μg/dL)	30-50	NL	>100	>200
RBC morphology	NL	NL	NL	Microcytic/ hypochromic

FIGURE 97-2 Laboratory studies in the evolution of iron deficiency. Measurements of marrow iron stores, serum ferritin, and total iron-binding capacity (TIBC) are sensitive to early iron-store depletion. Iron-deficient erythropoiesis is recognized from additional abnormalities in the serum iron (SI), percent transferrin saturation, the pattern of marrow sideroblasts, and the red blood cell (RBC) protoporphyrin level. Patients with iron-deficiency anemia demonstrate all the same abnormalities plus hypochromic microcytic anemia. *(Based on RS Hillman, CA Finch: The Red Cell Manual, 7th ed. Philadelphia, F.A. Davis and Co, 1996.)*

capacity (TIBC), and red cell protoporphyrin levels remain within normal limits. At this stage, red cell morphology and indices are normal.

When iron stores become depleted, the serum iron begins to fall. Gradually, the TIBC increases, as do red cell protoporphyrin levels. By definition, marrow iron stores are absent when the serum ferritin level is <15 μg/L. As long as the serum iron remains within the normal range, hemoglobin synthesis is unaffected despite the dwindling iron stores. Once the transferrin saturation falls to 15–20%, hemoglobin synthesis becomes impaired. This is a period of *iron-deficient erythropoiesis*. Careful evaluation of the peripheral blood smear reveals the first appearance of microcytic cells, and if the laboratory technology is available, one finds hypochromic reticulocytes in circulation. Gradually, the hemoglobin begins to fall, reflecting *iron-deficiency anemia*. The transferrin saturation at this point is <10–15%.

When moderate anemia is present (hemoglobin 10–13 g/dL), the bone marrow remains hypoproliferative. With more severe anemia (hemoglobin 7–8 g/dL), hypochromia and microcytosis become more prominent, target cells and misshapen red cells (poikilocytes) appear on the blood smear as cigar- or pencil-shaped forms, and the erythroid marrow becomes increasingly ineffective. Consequently, with severe prolonged iron-deficiency anemia, erythroid hyperplasia of the marrow develops, rather than hypoproliferation.

CAUSES OF IRON DEFICIENCY

Conditions that increase demand for iron, increase iron loss, or decrease iron intake or absorption can produce iron deficiency (Table 97-2).

CLINICAL PRESENTATION OF IRON DEFICIENCY

Certain clinical conditions carry an increased likelihood of iron deficiency. Pregnancy, adolescence, periods of rapid growth, and an intermittent history of blood loss of any kind should alert the clinician to possible iron deficiency. A cardinal rule is that the appearance of iron deficiency in an adult male or postmenopausal female means gastrointestinal blood loss until proven otherwise. Signs related to iron deficiency depend on the severity and chronicity of the anemia in addition to the usual signs of anemia—fatigue, pallor, and reduced exercise capacity. *Cheilosis* (fissures at the corners of the mouth) and *koilonychia* (spooning of the fingernails) are signs of advanced tissue iron deficiency. The diagnosis of iron deficiency is typically based on laboratory results.

LABORATORY IRON STUDIES

Serum Iron and Total Iron-Binding Capacity The serum iron level represents the amount of circulating iron bound to transferrin. The TIBC is an indirect measure of the circulating transferrin. The normal range for the serum iron is 50–150 μg/dL; the normal range for TIBC is 300–360 μg/dL. Transferrin saturation, which is normally 25–50%, is obtained by the following formula: serum iron × 100 ÷ TIBC. Iron-deficiency states are associated with saturation levels <20%. There is a diurnal variation in the serum iron. A transferrin saturation >50% indicates that a disproportionate amount of the iron bound to transferrin is being delivered to nonerythroid tissues. If this persists for an extended time, tissue iron overload may occur.

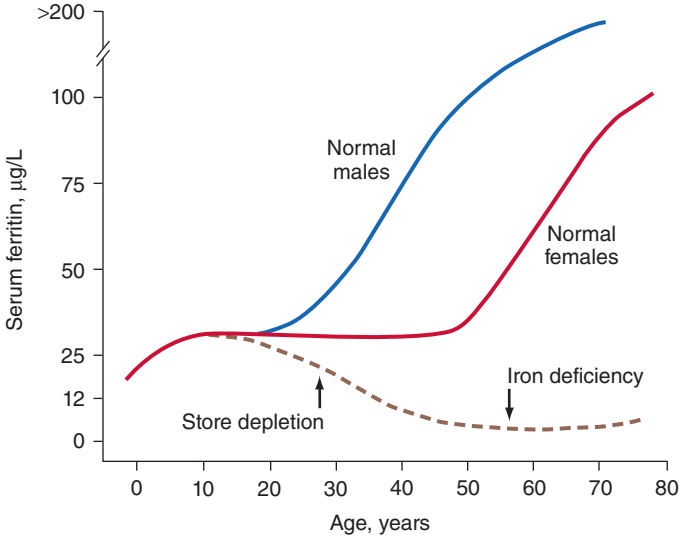

FIGURE 97-3 Serum ferritin levels as a function of sex and age. Iron store depletion and iron deficiency are accompanied by a decrease in serum ferritin level below 20 μg/L. *(Reproduced with permission from RS Hillman: Hematology in Clinical Practice, 5th ed. New York, McGraw-Hill, 2011.)*

Serum Ferritin Free iron is toxic to cells, and the body has established an elaborate set of protective mechanisms to bind iron in various tissue compartments. Within cells, iron is stored complexed to protein as ferritin or hemosiderin. Apoferritin binds to free ferrous iron and stores it in the ferric state. As ferritin accumulates within cells of the RE system, protein aggregates are formed as hemosiderin. Iron in ferritin or hemosiderin can be extracted for release by the RE cells, although hemosiderin is less readily available. Under steady-state conditions, the serum ferritin level correlates with total body iron stores; thus, the serum ferritin level is the most convenient laboratory test to estimate iron stores. The normal value for ferritin varies according to the age and gender of the individual (Fig. 97-3). Adult males have serum ferritin values averaging 100 μg/L, while adult females have levels averaging 30 μg/L. As iron stores are depleted, the serum ferritin falls to <15 μg/L. Such levels are diagnostic of absent body iron stores.

Evaluation of Bone Marrow Iron Stores Although RE iron stores can be estimated from the iron stain of a bone marrow aspirate or biopsy, the measurement of serum ferritin has largely supplanted these procedures for determination of storage iron (Table 97-3). The serum ferritin level is a better indicator of iron overload than the marrow iron stain. However, in addition to storage iron, the marrow iron stain provides information about the effective delivery of iron to developing erythroblasts. Normally, when the marrow smear is stained for iron, 20–40% of developing erythroblasts—called *sideroblasts*—will have visible ferritin granules in their cytoplasm. This represents iron in excess of that needed for hemoglobin synthesis. In states in which

TABLE 97-2 Causes of Iron Deficiency

Increased Demand for Iron
Rapid growth in infancy or adolescence
Pregnancy
Erythropoietin therapy
Increased Iron Loss
Chronic blood loss
Menses
Acute blood loss
Blood donation
Phlebotomy as treatment for polycythemia vera
Decreased Iron Intake or Absorption
Inadequate diet
Malabsorption from disease (sprue, Crohn's disease)
Malabsorption from surgery (gastrectomy and some forms of bariatric surgery)
Acute or chronic inflammation

TABLE 97-3 Iron Store Measurements

IRON STORES	MARROW IRON STAIN, 0–4+	SERUM FERRITIN, μg/L
0	0	<15
1–300 mg	Trace to 1+	15–30
300–800 mg	2+	30–60
800–1000 mg	3+	60–150
1–2 g	4+	>150
Iron overload	—	>500–1000

release of iron from storage sites is blocked, RE iron will be detectable, and there will be few or no sideroblasts. In the myelodysplastic syndromes, mitochondrial dysfunction can occur, and accumulation of iron in mitochondria appears in a necklace fashion around the nucleus of the erythroblast. Such cells are referred to as *ring sideroblasts*.

Red Cell Protoporphyrin Levels Protoporphyrin is an intermediate in the pathway to heme synthesis. Under conditions in which heme synthesis is impaired, protoporphyrin accumulates within the red cell. This reflects an inadequate iron supply to erythroid precursors to support hemoglobin synthesis. Normal values are <30 μg/dL of red cells. In iron deficiency, values >100 μg/dL are seen. The most common causes of increased red cell protoporphyrin levels are absolute or relative iron deficiency and lead poisoning.

Serum Levels of Transferrin Receptor Protein Because erythroid cells have the highest numbers of transferrin receptors of any cell in the body, and because transferrin receptor protein (TRP) is released by cells into the circulation, serum levels of TRP reflect the total erythroid marrow mass. Another condition in which TRP levels are elevated is absolute iron deficiency. Normal values are 4–9 μg/L determined by immunoassay. This laboratory test is becoming increasingly available and, along with the serum ferritin, has been proposed to distinguish between iron deficiency and the anemia of inflammation (see below).

DIFFERENTIAL DIAGNOSIS

Other than iron deficiency, only three conditions need to be considered in the differential diagnosis of a hypochromic microcytic anemia (Table 97-4). The first is an inherited defect in globin chain synthesis: the thalassemias. These are differentiated from iron deficiency most readily by serum iron values; normal or increased serum iron levels and transferrin saturation are characteristic of the thalassemias. In addition, the red blood cell distribution width (RDW) index is generally normal in thalassemia and elevated in iron deficiency.

The second condition is the anemia of inflammation (AI; also referred to as the anemia of chronic disease) with inadequate iron supply to the erythroid marrow. The distinction between true iron-deficiency anemia and AI is among the most common diagnostic problems encountered by clinicians (see below). Usually, AI is normocytic and normochromic. The iron values usually make the differential diagnosis clear, as the ferritin level is normal or increased and the percent transferrin saturation and TIBC are typically below normal.

Finally, the myelodysplastic syndromes represent the third and least common condition. Occasionally, patients with myelodysplasia have impaired hemoglobin synthesis with mitochondrial dysfunction, resulting in impaired iron incorporation into heme. The iron values again reveal normal stores and more than an adequate supply to the marrow, despite the microcytosis and hypochromia.

TREATMENT

Iron-Deficiency Anemia

The severity and cause of iron-deficiency anemia will determine the appropriate approach to treatment. As an example, symptomatic elderly patients with severe iron-deficiency anemia and cardiovascular instability may require red cell transfusions. Younger individuals who have compensated for their anemia can be treated more conservatively with iron replacement. The foremost issue for the latter patient is the precise identification of the cause of the iron deficiency.

For the majority of cases of iron deficiency (pregnant women, growing children and adolescents, patients with infrequent episodes of bleeding, and those with inadequate dietary intake of iron), oral iron therapy will suffice. For patients with unusual blood loss or malabsorption, specific diagnostic tests and appropriate therapy take priority. Once the diagnosis of iron-deficiency anemia and its cause is made, there are three major therapeutic approaches.

RED CELL TRANSFUSION

Transfusion therapy is reserved for individuals who have symptoms of anemia, cardiovascular instability, and continued and excessive blood loss from whatever source and who require immediate intervention. The management of these patients is less related to the iron deficiency than it is to the consequences of the severe anemia. Not only do transfusions correct the anemia acutely, but the transfused red cells provide a source of iron for reutilization, assuming they are not lost through continued bleeding. Transfusion therapy will stabilize the patient while other options are reviewed.

ORAL IRON THERAPY

In the asymptomatic patient with established iron-deficiency anemia and an intact gastrointestinal tract, treatment with oral iron is usually adequate. Encouraging dietary intake of iron-rich foods is also useful. Such foods include oysters, kidney beans, beef liver, tofu, beef (chuck roast, lean ground beef), turkey leg, whole-wheat bread, tuna, eggs, shrimp, peanut butter, leg of lamb, brown rice, raisin bran (whole grain–enriched cereals), lentils, and beans. Multiple preparations of oral iron supplements are available, ranging from simple iron salts to complex iron compounds designed for sustained release throughout the small intestine (Table 97-5). Although the various preparations contain different amounts of iron, they are generally all absorbed well and are effective in treatment. Some come with other compounds designed to enhance iron absorption, such as ascorbic acid. It is not clear whether the benefits of such compounds justify their costs. Typically, for iron replacement therapy, up to 200 mg of elemental iron per day is given, usually

TABLE 97-5 Oral Iron Preparations

GENERIC NAME	TABLET (IRON CONTENT), mg	ELIXIR (IRON CONTENT), mg IN 5 mL
Ferrous sulfate	325 (65) 195 (39)	300 (60) 90 (18)
Extended release	525 (105)	
Ferrous fumarate	325 (107) 195 (64)	 100 (33)
Ferrous gluconate	325 (39)	300 (35)
Polysaccharide iron	150 (150) 50 (50)	100 (100)

TABLE 97-4 Diagnosis of Microcytic Anemia

TESTS	IRON DEFICIENCY	INFLAMMATION	THALASSEMIA	SIDEROBLASTIC ANEMIA
Smear	Micro/hypo	Normal micro/hypo	Micro/hypo with targeting	Variable
Serum iron (μg/dL)	<30	<50	Normal to high	Normal to high
TIBC (μg/dL)	>360	<300	Normal	Normal
Percent saturation	<10	10–20	30–80	30–80
Ferritin (μg/L)	<15	30–200	50–300	50–300
Hemoglobin pattern on electrophoresis	Normal	Normal	Abnormal with β thalassemia; can be normal with α thalassemia	Normal

Abbreviation: TIBC, total iron-binding capacity.

as three or four iron tablets (each containing 50–65 mg elemental iron) given over the course of the day. Ideally, oral iron preparations should be taken on an empty stomach, since food may inhibit iron absorption. Some patients with gastric disease or prior gastric surgery require special treatment with iron solutions because the retention capacity of the stomach may be reduced. The retention capacity is necessary for dissolving the shell of the iron tablet before the release of iron. A dose of 200 mg of elemental iron per day should result in the absorption of iron up to 50 mg/d. This supports a red cell production level of two to three times normal in an individual with a normally functioning marrow and appropriate erythropoietin (EPO) stimulus. However, as the hemoglobin level rises, EPO stimulation decreases, and the amount of iron absorbed is reduced. The goal of therapy in individuals with iron-deficiency anemia is not only to repair the anemia, but also to provide stores of at least 0.5–1 g of iron. Sustained treatment for a period of 6–12 months after correction of the anemia will be necessary to achieve this.

Of the complications of oral iron therapy, gastrointestinal distress is the most prominent and is seen in at least 15–20% of patients. Abdominal pain, nausea, vomiting, or constipation may lead to noncompliance. Although small doses of iron or iron preparations with delayed release may help somewhat, the gastrointestinal side effects are a major impediment to the effective treatment of a number of patients.

The response to iron therapy varies, depending on the EPO stimulus and the rate of absorption. Typically, the reticulocyte count should begin to increase within 4–7 days after initiation of therapy and peak at 1–1½ weeks. The absence of a response may be due to poor absorption, noncompliance (which is common), or a confounding diagnosis. A useful test in the clinic to determine the patient's ability to absorb iron is the *iron tolerance test*. Two iron tablets are given to the patient on an empty stomach, and the serum iron is measured serially over the subsequent 2–3 h. Normal absorption will result in an increase in the serum iron of at least 100 μg/dL. If iron deficiency persists despite adequate treatment, it may be necessary to switch to parenteral iron therapy.

PARENTERAL IRON THERAPY

Intravenous iron can be given to patients who are unable to tolerate oral iron; whose needs are relatively acute; or who need iron on an ongoing basis, usually due to persistent gastrointestinal or menstrual blood loss. Parenteral iron use has been increasing rapidly over the past several years with the recognition that recombinant EPO therapy induces a large demand for iron—a demand that frequently cannot be met through the physiologic release of iron from RE sources or oral iron absorption. The safety of parenteral iron has been a concern largely driven by the high adverse reaction rate to high-molecular-weight iron dextran. The newer iron complexes that are available, such as ferumoxytol (Feraheme), sodium ferric gluconate (Ferrlecit), iron sucrose (Venofer), low-molecular-weight (LMW) iron dextran (InFed), ferric derisomaltose (Monoferric), and ferric carboxymaltose (Injectafer), have much lower rates of adverse effects. Ferumoxytol delivers 510 mg of iron per infusion; ferric gluconate 125 mg per infusion; LMW iron dextran up to 1500 mg per infusion; ferric carboxymaltose 750 mg per infusion; ferric derisomaltose 1000 mg per infusion; and iron sucrose 200 mg per infusion.

Parenteral iron is used in two ways: one is to administer the total dose of iron required to correct the hemoglobin deficit and provide the patient with at least 500 mg of iron stores; the second is to give repeated small doses of parenteral iron over a protracted period. The latter approach is common in dialysis centers, where it is not unusual for 100 mg of elemental iron to be given weekly for 10 weeks to augment the response to recombinant EPO therapy. The amount of iron needed by an individual patient is calculated by the following formula:

$$\text{Body weight (kg)} \times 2.3 \times (15 - \text{patient's hemoglobin, g/dL}) + 500 \text{ or } 1000 \text{ mg (for stores)}$$

In administering any intravenous iron preparation, anaphylaxis is a concern. Anaphylaxis is much rarer with the newer preparations. The factors that have correlated with an anaphylactic-like reaction include a history of multiple allergies or a prior allergic reaction to an iron preparation. Generalized symptoms appearing several days after the infusion of a large dose of iron can include arthralgias, skin rash, and low-grade fever. These may be dose-related, but they do not preclude the further use of parenteral iron in the patient. To date, patients with sensitivity to one iron preparation have been safely treated with other parenteral iron preparations. If a large dose of LMW iron dextran is to be given (>100 mg), the iron preparation should be diluted in 5% dextrose in water or 0.9% NaCl solution. The iron solution can then be infused over a 60- to 90-min period (for larger doses) or at a rate convenient for the attending nurse or physician. Although a test dose (25 mg) of parenteral LMW iron dextran is recommended, in reality, a slow infusion of a larger dose of parenteral iron solution will afford the same kind of early warning as a separately injected test dose. Early in the infusion of iron, if chest pain, wheezing, a fall in blood pressure, or other systemic symptoms occur, the infusion of iron should be stopped immediately.

OTHER HYPOPROLIFERATIVE ANEMIAS

In addition to mild to moderate iron-deficiency anemia, the hypoproliferative anemias can be divided into four categories: (1) chronic inflammation, (2) renal disease, (3) endocrine and nutritional deficiencies (hypometabolic states), and (4) marrow damage **(Chap. 102)**. With chronic inflammation, renal disease, or hypometabolism, endogenous EPO production is inadequate for the degree of anemia observed. For the anemia of chronic inflammation, the erythroid marrow also responds inadequately to stimulation, due in part to defective *iron reutilization*. As a result of the lack of adequate EPO stimulation, an examination of the peripheral blood smear will disclose only an occasional polychromatophilic ("shift") reticulocyte. In cases of iron deficiency or marrow damage, appropriate elevations in endogenous EPO levels are typically found, and shift reticulocytes will be present on the blood smear.

■ ANEMIA OF ACUTE AND CHRONIC INFLAMMATION/INFECTION (AI)

AI, which encompasses inflammation, infection, tissue injury, and conditions (e.g., cancer) associated with the release of proinflammatory cytokines, is one of the most common forms of anemia seen clinically. It is the most important anemia in the differential diagnosis of iron deficiency because many of the features of the anemia are brought about by inadequate iron delivery to the marrow, despite the presence of normal or increased iron stores. This is reflected by a low serum iron, increased red cell protoporphyrin, a hypoproliferative marrow, transferrin saturation in the range of 15–20%, and a normal or increased serum ferritin. The serum ferritin values are often the most distinguishing features between true iron-deficiency anemia and the iron-restricted erythropoiesis associated with inflammation. Typically, serum ferritin values increase threefold over basal levels in the face of inflammation. These changes are due to the effects of inflammatory cytokines and hepcidin, the key iron regulatory hormone, acting at several levels of erythropoiesis **(Fig. 97-4)**.

Interleukin 1 (IL-1) directly decreases EPO production in response to anemia. IL-1, acting through accessory cell release of interferon γ (IFN-γ), suppresses the response of the erythroid marrow to EPO—an effect that can be overcome by EPO administration in vitro and in vivo. In addition, tumor necrosis factor (TNF), acting through the release of IFN-β by marrow stromal cells, also suppresses the response to EPO. Hepcidin, made by the liver, is increased in inflammation via an IL-6–mediated pathway, and acts to suppress iron absorption and iron release from storage sites. The overall result is a chronic hypoproliferative anemia with classic changes in iron metabolism. The anemia is further compounded by a mild to moderate shortening in red cell survival.

With chronic inflammation, the primary disease will determine the severity and characteristics of the anemia. For example, many

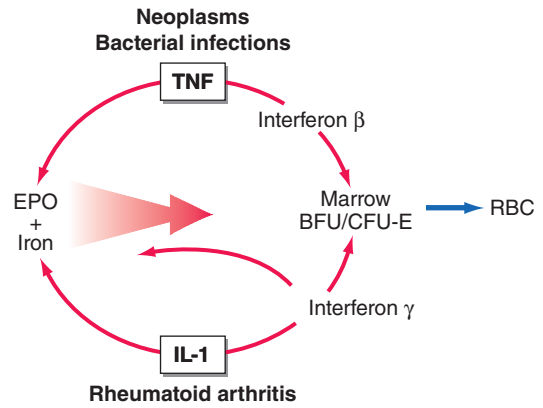

FIGURE 97-4 Suppression of erythropoiesis by inflammatory cytokines. Through the release of tumor necrosis factor (TNF) and interferon β (IFN-β), neoplasms and bacterial infections suppress erythropoietin (EPO) production and the proliferation of erythroid progenitors (erythroid burst-forming units and erythroid colony-forming units [BFU/CFU-E]). The mediators in patients with vasculitis and rheumatoid arthritis include interleukin 1 (IL-1) and IFN-γ. The *red arrows* indicate sites of inflammatory cytokine inhibitory effects. RBC, red blood cell.

patients with cancer also have anemia that is typically normocytic and normochromic. In contrast, patients with long-standing active rheumatoid arthritis or chronic infections such as tuberculosis will have a microcytic, hypochromic anemia. In both cases, the bone marrow is hypoproliferative, but the differences in red cell indices reflect differences in the availability of iron for hemoglobin synthesis. Occasionally, conditions associated with chronic inflammation are also associated with chronic blood loss. Under these circumstances, the measurement of soluble transferrin receptor protein may be necessary to rule out absolute iron deficiency. However, the administration of iron in this case will correct the iron-deficiency component of the anemia and leave the inflammatory component unaffected.

The anemia associated with acute infection or inflammation is typically mild but becomes more pronounced over time. Acute infection can produce a decrease in hemoglobin levels of 2–3 g/dL within 1 or 2 days; this is largely related to the hemolysis of red cells near the end of their natural life span. The fever and cytokines released exert a selective pressure against cells with more limited capacity to maintain the red cell membrane. In most individuals, the mild anemia is reasonably well tolerated, and symptoms, if present, are associated with the underlying disease. Occasionally, in patients with preexisting cardiac disease, moderate anemia (hemoglobin 10–11 g/dL) may be associated with angina, exercise intolerance, and shortness of breath. The erythropoietic profile that distinguishes the anemia of inflammation from the other causes of hypoproliferative anemias is shown in Table 97-6.

ANEMIA OF CHRONIC KIDNEY DISEASE (CKD)

Progressive CKD is usually associated with a moderate to severe hypoproliferative anemia; the level of the anemia correlates with the stage of CKD. Red cells are typically normocytic and normochromic, and reticulocytes are decreased. The anemia is primarily due to a failure of EPO production by the diseased kidney and a reduction in red cell survival. In certain forms of acute renal failure, the correlation between the anemia and renal function is weaker. Patients with the hemolytic-uremic syndrome increase erythropoiesis in response to the hemolysis, despite renal failure. Polycystic kidney disease also shows a smaller degree of EPO deficiency for a given level of renal failure. By contrast, patients with diabetes or myeloma have more severe EPO deficiency for a given level of renal failure.

Assessment of iron status provides information to distinguish the anemia of CKD from the other forms of hypoproliferative anemia (Table 97-6) and to guide management. Patients with the anemia of CKD usually present with normal serum iron, TIBC, and ferritin levels. However, those maintained on chronic hemodialysis may develop iron deficiency from blood loss through the dialysis procedure. Iron must be replenished in these patients to ensure an adequate response to EPO therapy (see below).

ANEMIA IN HYPOMETABOLIC STATES

Patients who are starving, particularly for protein, and those with a variety of endocrine disorders that produce lower metabolic rates, may develop a mild to moderate hypoproliferative anemia. The release of EPO from the kidney is sensitive to the need for O_2, not just O_2 levels. Thus, EPO production is triggered at lower levels of blood O_2 content in disease states (e.g., hypothyroidism and starvation) where metabolic activity, and thus O_2 demand, is decreased.

Endocrine Deficiency States The difference in the levels of hemoglobin between men and women is related to the effects of androgen and estrogen on erythropoiesis. Testosterone and anabolic steroids augment erythropoiesis; castration and estrogen administration to males decrease erythropoiesis. Patients who are hypothyroid or have deficits in pituitary hormones also may develop a mild anemia. Pathogenesis may be complicated by other nutritional deficiencies because iron and folic acid absorption can be affected by these disorders. Usually, correction of the hormone deficiency reverses the anemia.

Anemia may be more severe in Addison's disease, depending on the level of thyroid and androgen hormone dysfunction; however, anemia may be masked by decreases in plasma volume. Once such patients are given cortisol and volume replacement, the hemoglobin level may fall rapidly. Mild anemia complicating hyperparathyroidism may be due to decreased EPO production as a consequence of the renal effects of hypercalcemia or to impaired proliferation of erythroid progenitors.

Protein Starvation Decreased dietary intake of protein may lead to mild to moderate hypoproliferative anemia; this form of anemia may be prevalent in the elderly. The anemia can be more severe in patients with a greater degree of starvation. In marasmus, where patients are both protein- and calorie-deficient, the release of EPO is impaired in proportion to the reduction in metabolic rate; however, the degree of anemia may be masked by volume depletion and becomes apparent after refeeding. Deficiencies in other nutrients (iron, folate) may also complicate the clinical picture but may not be apparent at diagnosis. Changes in the erythrocyte indices on refeeding should prompt evaluation of iron, folate, and B_{12} status.

Anemia in Liver Disease A mild hypoproliferative anemia may develop in patients with chronic liver disease from nearly any cause. The peripheral blood smear may show spur cells and stomatocytes

TABLE 97-6 Diagnosis of Hypoproliferative Anemias

TESTS	IRON DEFICIENCY	INFLAMMATION	RENAL DISEASE	HYPOMETABOLIC STATES
Anemia	Mild to severe	Mild	Mild to severe	Mild
MCV (fL)	60–90	80–90	90	90
Morphology	Normo-microcytic	Normocytic	Normocytic	Normocytic
SI (μg/dL)	<30	<50	Normal	Normal
TIBC (μg/dL)	>360	<300	Normal	Normal
Saturation (%)	<10	10–20	Normal	Normal
Serum ferritin (μg/L)	<15	30–200	115–150	Normal
Iron stores	0	2–4+	1–4+	Normal

Abbreviations: MCV, mean corpuscular volume; SI, serum iron; TIBC, total iron-binding capacity.

from the accumulation of excess cholesterol in the membrane from a deficiency of lecithin-cholesterol acyltransferase. Red cell survival is shortened, and the production of EPO is inadequate to compensate. In alcoholic liver disease, nutritional deficiencies are common and complicate the management. Folate deficiency from inadequate intake, as well as iron deficiency from blood loss and inadequate intake, can alter the red cell indices.

ANEMIA IN AGING

Anemia is common in people over age 65 years. It has been estimated to affect ~11% of community-living older adults and up to 40% of nursing home residents. In at least one-third of these anemic people, a cause for the anemia is not found. Patients with the unexplained anemia of aging do not have nutrient deficiency or renal dysfunction, and although older people can have an increase in systemic inflammatory cytokines (the inflammation of aging), the levels are not high enough to mimic the anemia of chronic inflammation. If hepcidin levels are elevated at all, they are minimally so.

Investigations into the cause(s) of this form of anemia have noted that EPO levels are generally in the normal range, that is, they are inappropriately low for the hemoglobin level. In general, in older people who maintain a normal hemoglobin level, EPO levels increase with age. This compensatory increase to maintain normal oxygen delivery seems to be due to a relative resistance to EPO stimulation; studies of red cell life span in older people have not noted a decrease in red cell survival. More data on the mechanism are needed.

The importance of this unexplained anemia of aging is that low hemoglobin levels are associated with increases in falls, hospitalizations, development of frailty, and mortality. It is not clear whether reversing the anemia would influence these increased risks. Anecdotal evidence suggests that this form of anemia is responsive to exogenous EPO.

TREATMENT

Hypoproliferative Anemias

Many patients with hypoproliferative anemias experience recovery of normal hemoglobin levels when the underlying disease is appropriately treated. For those in whom such reversals are not possible—such as patients with end-stage kidney disease, cancer, and chronic inflammatory diseases—symptomatic anemia requires treatment. The two major forms of treatment are transfusions and EPO.

TRANSFUSIONS

Thresholds for transfusion should be determined based on the patient's symptoms. In general, patients without serious underlying cardiovascular or pulmonary disease can tolerate hemoglobin levels above 7–8 g/dL and do not require intervention until the hemoglobin falls below that level. Patients with more physiologic compromise may need to have their hemoglobin levels kept above 11 g/dL. Usually, a unit of packed red cells increases the hemoglobin level by 1 g/dL. Transfusions are associated with certain infectious risks **(Chap. 113)**, and chronic transfusions can produce iron overload. Importantly, the liberal use of blood has been associated with increased morbidity and mortality, particularly in the intensive care setting. Therefore, in the absence of documented tissue hypoxia, a conservative approach to the use of red cell transfusions is preferable.

ERYTHROPOIETIN

EPO is particularly useful in anemias in which endogenous EPO levels are inappropriately low, such as CKD or AI. Iron status must be evaluated and iron replaced to obtain optimal effects from EPO. In patients with CKD, the usual dose of EPO is 50–150 U/kg three times a week intravenously. Hemoglobin levels of 10–12 g/dL are usually reached within 4–6 weeks if iron levels are adequate; 90% of these patients respond. Once a target hemoglobin level is achieved, the EPO dose can be decreased. A decrease in hemoglobin level occurring in the face of EPO therapy usually signifies the development of an infection or iron depletion. Aluminum toxicity and hyperparathyroidism can also compromise the response to EPO. When an infection intervenes, it is best to interrupt the EPO therapy and rely on transfusions to correct the anemia until the infection is adequately treated. The dose of EPO needed to correct chemotherapy-induced anemia in patients with cancer is higher, up to 300 U/kg three times a week, and only ~60% of patients respond. Because of evidence that there is an increased risk of thromboembolic complications and tumor progression with EPO administration, the risks and benefits of using EPO in such patients must be weighed carefully, and the target hemoglobin should be that necessary to avoid transfusions.

Longer-acting preparations of EPO can reduce the frequency of injections. Darbepoetin alfa, a molecularly modified EPO with additional carbohydrate, has a half-life in the circulation that is three to four times longer than recombinant human EPO, permitting weekly or every other week dosing.

Orally bioavailable EPO mimetics such as roxadustat (usual dose 50 mg PO thrice weekly) that act to increase the biological half-life of active hypoxia-inducible factor (HIF) are demonstrating activity to increase hemoglobin levels in patients with chronic renal disease and other settings.

98 Disorders of Hemoglobin

Martin H. Steinberg

Hemoglobinopathies affect the amino acid sequence of globin; thalassemia is a disorder of reduced globin biosynthesis. Together, these disorders of the hemoglobin molecule are our most common Mendelian genetic diseases. They are responsible for most cases of hemolytic anemia. Sickle cell disease and the hemoglobin E (HbE)–associated syndromes are the most prevalent hemoglobinopathies; β and α thalassemia are the most prevalent thalassemias. In addition to these common disorders of hemoglobin, rare globin mutations can cause hemoglobin instability, increased or decreased affinity of hemoglobin for oxygen (O_2), and oxidized hemoglobin reducing O_2 transport. O_2 transport by hemoglobin can also be reduced by exposure to carbon monoxide (CO) and some oxidizing agents **(Table 98-1)**.

Phenotypic diversity among hemoglobin disorders is enormous. Mutations can be asymptomatic, for example in heterozygous carriers of sickle hemoglobin (HbS) and thalassemia, or cause intrauterine death as when all α-globin genes are deleted. Impressive gains in understanding the biological basis of hemoglobinopathies and thalassemia have led to novel therapeutics with the promise of improved patient outcomes.

TABLE 98-1 Disorders of Hemoglobin

I. **Hemoglobinopathies**—hemoglobin variants with amino acid sequence variants that alter the physical, chemical, or functional properties of hemoglobin
  A. Common variants with unusual properties
    1. HbS—polymerization
    2. HbE—reduced biosynthesis
    3. HbC—hemoglobin-membrane interaction
  B. Altered oxygen affinity
    1. High affinity—erythrocytosis
    2. Low affinity—cyanosis, anemia
  C. Hemoglobins that oxidize readily
    1. Unstable hemoglobins—hemolytic anemia, jaundice
    2. M hemoglobins—methemoglobinemia, cyanosis
II. **Thalassemias**—defective biosynthesis of globin chains
  A. α Thalassemias
  B. β Thalassemias
  C. Complex thalassemias
III. **Hereditary persistence of fetal hemoglobin**—persistence of higher than normal levels of HbF into adult life
  A. Deletions within the *HBB* cluster—15–30% HbF in heterozygotes, pancellular
  B. Point mutations in *HBG2/1* promoters—5–30% HbF in heterozygotes; pancellular or heterocellular
IV. **Acquired hemoglobinopathies**
  A. Methemoglobin due to toxic exposures
  B. Sulfhemoglobin due to toxic exposures
  C. Carboxyhemoglobin
  D. HbH in erythroleukemia
  E. Elevated HbF in myelodysplasia

HEMOGLOBIN

Easy access to erythrocytes to study hemoglobin structure and function, reticulocytes to examine hemoglobin biosynthesis, and leukocyte DNA to define the mutations of hemoglobin and the availability of hematopoietic stem and progenitor cells from blood and bone marrow have placed hemoglobin disorders in the forefront of molecular medicine. A review of the biology of hemoglobin provides the background for understanding the pathophysiology of its many genetic and acquired disorders and approaches to their treatment.

DEVELOPMENTAL BIOLOGY

Successive waves of erythropoiesis beginning in the yolk sac, moving to the fetal liver and bone marrow, and culminating in the adult marrow direct the synthesis of different hemoglobin molecules that result from sequential activation and silencing of the globin genes (Fig. 98-1).

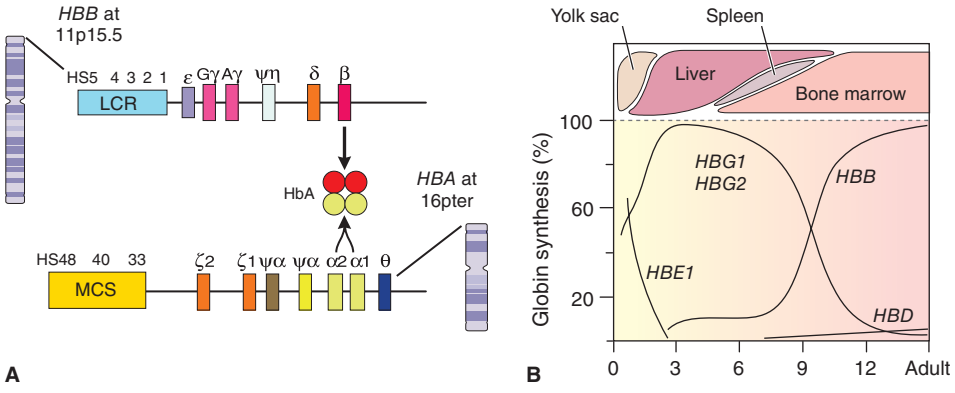

FIGURE 98-1 Globin gene clusters and their hemoglobin products during gestation. ***A.*** The order of globin genes in the β- and α-globin gene clusters along with their upstream enhancers, the locus control region (LCR) and multispecies conserved sequences (MCS). Normal hemoglobin tetramers contain two α-globin chains and two non-α-globin chains. In the example shown, this is adult HbA. ***B.*** Sites of erythropoiesis and globin synthesized from the yolk sac and the early embryo (months 1–3), the fetus (months 3–9), after delivery (months 9–12), and afterward (adult).

Hemoglobin is a tetramer of two pairs of unlike globin polypeptide chains, each chain containing a tetrapyrrole heme group. O_2 binds to heme as erythrocytes traverse the lungs and is released in the tissues. Heme is nestled within a protective pocket of each globin subunit.

GLOBIN GENE CLUSTERS

Globin is encoded in two nonallelic gene clusters. The β-globin gene cluster is on the short arm of chromosome 11 (11p15.4); the α-globin gene cluster is on chromosome 16 (16p13.3) (Fig. 98-1). The β-globin gene cluster contains an embryonic ε-globin gene (*HBE*), two nearly identical fetal γ-globin genes (*HBG2, HBG1*) a major adult β-globin gene (*HBB*), and a minor adult δ-globin gene (*HBD*). The α-globin gene cluster contains an embryonic ζ-globin gene (*HBZ*) and duplicated α-globin genes (*HBA2, HBA1*) with identical proteins. Embryonic hemoglobins include Gower I ($\zeta_2\varepsilon_2$), Gower II ($\alpha_2\varepsilon_2$), Portland I ($\zeta_2\gamma_2$), and Portland II ($\zeta_2\beta_2$). Fetal hemoglobin (HbF, $\alpha_2\gamma_2$) production begins at 6–8 weeks' gestation, peaks during mid-gestation, then falls to <1% of total hemoglobin during the first 6 months of extrauterine life. Adult hemoglobin A (HbA; $\alpha_2\beta_2$) production follows a pattern reciprocal to that of HbF. The hemoglobin composition of normal adults is >95% HbA, ~1% HbF, and 2–3% HbA_2 ($\alpha_2\delta_2$). In adults, HbF and HbA_2 have little functional significance because of their low concentrations, although they can be diagnostically important. Hemoglobin is also subject to posttranslational modifications, the most important being the nonenzymatic glycosylation of HbA forming the adduct HbA_{1c}, which is of diagnostic utility in the management of diabetes mellitus.

HEMOGLOBIN STRUCTURE

All globin polypeptides have similar but not identical primary structures. α-Globins contain 141 amino acids, and β-like globins have 146 amino acids. This primary structure dictates, according to the constraints of protein folding, the secondary structure of globin into α-helical sections joined by small nonhelical stretches. Each globin chain folds into a tertiary conformation known as the globin fold, whereby charged amino acid residues face the exterior of the molecules and uncharged residues face the hydrophobic interior. The iron-containing tetrapyrrole heme moiety is protected from oxidation and located between two of the helical segments; O_2 loading and unloading occur when heme iron is in its reduced ferrous form. Globin gene mutations affecting critical heme-binding amino acid residues allows iron to be oxidized, forming methemoglobin, which has high O_2 affinity and does not release O_2 in tissues. Dimers of α- and non-α-globin chains reversibly assemble into tetramers, forming a quaternary structure.

HEMOGLOBIN FUNCTION

Hemoglobin transports O_2 from lungs to tissues and carbon dioxide (CO_2) from tissues to lungs and is a nitrate reductase that releases nitric oxide (NO) from nitrite to promote vasodilation. Oxygen binding is defined by the sigmoidal shape of the hemoglobin-O_2 dissociation curve. P_{50} is a point on this curve that indicates the partial pressure of O_2 where hemoglobin is half saturated (Fig. 98-2). The P_{50} is influenced by the binding of 2,3-bisphosphoglycerate, a product of glycolysis, in the central cavity of hemoglobin, and by pH and temperature. Normal P_{50} is ~26 mmHg; low P_{50} indicates that hemoglobin has high O_2 affinity, decreasing O_2 delivery to tissues; high P_{50} indicates that hemoglobin has low O_2 affinity, releasing more O_2 to tissues. The conformation of hemoglobin fully saturated with O_2 is known as the R or relaxed state; desaturated hemoglobin is in the T or tense state. The transition between T and R states occurs when two or three O_2 molecules are bound. Cooperativity describes the progressively more rapid binding of O_2 once the first molecule

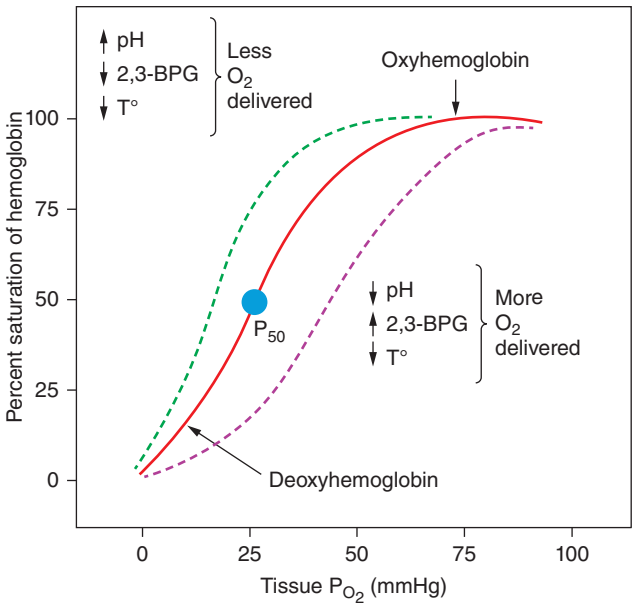

FIGURE 98-2 Hemoglobin-oxygen dissociation curve. The hemoglobin tetramer can bind up to four molecules of oxygen (O_2) in the iron-containing sites of the heme molecules. As O_2 is bound, 2,3-bisphosphoglycerate (2,3-BPG) and carbon dioxide (CO_2) are expelled. Salt bridges are broken, and each of the globin molecules changes its conformation to facilitate O_2 binding. O_2 release to the tissues is the reverse process, with salt bridges being formed and 2,3-BPG and CO_2 bound. Deoxyhemoglobin does not bind O_2 efficiently until the cell returns to conditions of higher pH, the most important modulator of O_2 affinity (Bohr effect). When acid is produced in the tissues, the dissociation curve shifts to the right, facilitating O_2 release and CO_2 binding. Alkalosis has the opposite effect, reducing O_2 delivery.

is bound. Hemoglobin variants that decrease P_{50} are characterized by isolated erythrocytosis as compensation for hypoxia; variants with increased P_{50} sometimes are accompanied by cyanosis and anemia as hemoglobin becomes unsaturated and O_2 delivery is enhanced. Mutations of residues critical for heme binding, R-T transitions, or tetramer stability cause hemoglobinopathies characterized by hemolytic anemia, methemoglobinemia, erythrocytosis and cyanosis.

GLOBIN GENE SWITCHING

The sequential activation and inactivation of globin genes during development shown in Fig. 98-1 is called "hemoglobin switching." Transcription factors along with epigenetic elements such as DNA methyltransferases and demethylases, interact with enhancers "upstream" of the β-globin gene cluster that contact globin gene promoters, silencing the embryonic and fetal genes. Activation of fetal globin gene repressors during development allows expression of the adult genes. Developmental factors such as RNA-binding factors and microRNAs also impact hemoglobin switching.

β-Globin Gene Switching HbF reactivation by drugs and gene therapy is a prime therapeutic goal for treating the common disorders of hemoglobin, meriting a discussion of the controls of HbF gene silencing. An upstream super-enhancer called the β-globin locus control region (LCR) binds erythroid-specific and ubiquitous transcription factors. The LCR interacts directly with globin gene promoters; transcription factors that silence and activate genes also interact with elements of the globin genes. Competition among the β-like genes for the LCR and autonomous silencing of the embryonic and fetal globin genes depends on transcription factors. Silencing, first of *HBE* and then of *HBG2* and *HBG1*, favors the interaction of the LCR with *HBB*. When *HBG2* or *HBG1* is upregulated by rare point mutations in their promoters, expression of the linked *HBB* is downregulated. Deletions of the *HBB* promoter remove competition for the LCR, increasing the expression of *HBG2*, *HBG1*, and *HBD*. The transcription factors BCL11A (2p16) and ZBTB7A (19p13) silence the HbF genes; BCL11A binds to the HbF gene promoters, repressing them and silencing transcription; ZBTB7A binds upstream of BCL11A with similar repressive effects. This accounts for the bulk of the switch from HbF to HbA. Mutations in these binding sites abolish the normal silencing of the HbF genes, leading to one type of the benign condition called hereditary persistence of fetal hemoglobin (HPFH). Disruption of the *BCL11A* regulatory elements or the binding sites for BCL11A by gene editing is a prime therapeutic target for HbF induction.

α-Globin Gene Switching A less complex switch takes place in the α-globin gene cluster where a regulatory locus of four elements termed R1–R4 is present within introns of the gene *NPRL3* that is upstream of *HBA2*. A developmental switch from embryonic ζ- to adult α-globin gene expression occurs at about 6 weeks' gestation.

Modulation of HbF Level Variations in three quantitative trait loci (QTL), *BCL11A*, *MYB* (6q23), and a locus linked to the *HBB* cluster, account for a major portion of HbF variation among normal individuals and patients with sickle cell anemia and β thalassemia. BCL11A, a zinc finger protein that represses HbF genes, binds TGACCA motifs, the most important at position –115 in the promoter of each γ-globin gene. ZBTB7A binds 85 nucleotides upstream of these BCL11A binding sites; its binding also represses γ-globin gene transcription. When binding of either BCL11A or ZBTB7A is disrupted, silencing of *HBG2* and *HBG1* is abrogated. The unique impact of *BCL11A* variants on HbF in sickle cell anemia and β thalassemia is due their large effect and the high frequency of the variant allele associated with increased HbF.

The *MYB* gene is essential for hematopoiesis and erythroid differentiation. *MYB* inhibits HbF expression directly by activation of *KLF1* and other repressors and indirectly through alteration of the kinetics of erythroid differentiation.

The third QTL is marked by a common variant 158 nucleotides upstream of the transcription start site of *HBG2* and could be a binding site for an uncharacterized HbF repressor. Haplotypes associated with the *HBB* cluster have been defined by single nucleotide polymorphisms (SNPs) among these genes. Sickle cell anemia patients with the Senegal and Arab-Indian HbS gene-associated haplotypes have higher HbF levels than patients with other haplotypes. These two haplotypes have the common–158 C-T variant in the *HBG2* promoter.

DIAGNOSIS OF HEMOGLOBIN DISORDERS

α-Globin gene mutations are expressed in the embryo and fetus and persist throughout life; HbF mutations are expressed in the fetus and in the first months of life, vanishing from notice afterward; δ-globin gene mutations are innocuous and usually not detected; β-globin gene mutations can become clinically apparent after the synthesis of HbF dwindles to stable adult levels.

With rare exceptions, all disorders of hemoglobin are autosomal recessive or co-dominant disorders; a family history of anemia, a common feature of most symptomatic hemoglobinopathies and thalassemias, is often present. In addition to pallor and jaundice, splenomegaly is often present. In sickle cell disease, acute painful vasoocclusive episodes are a diagnostic feature. A small number of laboratory tests can confirm the diagnosis starting with a complete blood count that includes a reticulocyte count with a careful review of a peripheral blood film. A sustained increase in reticulocyte count indicates the presence of hemolytic anemia. Hemoglobin fractionation by high-performance liquid chromatography (HPLC) or capillary electrophoresis, especially when, in addition to the index case, family members are available for study, is often sufficient to confirm a diagnosis at the level of hemoglobin phenotype. DNA sequencing of the globin genes should allow definitive diagnosis. DNA-based diagnosis, which is readily available from excellent reference laboratories, is a prerequisite for most instances of genetic counseling.

Sickle cell disease and β thalassemia have some features in common. They are caused by mutations in the β-globin gene; both are chronic hemolytic anemias sharing complications associated with hemolysis such as venous thrombosis, leg ulcers, and pulmonary hypertension; and they can be cured by hematopoietic stem cell transplantation. Key differences are that only HbS polymerizes and that ineffective

erythropoiesis is a prominent feature of β thalassemia and responsible for its severe anemia. Both diseases could be cured by inducing sufficiently high levels of HbF; in sickle cell disease, HbF prevents the polymerization of HbS; in β thalassemia, sufficient HbF compensates for the deficit of HbA.

SICKLE CELL DISEASE

Sickle cell disease is a clinical and hematologic phenotype caused by an assortment of genotypes (Table 98-2). Sickle cell anemia, defined as homozygosity for the sickle hemoglobin mutation ($\alpha_2\beta^S_2$; glutamic acid [E] 7 valine [V] *GAG-GTG*), is the most common of these genotypes, followed by HbSC disease or compound heterozygosity for HbS and HbC ($\alpha_2\beta^C_2$; E 7 lysine [K] *GAG-AAG*) genes. Many different thalassemia mutations contribute to the HbS-β thalassemias. The compound heterozygous genotypes are less common than HbS homozygotes; as a rule, their symptoms develop later in life and are less severe. HbS has also been described with many other variant hemoglobins. Few of these genotypes, other than $HbSO^{Arab}$, HbSE, and $HbSD^{Punjab}$ are symptomatic.

ORIGIN, SPREAD, AND EPIDEMIOLOGY

HbS originated in Africa between 7000 and 22,000 years ago, reaching high frequencies because of the increased genetic fitness of heterozygotes under selective pressure from *Plasmodium falciparum*. The HbS gene became associated with five common β-globin gene haplotypes: Benin, Bantu, Senegal, Cameroon, and Arab-Indian. These haplotypes have a loose association with the severity of disease because each haplotype has a different average level of HbF. In some regions of Africa, India, and the Middle East, nearly half the population have sickle cell trait. Nigeria alone has ~150,000 newborns each year with sickle cell anemia, about one-third of the world's total newborns; most die before age 5. Coerced and free population movement have spread the HbS gene throughout the world. The HbS carrier, or sickle cell trait, prevalence is 2–15% in emigrant populations; ~100,000 patients in the United States have sickle cell disease; their death in childhood is rare, with the median age of death in the fifth or sixth decade.

PATHOPHYSIOLOGY

Pathophysiologic features of sickle cell disease are summarized in Fig. 98-3. HbS is physiologically similar to HbA in most respects except it polymerizes when deoxygenated. Contacts between one of the β^7 valine residues of deoxyHbS and specific amino acid residues of β- and α-globin culminate in fascicles of hemoglobin that injure the sickle erythrocyte. A delay occurs between the initiation of polymerization and the accumulation of sufficient polymer to damage the cell. It is unclear how much polymer is needed for cell injury, but it is clear that polymer leads directly and indirectly to the multiple abnormalities of the sickle erythrocyte that generate the pathophysiology of disease. Prominent among these abnormalities are HbS polymer penetration of the membrane causing vesiculation with membrane microparticle release; increased activity of the Gardos, K/CL cotransport, and P_{sickle} channels that dehydrate the cell, increasing mean corpuscular sickle hemoglobin concentration (MC[HbS]C), reducing cellular deformability, and increasing the polymerization potential of HbS; translocation of amino phospholipids such as phosphatidylserine to the outer leaflet of the membrane; and oxidation of erythrocyte contents. These and other abnormalities lead to the formation of irreversibly sickled cells (ISCs), which are sickle erythrocytes that are forever deformed because of permanent membrane damage regardless of whether HbS remains polymerized. Damaged sickle erythrocytes are responsible for initiating the vasoocclusive, hemolytic, and inflammatory features of the disease shown in Fig. 98-3.

DIAGNOSIS

Although sickle cell disease can appear in any ethnic group, most often it is present in people of African, Middle Eastern, Mediterranean, and

TABLE 98-2 Common Sickle Hemoglobinopathies

GENOTYPE	CLINICAL ABNORMALITIES	HEMOGLOBIN LEVEL, g/L (g/dL)/MCV, fL	HEMOGLOBIN FRACTIONS (%)
Sickle cell trait (HbAS)	8% of African Americans; hematuria, papillary necrosis, hyposthenuria, increased incidence of chronic kidney disease; 2–4 times increased VTE risk; ? stroke; splenic infarction at altitude; rhabdomyolysis	Normal	HbA: 60–70 HbS: 30–40 Percent HbS dependent on presence or absence of α thalassemia
Sickle cell anemia (HbSS)	Vasoocclusion related: pain, acute chest syndrome, osteonecrosis, splenic infarction Hemolysis related: stroke, pulmonary and systemic vasculopathy, nephropathy, leg ulceration gallstones, priapism, leg ulcers	70–100 (7–10)/80–100	HbS: >75 HbF: 2–25 HbA_2: 3–4
HbS-β^0 thalassemia	Rate of complications similar to HbSS	80–100 (8–11)/60–85	HbS: >75 HbF: 2–15 HbA_2: 5–6
HbS-β^+ thalassemia	Rate of complications about half the rate of HbSS depending on percent HbA	100–140 (10–14)/70–80	HbS: 60–90 HbA: 5–40 HbF: 1–10 HbA_2: 5–6
Hemoglobin SC disease (HbSC)	Nearly asymptomatic to severe disease; about half the rate of complications as HbSS. Increased risk of retinopathy	100–140 (10–14)/70–100	HbS: 50 HbC: 50
HbSE	Resembles clinically HbS-β^+ thalassemia; symptoms delayed; often Asian/Indian ancestry	90–130 (9–13)/65–75	HbS: 65 HbE: 35 HbF: 1-5
HbSS-α thalassemia	Present in 30% of HbSS; phenocopies HbS-β^0 thalassemia; similar to HbSS but with fewer strokes and leg ulcers and less pulmonary vascular and renal disease	80–100 (8–11)/60–85	HbS: >75 HbF: 2–15 HbA_2: 4–5
HbS-HPFH	Most common genotype is due to large *HBB* deletions and is asymptomatic	110–140 (11–14)/70–80	HbS: 70 HbF: 20–30 HbA_2: 1–2

Note: Laboratory values are averages in untreated adults.

Abbreviation: VTE, venous thromboembolism.

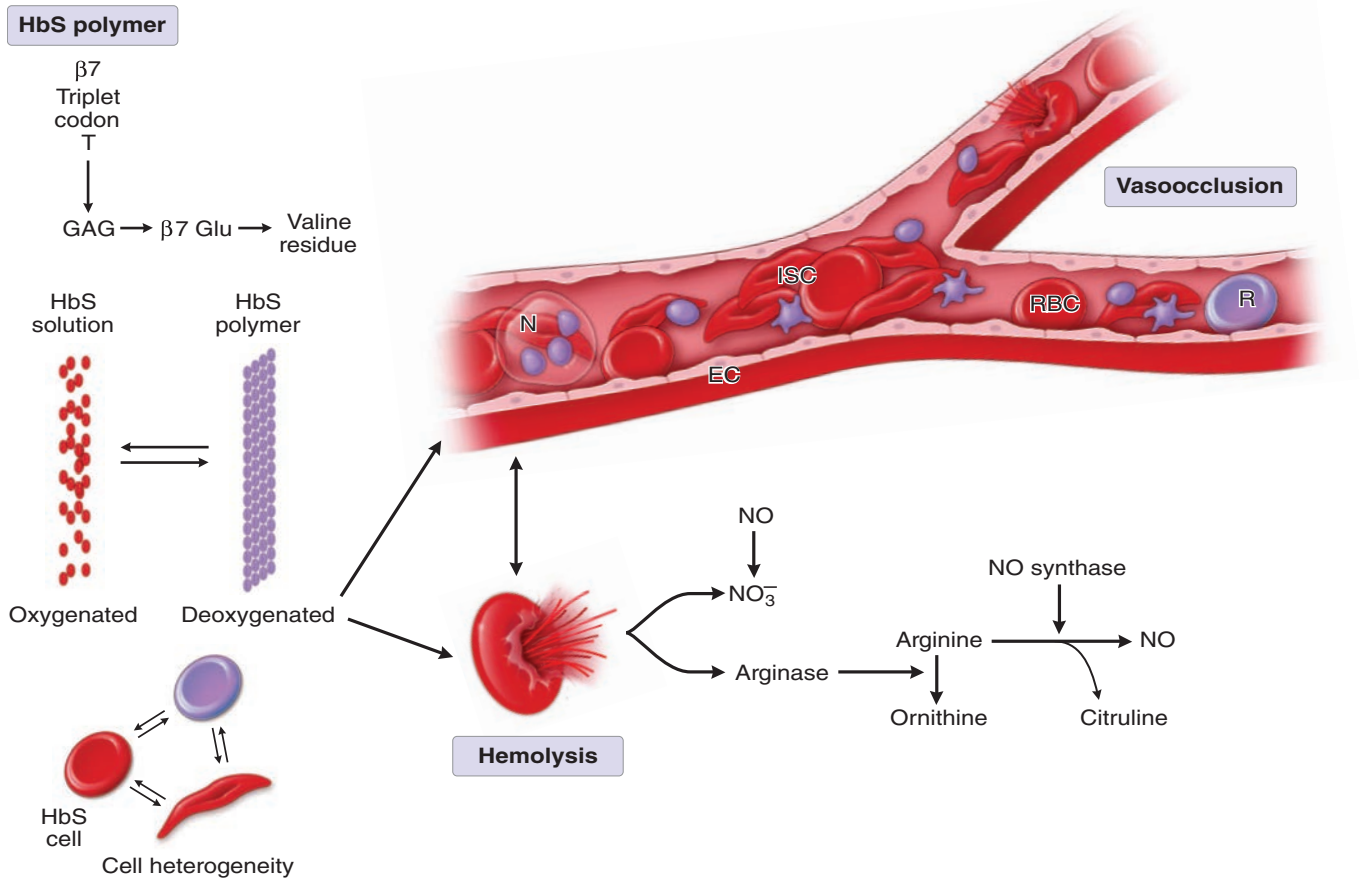

FIGURE 98-3 Pathophysiology of sickle cell disease. HbS is in solution when oxygenated but reversibly polymerizes when deoxygenated. Polymerization is dependent on the 30th power of hemoglobin concentration. In the sickle cell, this means that small changes in hemoglobin concentration or cell hydration can have large effects on polymerization. Polymerization begins seconds to minutes following deoxygenation. Erythrocyte deformation, or sickling, is initially reversible, but after an undetermined number of cell sickling events, the cell becomes irreversibly deformed. These are known as irreversibly sickled cells (ISCs). Their membrane is permanently damaged, although depending on their oxygen (O_2) content, HbS could be in solution. Sickle erythrocytes lead to the clinical and laboratory phenotypes of disease. Sickle cells interact with endothelial cells and other blood cells, occluding flow in small and sometimes large vessels and causing the many complications thought to be a result of vasoocclusion. Sickle cells also live <20 days (normal ~120 days) hemolyzing intra- and extravascularly. Intravascular hemolysis depletes haptoglobin and hemopexin while liberating heme, arginase, and other danger-associated molecular patterns (DAMPs) into the blood. This scavenges nitric oxide (NO), activates platelets and endothelium, reduces antioxidant activity, causes vasoconstriction, and is proinflammatory.

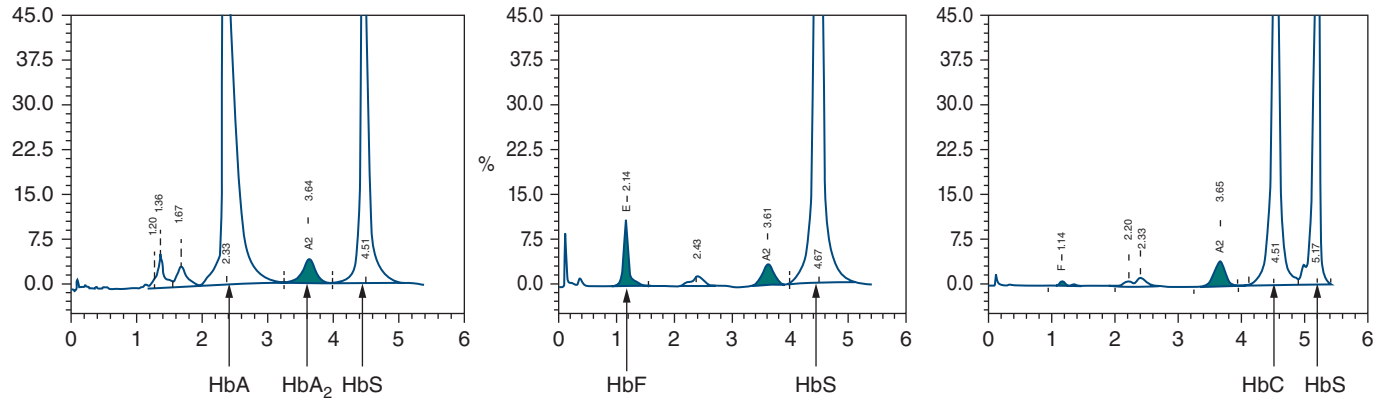
Indian descent. The chief presenting symptom is pain that might be an arthritis-like hand-foot syndrome in young children or the typical acute painful episode in older children and adults. In HbSC disease and HbS-β^+ thalassemia, acute vasoocclusive episodes occur less often and complications develop later in life; rarely, patients with these genotypes are asymptomatic. The key elements of laboratory diagnosis are outlined in Table 98-2 showing typical hematologic findings and hemoglobin fractions. Figure 98-4 displays HPLC profiles and blood films in typical patients with sickle cell trait, sickle cell anemia, and HbSC disease. Clinical and basic laboratory diagnosis is sufficient for general management and counseling; genetic counseling and family planning usually require DNA-based diagnosis.

COMPLICATIONS

Complications of sickle cell disease can be grouped into those that likely are a consequence of sickle vasoocclusion and ones that appeared to be triggered by intravascular hemolysis. Although there is a relationship between these two limbs of pathophysiology, complications associated with vasoocclusion seem to respond best to induction of HbF. Some complications of disease are presented in Table 98-3. Early and effective treatment with hydroxyurea and the integration into management of new treatments discussed below should change this profile.

Acute Painful Episodes Characterized by unprovoked severe pain in extremities or torso that is often symmetrical and stereotypical for each patient and usually requires treatment with strong opioids in the emergency department, acute painful episodes are the most common acute events in sickle cell disease. They are the chief cause of concern for patients, most of whom have them at some time in their life. Their frequency varies; most patients have one to two episodes a year; some rarely have them; others are hardly ever without them. Acute painful episodes last days to weeks. Complicating the diagnosis and management of the acute pain episode, pain in sickle cell disease can be chronic from complications such as osteonecrosis, osteoporosis, or leg ulcers; chronic and acute pain can overlap; and pain can also be induced by opioid treatment of pain. Diary studies have shown that most of the time patients have some degree of pain that does not reach the intensity of the acute episode. Most patients use oral opioid analgesics for control of this pain. Reliable patients can be given a reasonable supply of oral opioids on a monthly basis.

No diagnostic test can confirm or refute the presence of an acute pain episode; often a 1 to 2 g/dL decrease in hemoglobin level and a modest increase in the leukocyte count are noted during the painful episode. Drastic decreases in hemoglobin and platelet levels with more extreme leukocytosis can portend development of severe acute chest syndrome or multiorgan failure. Acute painful episodes have little to do with the presence of ISCs in the blood or the reticulocyte count. The most anemic patients seem to have the least pain. It is unusual for a cause of acute painful episodes to be identified. Physical examination is not often useful diagnostically. Some patients will have pain on



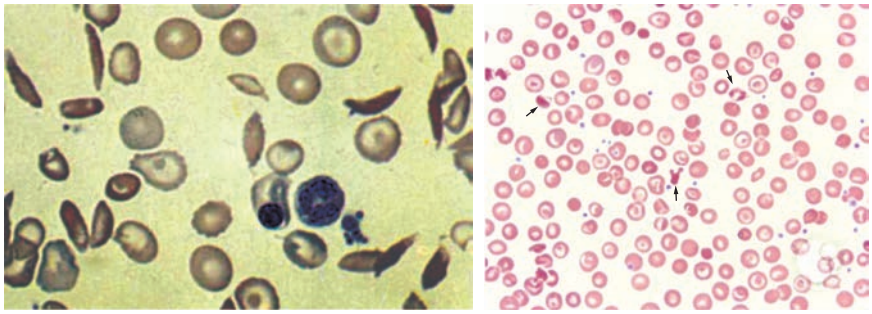


FIGURE 98-4 Diagnosis of sickle cell disease. ***A.*** From *left to right*, high-performance liquid chromatography separation in sickle cell trait, sickle cell anemia, and HbSC disease. Beneath each chromatogram, the individual protein peaks are identified. ***B.*** *Left:* Dense, elongated, and pointed cells are the irreversibly sickled cells characteristic of the sickle cell anemia and sickle cell-β^0 thalassemia. Target cells and nucleated red cells are also present. *Right:* Target cells, cells with squared ends of HbC crystals, cells folded like tacos, and contracted microspherocytes are typical of HbSC disease. *(Source: B [right]: Reproduced with permission from American Society of Hematology.)*

TABLE 98-3 Complications of Sickle Cell Disease

COMPLICATION	INCIDENCE, DIAGNOSIS, AND FEATURES	TREATMENT
Priapism	~30% of males; can be episodic and short duration (stuttering); severe episodes can cause impotence; associated with markers of hemolysis	Many unproven therapies including α-adrenergic agonists, stilbesterol; consult urology for therapy, which is time-critical
Stroke and silent infarction	10–15% of all cases; infarction in early childhood into adulthood; hemorrhagic in adults; neurocognitive abnormalities in adults even without apparent stroke; associated with markers of hemolysis	Transcranial Doppler screening in children aged 2–16; transfusion for at-risk patients; hydroxyurea
Gallstones/surgery	~40% of patients; bilirubin levels and stones related to polymorphisms of *UGT1A*; in surgery requiring general anesthesia, simple preoperative transfusion to a hemoglobin of 10 g/dL is recommended	If asymptomatic, usually let be; otherwise, laparoscopic cholecystectomy
Hepatic disease	>80% of patients have hepatomegaly; intrahepatic cholestasis can have bilirubin ~100 mg/dL; viral hepatitis, iron overload, RBC sequestration, extrahepatic cholestasis also contribute	Exchange transfusion for intrahepatic cholestasis; transplant for end-stage liver failure
Nephropathy	~30% of adults age >30 years; hyperfiltration in children, renal failure in adults; early albuminuria, later nephrotic-range proteinuria; associated with markers of hemolysis	Screen for microalbuminuria by age 10 years; avoid NSAIDs; use ACE inhibitors or receptor antagonists for albuminuria; erythropoietin for symptomatic anemia; dialysis or transplant for renal failure
Lung/pulmonary hypertension	Restrictive disease; asthma common; 5–10% have pulmonary hypertension by right heart catheterization; 30% have increased TRV that portends poor prognosis; associated with markers of hemolysis	Consult expert pulmonologist; screen yearly by echocardiography measurement of TRV
Retinopathy	30% in HbSC disease, 3% in HbSS,[a] develops in peripheral retina; vitreous hemorrhage and retinal detachment can cause blindness	Screen annually starting at age 10 tears with fluorescein angiography; laser photocoagulation for proliferative disease
Acute anemic episodes	B19 parvovirus infection, folic acid deficiency, splenic sequestration, delayed hemolytic transfusion reaction with destruction of transfused and sometimes autologous red cells	RBC transfusion if symptomatic; splenectomy if more than one or two episodes of sequestration; anti-parvovirus IgM positive in acute infection, IgG in past infection
Multiorgan failure	Can accompany severe acute chest syndrome; often confused with sepsis and can coexist with sepsis; CNS, liver, muscle, lung, kidney affected	Exchange transfusion, ICU support
Pregnancy	Screening both partners for hemoglobin disorders with risk counseling is critical component of family planning.	All pregnancies are "high risk"; transfuse if sickle cell events increase, if previous miscarriage, multiple fetuses

[a]Sickle cell anemia (HbSS).

Abbreviations: ACE, angiotensin-converting enzyme; CNS, central nervous system; ICU, intensive care unit; NSAIDs, nonsteroidal anti-inflammatory drugs; TRV, tricuspid regurgitant jet velocity.

pressure over an affected area, perhaps accompanied by swelling; mild fever is common.

Some patients die suddenly shortly after admission for an acute painful episode. The cause of this sudden unexpected death is usually unknown; among the possibilities are arrhythmias and pulmonary embolism. Admitting patients to monitored beds or continuous pulse oximetry for the first 48–72 h of hospitalization might prevent some of these deaths and help identify acute chest syndrome that follows within 72 h in about a quarter of admissions for acute pain. After searching for possible precipitants such as infection or dehydration and treating these appropriately, the foundation of treatment is the proper dosing of opioid analgesics. By the time a patient presents at the emergency department or clinic requesting treatment, they have usually tried nonsteroidal anti-inflammatory drugs (NSAIDs) and oral opioids. In most patients, relief of pain requires the intravenous opioids morphine or hydromorphone. Many patients are opioid tolerant and require higher than usual doses for satisfactory relief. Dosing should not be on an "as-needed" schedule; patient-controlled analgesia or a frequent fixed dose of opioids with rescue doses for breakthrough pain are the preferred means of treatment, with frequent assessments to ensure pain relief without excessive sedation. Adjunctive treatment includes incentive spirometry to forestall pulmonary complications, maintaining hydration with half-normal saline with care not to overhydrate, prophylaxis for thromboembolism, and antihistamines and laxatives to counter expected side effects of opioids; unless hypoxia is present, supplemental O_2 is unnecessary. Ketorolac should not be used, and NSAIDs have little value in patients receiving intravenous opioids.

Acute Chest Syndrome This pneumonia-like illness is the second most frequent acute sickle cell–related event. It occurs in >50% of patients, often more than once. Acute chest syndrome can be mild, especially in children, in whom it can result from viral infection, or devastating, where multiple lobes of the lung are affected with severe hypoxia, multiorgan failure, and death. Chest pain, cough, fever, and hypoxia and a pulmonary infiltrate on chest x-ray are the major diagnostic criteria. The etiology includes in situ thrombosis, emboli, any type of infection, and postoperative hypoventilation. Management in adults is dictated by the severity of the episode. Patients who are hypoxic and febrile are often admitted directly to the intensive care unit. Antibiotics are almost always used in febrile patients even though a causative bacterium is not often cultured. Supplemental O_2 is given for an O_2 saturation <95%. Overhydration and excessive opioids can compound dyspnea and hypoxia. Hypoxic patients who are febrile with leukocytosis and have more than a trivial infiltrate on x-ray are transfused. In the more severely ill patient, exchange transfusion is the preferred modality. When hemoglobin level or symptoms indicate the need for transfusion of the severely ill patient and hours are needed to arrange red cell exchange, simple or top-up transfusion should be started first. Simple transfusions also suffice for less severely affected patients. Most patients survive acute chest syndrome, but in the most severe cases, often caused by embolization of necrotic bone marrow, death can be rapid even with prompt and proper treatment. Thrombocytopenia, leukocyte counts in excess of 20,000/dL, and rapidly developing acute anemia often portend severe acute chest syndrome with the possibility of acute respiratory distress syndrome and multiorgan failure. Many adults have chronic lung disease that could be a sequela of acute chest syndrome, and asthma is very common in patients with sickle cell disease.

Osteonecrosis This painful and sometimes crippling complication that most often affects hips bilaterally occurs in about half of all patients with sickle cell anemia and is also common in HbSC disease; shoulders are less often affected. Beginning with chronic pain that can become severe, loss of function is often the final stage, especially in the hips. MRI can detect the earliest stages, whereas x-ray is less sensitive. Physical therapy and NSAIDs provide some relief; unfortunately, oral opioids are sometimes required. Joint replacement can restore lost mobility and relieve pain, but the life span of prosthetic joints is finite so surgery should be delayed as long as mobility is satisfactory and pain tolerable.

Leg Ulcers The incidence of leg ulcers is highly dependent on geography and hemoglobin genotype. They are far less common in HbSC disease and HbS-β^+ thalassemia than in sickle cell anemia and HbS-β^0 thalassemia. In temperate climates, 10–20% of patients are affected; tropical and subtropical areas have an incidence rate up to 75%; ulcers rarely occur in the Middle East. They can be small and superficial or deep and encompass most of the lower leg. Ulcers can be extraordinarily painful. Long-standing, recurrent large ulcers are difficult to treat. Wet-to-dry dressings and Unna boots are reasonable choices for initial treatment.

SICKLE CELL TRAIT (CARRIERS, OR SIMPLE HETEROZYGOSITY FOR THE HbS GENE)

Carriers of sickle cell trait outnumber patients with the disease by 25 to 1. Counseling and follow-up of carriers detected by cord blood screening are imperfect. Adolescents and adults can forget that they have sickle cell trait. Although usually a benign condition with a normal life expectancy, some features of this trait are shown in Table 98-2. Counseling sickle cell trait carriers about the small risks of complications and their likelihood of having offspring with sickle cell disease is essential. Counseling prior to participation in sports is also important because of the risk, albeit a very small one, of sudden death from heat-related exertional rhabdomyolysis. Optimal hydration before and during exercise can prevent most episodes of heat-related illness.

TREATMENT, SCREENING, COUNSELING, AND ANTENATAL DIAGNOSIS

Patients should, if possible, be referred to a sickle cell center for initial consultation, follow-up, and institution of therapy. Cooperation among primary care providers, hematologists, and other specialists can provide the best preventive care and management of complications. The frequency at which a patient is seen depends on their therapeutic regimen.

Remarkable changes in the treatment landscape have occurred with the promise of even greater benefits from new curative approaches based on gene therapy. The following discussion focuses on treatment to prevent the complications of disease.

Hydroxyurea Hydroxyurea is the standard of care for all patients with sickle cell anemia and HbS-β^0 thalassemia. It is recommended for patients of all ages regardless of symptoms and should be started in the first year of life. The major mechanism of action of hydroxyurea is to induce high levels of HbF. Hydroxyurea increases HbF unevenly in the red cell population (heterocellularly), so some cells have greater protection from HbS polymerization than others. Although often employed in symptomatic patients with HbSC disease, its benefits in this genotype are understudied. In adults, where the average HbF is ~5%, the increase in HbF is often modest. Nevertheless, pain and acute chest syndrome are reduced by about half, hemoglobin concentration increases by ~1 g/dL, and after 17.5 years of follow-up, mortality was reduced by 49%. In contrast, all children respond robustly to hydroxyurea. When started at <1 year of age at a dose of ~27 mg/kg, HbF levels were 33.3 ± 9.1% and hemoglobin concentration was 10.1 ± 1.3 g/dL. Acute events were markedly reduced with little toxicity. Based on these and other studies in high- and low-resource countries, unless there is a contraindication, hydroxyurea is standard of care for all patients starting in the first year of life at a dose of ~20 mg/kg and titrated to the maximal tolerated dose based on neutrophil and platelet counts.

Voxelotor Voxelotor increases the affinity of the hemoglobin molecule for O_2 (decreases the P_{50}). Voxelotor, 1500 mg daily, was associated with a 1-g/dL increase in hemoglobin concentration in 59% of patients with a reduction in the biomarkers of hemolysis. Although vasoocclusive events were not significantly reduced in the initial report of efficacy, further analysis after a longer observation period suggested that patients achieving the highest hemoglobin had the fewest acute vasoocclusive events. Voxelotor increases hemoglobin-oxygen affinity in all

erythrocytes (pancellularly), and this should provide an increment in polymerization inhibition beyond hydroxyurea. Many questions remain about the long-term effects of voxelotor. Less hemolysis reduces the propensity for stroke, nephropathy, pulmonary hypertension, leg ulcers, and priapism. Will voxelotor be accompanied by these long-term benefits? Could the high O_2 affinity of a modified hemoglobin be harmful for some patients? The answers to these important questions require further study.

Crizanlizumab Downstream effects of HbS polymerization include adhesive interactions among endothelial cells, leukocytes, platelets, and erythrocytes. P-selectin is one molecule involved in these interactions; blocking selectins prevents sickle cell–endothelial adhesion. A P-selectin-blocking monoclonal antibody given intravenously every month reduced acute painful episodes by ~45%, a reduction similar to that seen with hydroxyurea. There were no effects on hemolysis.

L-Glutamine The mechanism of action of this agent, presumed to be the reduction of oxidative stress in sickle erythrocytes, is unsettled. In a phase 3 clinical trial, compared with a placebo, L-glutamine was associated with a 25% reduction in painful episodes and 33% reduction in hospitalization.

There is little consensus regarding how recently approved drugs should be integrated into treatment with hydroxyurea. The effects of voxelotor and crizanlizumab appear to be additive to those of hydroxyurea. Voxelotor can be added to hydroxyurea if the benefits of hydroxyurea alone are insufficient, as they are in most adults. If both hydroxyurea and voxelotor are taken at effective doses and acute vasoocclusive complications continue, crizanlizumab could then be added. The dropout rates in the crizanlizumab and L-glutamine trials was ~35% so adherence to these therapeutics could be problematic.

Transfusion Transfusions are overutilized and underutilized. Major indications for transfusion include severe symptomatic anemia; treatment and prevention of stroke; increasing hemoglobin level to ~10 g/dL before surgery requiring general anesthesia; and acute chest syndrome with hypoxia or multiple lobe involvement. Sometimes transfusions are given during pregnancy when there is a history of complications or fetal loss. Transfusions should usually be avoided in acute pain episodes and for repair of stable chronic anemia. There is a preference for automated red cell exchange transfusion in acute stroke, severe acute chest syndrome, or multiorgan failure or when chronic transfusions are planned. Recent guidelines formulated by experts recommended extended red cell antigen profiling, if possible before the first transfusion, and antigen matching for Rh (C, E or C/c, E/e) and K antigens in addition to ABO/RhD. Complications of transfusion include hyperviscosity, alloimmunization (which occurred in 18.6% of patients transfused between 1979 and 1984 and 27.3% of patients transfused between 2001 and 2011), iron overload, delayed hemolytic transfusion reactions, and hyperhemolysis.

Stem Cell Transplantation Given the excellent results of human leukocyte antigen (HLA)–identical related donor transplants, which have an event-free survival of >95%, this option might be extended to all patients with a suitable donor. Unfortunately, only 15% of patients have a fully matched donor. New approaches to haploidentical transplants are improving event-free survival in these patients.

Preventive Measures and Screening Cord blood screening for sickle cell disease is done in many countries and all 50 states. Affected patients are then directed to clinics that can initiate early preventive care. In childhood, transcranial Doppler screening beginning at age 2 years and repeated annually until age 16 years, prophylactic penicillin (125 mg for children younger than 3 years; 250 mg for children 3 years and older) twice daily until age 5 years, and vaccination with pneumococcal vaccines are the main measures to prevent stroke and invasive pneumococcal infection. Folic acid, 1 mg daily, is given to prevent megaloblastic erythropoiesis; it is probably unnecessary in people with nutritious diets.

All women planning pregnancy should be screened for disorders of hemoglobin by blood counts, erythrocyte indices, and HPLC analysis of hemoglobin. Individuals with HbS or β thalassemia trait should have their partners tested. Only then is it possible to know the risks of a fetus having sickle cell disease (Table 98-2). Antenatal diagnosis using chorionic villus sampling is widely available.

Emerging Treatments Gene therapy has curative potential and requires neither matched donors nor immunosuppression. Autologous hematopoietic CD34+ stem cells are mobilized and modified ex vivo to produce an antisickling globin. These cells are reinfused following myeloablative conditioning. Phase 1/2 clinical trials have used lentivirus transduction of CD34+ cells with an antisickling β-globin or have interfered with the HbF-suppressive effects of BCL11A using CRISPR/Cas, zinc finger nucleases, or shRNA. These approaches have resulted in HbF or antisickling hemoglobin levels of nearly 50%, reduced hemolysis, total hemoglobin levels of >11 g/dL, and resolution of acute vasoocclusive events. It is too early to know their long-term safety or cure rate.

THALASSEMIA

Thalassemia is caused by reduced accumulation of either α- or β-globin chains causing a relative excess of the unaffected chain. Unbalanced globin synthesis is the hallmark of thalassemia and the proximate cause of its pathophysiology; unpaired globin chains damage the developing erythroblast. Like the HbS mutation and many other red cell traits, thalassemia reached polymorphic levels in tropical and subtropical populations because heterozygotes are protected from *Plasmodium falciparum* infection. Estimates are that 1–5% of the world's population carries a thalassemia mutation; in some locales, most people have a thalassemia mutation. These mutations can affect any globin gene, but clinically, β and α thalassemia are the most important. With nearly 500 unique thalassemia-causing mutations *(www.globin.bx.psu.edu)* that can interact with each other and with hemoglobinopathies, thalassemia syndromes are remarkably diverse. Where resources permit and the mutation is known, genetic counseling can be provided and antenatal diagnosis is possible.

HbE (β^{27} glu-lys) is a common variant whose biosynthesis is reduced because the site of the mutation alters its mRNA processing. Its reduced biosynthesis leads to a deficit of β^E-globin chains and features of β thalassemia. Hemoglobin Constant Spring is caused by a mutation of the termination codon of *HBA2* that leads to the synthesis of an elongated α-globin chain that is unstable and suboptimally synthesized. This variant therefore behaves as an α thalassemia variant.

β THALASSEMIA

EPIDEMIOLOGY

Once known as Mediterranean anemia, because of the concentration of cases in Italy, Greece, and other countries bordering the Mediterranean Sea, or as Cooley's anemia after the physician first describing cases, β thalassemia is common in most areas of the world where malaria was endemic. Effective programs of screening, counseling, and antenatal diagnosis have reduced the birth of new cases from the Mediterranean region. The bulk of new patients now are of Asian, Middle Eastern, and Indian origin. About 40,000 β thalassemia patients are born yearly. In the United States there are ~1000 cases of severe β thalassemia.

CLASSIFICATION

β^0 Thalassemia mutations totally prevent the accumulation of any globin from the affected gene; β^+ thalassemia mutations cause minor or extreme reductions in β-globin synthesis. β Thalassemia major and β thalassemia intermedia are now categorized as transfusion-dependent and non-transfusion-dependent based on the number and frequency of transfusions required to sustain a good quality of life.

Pathophysiology Single nucleotide changes are the most common β thalassemia mutations, but gene deletions also occur. A partial listing of the classes of mutations causing β thalassemia include mutations in the promoter elements affecting gene transcription causing mild and sometimes silent β^+ thalassemia; mutations in the junctions between

exons and introns that affect mRNA processing causing β^0 and β^+ thalassemia; introduction of alternative splice sites into introns or exons usually causing β^+ thalassemia; 3′ end-processing sequence mutations preventing RNA polyadenylation leading to mild or silent β^+ thalassemia; mutations preventing initiation of translation causing β^0 thalassemia; and introduction of stop codons that prematurely terminate translation (nonsense mutations) producing reading frameshifts and resulting in truncated globin mRNA and β^0 thalassemia.

In β thalassemia, the deficit in β-globin chain synthesis allows α-globin chains to accumulate in excess. Without a non-α-globin chain partner in dimer and tetramer formation, unpaired α-globin chains are unstable, cannot form a tetramer, and precipitate within the developing erythroblast, causing membrane lipid oxidation and damage. The predominant cause of anemia is intramedullary destruction of erythroid precursors, known as ineffective erythropoiesis. Reduced deformability and phosphatidyl serine exposure also cause extra- and intravascular hemolysis of those erythrocytes that gain entrance into the circulation. In poorly treated β thalassemia, severe anemia leads to bone marrow expansion; hepatosplenomegaly; iron accumulation in liver, heart, and endocrine organs; pulmonary hypertension; and thromboembolic disease.

Frightening pictures of children with severe β thalassemia permeate the literature. These examples of near-terminal disease should be relegated to history because treatment with transfusion and iron chelation can prevent their occurrence and hematopoietic stem cell transplantation can "cure" patients who have suitable donors.

DIAGNOSIS

Heterozygous β thalassemia, also known as β thalassemia trait and β thalassemia minor, has mild or no anemia but microcytic/hypochromic erythrocytes with minimal or no increase in reticulocyte count. After recognizing these hematologic abnormalities and excluding iron deficiency, finding an elevated level of HbA_2 and perhaps HbF by HPLC is sufficient to establish this diagnosis. The hematologic characteristics of this heterozygous carrier state are listed in **Table 98-4**. Sometimes, the spleen is enlarged. Before genetic counseling and antenatal diagnosis are considered after carrier identification by red cell indices and quantitation of HbA_2, the thalassemia-causing mutation should be identified. This is the key to preventing homozygotes or compound heterozygotes with transfusion-dependent thalassemia.

The more severe forms of β thalassemia are hemolytic anemias with hypochromia, microcytosis, reticulocytosis, marked anisocytosis, and poikilocytosis with variable numbers of circulating nucleated red cells **(Fig. 98-5)**.

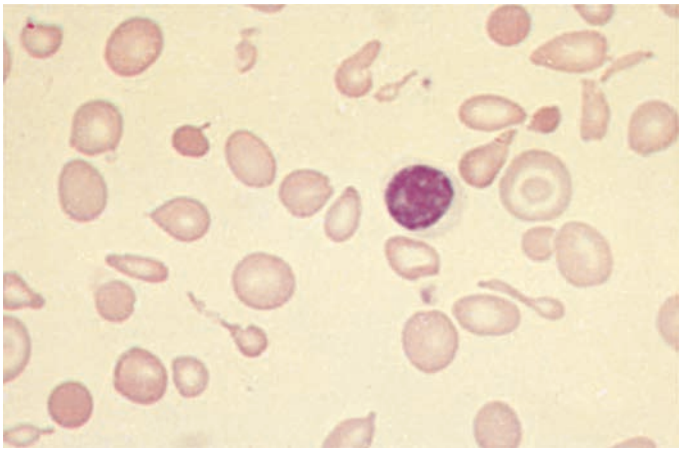

FIGURE 98-5 β Thalassemia intermedia. Target cells and marked variation in cell size and shape but with general hypochromia and microcytosis characterize the blood film. A lymphocyte is shown for size comparison.

COMPLICATIONS

Complications of severe β thalassemia are many. They are a consequence of chronic hemolytic anemia, chronic transfusion, and iron loading. Increased iron absorption is especially common in non-transfusion-dependent thalassemia. Most complications, listed in **Table 98-5**, develop because of either inadequate blood transfusion and/or poor iron chelation and iron loading. Even when chelation is optimized, some complications attributable to iron toxicity will develop. Many complications have complex and multifactorial etiologies. Iron stores are estimated by serum ferritin levels; MRI is the most widespread means of noninvasively measuring iron accumulation in liver and heart.

MANAGEMENT, SCREENING, COUNSELING, AND ANTENATAL DIAGNOSIS

Heterozygote screening and counseling couples at risk for affected fetuses, with antenatal diagnosis, if needed, is an effective preventive approach. Severe thalassemia should be dealt with in specialized

TABLE 98-4 β Thalassemias

CLASSIFICATION	HEMOGLOBIN (g/dL)/ MCV (fL)	HEMOGLOBIN FRACTIONS (%)	CLINICAL FEATURES
β Thalassemia trait	100–140 (10–14)/60–80	HbA: 94 HbF: 1–2 HbA_2: 4–6	Heterozygosity for β^+ or β^0 thalassemia mutations; "silent" carriers can have normal HbA_2 and red cell indices.
Non-transfusion-dependent β thalassemia (thalassemia intermedia)	70–120 (7–12)/65–80	HbA: 60–90 HbF: 10–40 HbA_2: 4–6	Defined by infrequent or no transfusion requirement; caused by many different genotypes including homozygosity for "mild" β^+ mutations, combinations of β and α thalassemia, homozygous β thalassemia with high HbF producing capacity, and many others. Iron loading, thromboembolic disease, and pulmonary hypertension are major clinical events.
Transfusion-dependent β thalassemia (thalassemia major)	20–40 (2–4)/50–80	HbA: 0–5 HbF: 90–100 HbA_2: 2–5	Caused by many different genotypes including homozygosity and compound heterozygosity for β^0 and β^+ mutations, combinations of β and α thalassemia; transplantation curative; iron chelation required.
HbE-β thalassemia	50–80 (5–8)/60–70	HbE: 50–70 HbF: 30–50	Common in SE Asian populations; in some parts of the word, the most prevalent severe thalassemia; in HbE-β^0 thalassemia, only HbE and HbF are found; in HbE-β^+ thalassemia, HbA is present. Transfusion dependence depends in part on the thalassemia mutation.
δβ Thalassemia and hemoglobin Lepore	110–120 (11–12)/65–75	HbA: 70 HbF: 7–13 HbA_2: 2	Rare; deletions removing the δ- and β-globin genes cause δβ thalassemia; Lepore hemoglobins are fusion globin chains; values are for heterozygotes; homozygotes have 100% HbF with hemoglobin 10–11 g/dL.
Gene deletion HPFH	120–140 (12–14)/75–85	HbA: 70 HbF: 15–30 HbA_2: 2	Rare; large deletions removing the δ- and β-globin genes; values are for heterozygotes; homozygotes, who are asymptomatic, have 100% HbF without anemia.

Note: Laboratory results are averages in adults.

TABLE 98-5 Complications of β Thalassemia

COMPLICATION	INCIDENCE, DIAGNOSIS, AND FEATURES
Growth retardation	Most often a feature of delayed or inadequate transfusions but can occur in well-transfused children.
Delayed puberty; secondary amenorrhea	50% and 25%, respectively.
Splenomegaly	Can trap 1–40% of red blood cell volume; increases plasma volume, worsening heart failure. Splenectomy indicated when transfusion requirement to maintain ideal hemoglobin increases. Prophylactic penicillin after splenectomy.
Heart	Due to chronic anemia, heightened sensitivity to iron toxicity, thromboembolic pulmonary hypertension, other causes. Progresses through stages to congestive failure and arrhythmias. Assessed by T2* on MRI. The available chelating agents might have differential effects on different measures of cardiac function and can be used in combination.
Leg ulcers	Common in thalassemia intermedia.
Hepatic disease	Fibrosis progressing to cirrhosis is related to hepatic iron concentration that can be monitored by MRI. Hepatitis also plays a role.
Lung disease/ pulmonary hypertension	Fibrosis, chronic thromboembolic disease, restrictive pathophysiology, intravascular hemolysis, and reduced nitric oxide bioavailability
Thromboembolism	Multifactorial etiology including platelet activation, red cell–endothelial interactions, thrombocytosis; endothelial activation; splenectomy.
Endocrinopathies	Diabetes, hypothyroidism, hypoparathyroidism, adrenal insufficiency; hypogonadism; hypothalamic-pituitary axis might be especially sensitive to iron.
Bone disease	Caused by bone marrow expansion, severe iron loading, hypogonadism; osteoporosis in ~50% of patients, even those well treated. Extramedullary hematopoietic masses are a feature of thalassemia intermedia.
Infections	Transfusion associated; linked to iron overload (*Yersinia*); malaria.

centers where these and other services are available and managed by a team led by a hematologist experienced with this disease with help from endocrinologists, cardiologists, transfusion medicine specialists, and social services.

Transfusion and Iron Chelation Transfusion every 2–4 weeks with a goal pretransfusion hemoglobin concentration of 9–10.5 g/dL, coupled with oral iron chelation to prevent the accumulation of excess toxic iron that accompanies transfusion, has prevented the development of cardiomyopathy and endocrinopathies while extending life to at least 50 years. When to begin transfusions, whether partial exchange transfusion is preferable to simple transfusion, and the choice of blood product require consultation with experts. To be effective, transfusions and iron chelation must be started early, be uninterrupted, and continue lifelong. Older patients who did not have the advantage of effective chelation are more likely to develop multiple disease-related morbidities such as osteoporosis, endocrinopathies, liver disease, and renal failure. Two orally effective chelating agents, deferasirox and deferiprone, and one intravenous chelator, deferoxamine, are available.

Hematopoietic Stem Cell Transplantation There is consensus that patients with available donors should be offered transplantation because of the difficulty of lifelong transfusion and chelation and its imperfect efficacy. Quality of life in successfully transplanted patients exceeds that in patients treated with transfusion and chelation. Transplantation from matched sibling donors is curative in >80% of all cases. Unfortunately, only a third of patients have matched donors. The best results are in the youngest patients who have been effectively chelated and received fewer transfusions. Graft failure, graft rejection, graft-versus-host disease, and a mortality of 5–20% depending on risk factors are the major drawbacks of this procedure. Results of haploidentical and unrelated donor transplants are improving but lag those of matched sibling donors.

Improving Ineffective Erythropoiesis Luspatercept, a fusion protein containing the extracellular domain of human activin type IIB receptor and the Fc domain of human IgG, was recently approved for treatment of transfusion-dependent thalassemia. By binding transforming growth factor β superfamily ligands and reducing Smad2/3 signaling, luspatercept enhances late-stage erythropoiesis. Given subcutaneously, 1 mg/kg every 3 weeks, it was associated with a 33% reduction in transfusion requirements.

Gene Therapy Lentiviral mediated gene therapy using autologous CD34+ hematopoietic stem cells has been approved in Europe for some patients with transfusion-dependent thalassemia who lack a matched donor. In a clinical trial with a median follow-up of 26 months, where patients received autologous CD34+ cells transduced with a lentiviral vector containing a modified HbA, transfusions were reduced or eliminated and hemoglobin levels stabilized between 8.2 and 13.7 g/dL. However, the results were dependent on the β thalassemia mutation, and although transfusion independence was achieved, some features of disease such as ineffective erythropoiesis were not eliminated. The initial results of CRISPR/Cas editing to downregulate *BCL11A* in β thalassemia have eliminated the need for transfusion and normalized hemoglobin levels (see Sickle Cell Disease).

α THALASSEMIA

In some respects the obverse of β thalassemia, clinically consequential α thalassemia is less common than severe β thalassemia. α Thalassemia is most often found in Asian populations and is usually caused by deletion of α-globin genes rather than point mutations.

EPIDEMIOLOGY

Carriers of the most common α thalassemia chromosomes (Table 98-6) are found in 5–80% of people from tropical and subtropical regions of Africa, the Middle East, India, Southern China, and Melanesia. About 30% of African Americans carry the common $-\alpha^{3.7}$ chromosome that contains a single functional α-globin gene. HbH disease, the chief clinically important α thalassemia, is most prevalent in Southern China and Southeast Asia. Estimates are that in Thailand ~3500 patients with severe α thalassemia are born yearly. Pregnancies affected by hemoglobin (Hb) Bart's hydrops fetalis occur mainly in Southern China and Southeastern Asia.

CLASSIFICATION

Each normal chromosome 16 contains two α-globin genes; normal diploid individuals have four α-globin genes. A classification of inherited α thalassemia, as summarized in Table 98-6, is based on the number of functional α-globin genes. If one or two α-globin genes are missing or poorly expressed, these people have α thalassemia trait. Their hematologic abnormalities are almost always trivial. HbH disease is usually caused by deletion or malfunction of three α-globin genes. Hb Bart's hydrops fetalis fetuses have no normally functioning α-globin genes. Hundreds of different sized deletions and rarer point mutations affect the production of α globin and the magnitude of imbalanced globin synthesis. Because of this mutational complexity, many different variations of the common α thalassemia syndromes are found.

PATHOPHYSIOLOGY

Reduced accumulation of α-globin leaves non-α-globins unpaired and unable to participate in the formation of functional hemoglobin tetramers. In the fetus, absent or reduced synthesis of α-globin allows unpaired γ-globin chains, which are usually part of the HbF tetramer, to form γ_4 or Hb Bart's; in adults, when γ-globin synthesis is mostly silenced, unpaired β-globin chains, lacking a suitable partner to form HbA, tetramerize as β_4 or HbH. Both Hb Bart's and HbH have very high O_2 affinity and do not unload O_2 in tissues; HbH is also unstable. Severe anemia in Hb Bart's hydrops fetalis is a result of absent normal

TABLE 98-6 α Thalassemias

CLASSIFICATION	α-GLOBIN GENE ARRANGEMENT	HEMOGLOBIN LEVEL, g/L (g/dL)/MCV (fL)	CLINICAL FEATURES
α Thalassemia trait	–α/αα –α/–α – –/αα $\alpha^T\alpha/\alpha\alpha$	120–150 (12–15)/65–80	The chromosome with one deleted α gene (–α/) is called α^+ thalassemia (α thalassemia-2); the chromosome with both deleted α genes is α^0 thalassemia (α thalassemia-1); non–gene deletion α thalassemias (α^T) often have a more severe phenotype.
Hemoglobin H disease	– –/–α $\alpha^T\alpha$/– – $\alpha^T\alpha/\alpha^T\alpha$	50–120 (5–12)/60–70	Mild to moderate anemia depending on genotype; non–gene deletion forms of α thalassemia can produce severe HbH disease.
Hb Bart's hydrops fetalis	–-/–-		Fatal in utero or at birth with rare survivors. Hydrops can also result from combinations of gene deletion and non–gene deletion α thalassemia.
α Thalassemia/intellectual disability syndromes (ATR-16) (ATR-X)	– –/αα or – –/–α in ATR-16 αα/αα in ATR-X		ATR-16: Large deletions and rearrangements in chr16p. ATR-X: No α-globin gene deletion or mutation, *ATRX* mutations, X-linked.
α Thalassemia with myelodysplasia (ATMDS)	αα/αα		Mutations in *ATRX*; striking male predominance. Hematologic findings of HbH disease.

Note: Laboratory values are averages in adults. αα/ denotes the chromosome with two intact α-globin genes; –α/ chromosome with one α-globin gene deleted; – –/ chromosome with both α-globin genes deleted; α^T represents non–gene deletion α thalassemia caused by point mutations. The –α/ chromosome, referred to as α^+ or α thalassemia-2, most often has a deletion of 3.7 kb of DNA ($-\alpha^{3.7}$) or 4.2 kb of DNA ($-\alpha^{4.2}$) that leaves but a single α-globin gene intact. The chromosome where both α-globin genes are deleted (– --/) is called α^0 thalassemia or α thalassemia-1. These chromosomes are caused by different-sized deletions that are usually named after their regions of highest frequency such as -SEA, -MED, -FI, and -THAI.

hemoglobin and ineffective erythropoiesis; in HbH disease, unstable HbH leads to oxidative membrane damage with extravascular hemolysis in the spleen and ineffective erythropoiesis.

DIAGNOSIS

Microcytosis/hypochromia with nearly normal hemoglobin concentrations, in the absence of iron deficiency and the increased level of HbA_2 that is diagnostic of β thalassemia, is sufficient for a presumptive diagnosis of α thalassemia trait. When genetic counseling is needed and antenatal diagnosis contemplated, the molecular basis of the presumed α thalassemia is required. HbH disease, which is usually due to compound heterozygosity for one chromosome with both α-globin genes deleted and one chromosome with only a single α-globin gene, is defined by the hematologic findings shown in Table 98-6 along with varying levels of reticulocytosis. At birth, when hemoglobin is separated by HPLC, 20–30% Hb Bart's is present; in adults, traces to 40% HbH are present along with residual Hb Bart's in some cases. HbH inclusions can be induced in some red cells after incubation and staining with brilliant cresyl blue. Hemoglobin composition in Hb Bart's hydrops fetalis is predominantly Hb Bart's with some Hb Portland if the deletion removing α-globin genes preserves the ζ-globin gene.

COMPLICATIONS

HbH disease is very heterogeneous because of the different combinations of genotypes that can cause this phenotype. Generally, when non–gene deletion mutants, such as Hb Constant Spring, contribute to the genotype, the disease is more severe. In the most common – –/–α genotype, mean hemoglobin in adults is ~11 g/dL Hepatosplenomegaly, jaundice, thalassemic bone changes in the face, and growth impairment are seen 20–50% of cases, depending on the underlying genotype. Iron loading occurs but is not the severe problem it is in β thalassemia. Pregnancy in these patients should be considered high risk and managed accordingly. Mothers of infants with Hb Bart's hydrops fetalis have a history of stillbirth and develop preeclampsia, polyhydramnios, and antepartum hemorrhage and have difficult labor and delivery. Intrauterine transfusion of the fetus is possible.

MANAGEMENT, SCREENING, COUNSELING, AND ANTENATAL DIAGNOSIS

When planning families, couples from regions where α thalassemia is common who have red cell indices that suggest the possibility of carrying an α thalassemia gene should have genetic counseling based on DNA analysis of their globin genes. Iron should be avoided in non-iron-deficient individuals with α thalassemia trait and microcytosis. Transfusions are not usually needed in HbH disease. Nevertheless, depending on the genotype of disease, transfusions might be necessary especially when anemia becomes more severe, for example, with acute anemic episodes or pregnancy. Iron stores should be checked periodically by measuring serum ferritin or MRI; chelation does not appear to be needed.

Hb Bart's hydrops fetalis is best prevented by screening couples at risk and antenatal diagnosis. Intrauterine therapy and perinatal intensive care have permitted survival of some infants with Hb Bart's hydrops fetalis. As growth retardation affects ~40% and neurodevelopmental delay is present in 20% of survivors, prevention is the best approach.

OTHER HEMOGLOBINOPATHIES OF CLINICAL IMPORTANCE (TABLE 98-7)

Thirteen-hundred mutations affecting hemoglobin structure have been described *(www.globin.bx.psu.edu)*. Most are clinically silent. HbC and HbE are common. HbC is found in people of African descent and HbE in South China and Southeast Asia. Heterozygotes for HbC and HbE are clinically well. Even individuals homozygous for these mutations, where the variant hemoglobin comprises >90% of the hemolysate, are clinically well with very mild anemia and microcytosis. The major importance of these variants is the interaction of HbC with HbS and HbE with β thalassemia, as outlined in Tables 98-2 and 98-4. A definitive diagnosis for all rare variants depends on DNA analysis.

Unexpected low O_2 saturation by pulse oximetry (SpO_2) with normal O_2 saturation of arterial blood is occasionally seen in rare hemoglobin variants with clinical phenotypes. Asymptomatic patients with unexpectedly low SpO_2 should not be subjected to unneeded cardiopulmonary investigations in search of the cause of their "hypoxemia" until the existence of a hemoglobin variant is excluded.

M HEMOGLOBINS

M (met) hemoglobins are characterized by oxidation of the heme-iron from its ferrous (Fe^{++}) to ferric (Fe^{+++}) form. The major clinical feature of these disorders is cyanosis that is asymptomatic. Nine M hemoglobin variants have been described. In seven, the mutation involves histidine residues that interact with heme. Asymptomatic slate gray/brownish pseudocyanosis is the main clinical finding. Spectrophotometric recording of the visible spectrum of the hemolysate is

TABLE 98-7 HbC, HbE, and Rare Hemoglobinopathies

CLASSIFICATION	CLINICAL ABNORMALITIES	HEMOGLOBIN LEVEL, g/L (g/dL)/MCV, fL	HEMOGLOBIN FRACTIONS (%)
HbC trait	2% of African Americans; target cells; no disease	Normal	HbC: 30–40 HbA_2: 2–3
HbC disease	Target cells; HbC crystals; mild reticulocytosis; splenomegaly	100–130 (10–13)/60–70	HbC: >95 HbF: 2–4 HbA_2: 2–3
HbE trait	50% incidence in some Asian populations; a few target cells; clinically normal	120–140 (12–14)/80–90	HbE: 27–31[b] HbF: 1 HbA_2: 3
HbE disease	No hemolysis; 20–80% target cells; no splenomegaly	100–120 (10–12)/65–75	HbE: 85–95 HbF: 3–7 HbA_2: 3
High O_2 affinity hemoglobins	Isolated erythrocytosis; often familial; no splenomegaly; no *JAK2*^{V617F} mutation	150–200 (15–20)	Variants in α- and β-globin genes; patients are heterozygotes; ~25–50% variant
Low O_2 affinity hemoglobins	Asymptomatic mild anemia; cyanosis	100–140 (10–14)	~50% variant
Unstable hemoglobins	Pigmenturia; hemolysis; reticulocytosis; splenomegaly	90–140 (9–14)/70–90	20–35% variant; rare hyperunstable variants can be undetectable and have the phenotype of thalassemia
M hemoglobins	Some have mild hemolysis; few symptoms	100–140 (10–14)/80–90	20–50% variant depending on gene affected

Note: Laboratory values are averages in adults. As noted for HbAS, the amount of HbC and HbE in heterozygotes depends on the number of α-globin genes.

diagnostic. To distinguish M hemoglobins from methemoglobinemia due to drugs or cytochrome b5 reductase (*CYB5R3*) deficiency, potassium cyanide (KCN) can be added to the hemolysate; methemoglobin-containing blood will turn red, but KCN has no effect on M hemoglobin. Treatment is not needed.

UNSTABLE HEMOGLOBINS

Sometimes referred to as congenital Heinz body hemolytic anemias, some mutations result in a hemoglobin tetramer that is unstable and precipitates intracellularly. Such variants are rare and often a result of a new mutation that affects the tertiary or quaternary structure of the molecule. The most common class of mutations introduce a proline residue in the α helix or a polar amino acid into the interion of the molecule. Heinz bodies are intraerythrocytic precipitates that are detectable as dark globular aggregates after staining with a dye such as brilliant cresyl blue. Three unstable hemoglobins are the most common of these rare variants. Hemoglobin Köln (β^{99} val-met) has been found in multiple families, Hb Hasharon (α^{47} asp-his) is found in Ashkenazi Jews, and Hb Zurich (β^{63} his-arg) is susceptible to oxidant drug-induced hemolysis. Unstable variants present with nonspherocytic hemolytic anemia, but presentation is highly variable. The associated disease is usually mild and does not require transfusion. Heating blood to 50°C or incubation with isopropanol precipitates unstable hemoglobins but must be done with careful controls. Some variants can be detected by HPLC.

HEMOGLOBINS WITH HIGH OXYGEN AFFINITY AND LOW OXYGEN AFFINITY

Rare mutations in areas involved in the R-T transition, at critical interfaces between globin chains of the tetramer that reduce the affinity for 2,3-bisphosphoglycerate, or present in the heme pocket account for most of these variants. High O_2 affinity hemoglobins outnumber low O_2 affinity variants by two to one. Isolated erythrocytosis in the absence of splenomegaly suggests the presence of a high O_2 affinity hemoglobin. High O_2 affinity hemoglobin variants shift the hemoglobin-O_2 dissociation curve leftward, causing a low P_{50} and thereby stimulating erythropoiesis. Many of these variants are due to new mutations. The clinical course is benign, and phlebotomy because of erythrocytosis is usually not required. Early diagnosis is important to forestall unnecessary diagnostic procedures and therapeutics such as cardiac catheterization to exclude congenital heart disease or treatment for polycythemia vera. Low O_2 affinity variants often present with cyanosis. Their hemoglobin-O_2 dissociation curve is right-shifted with high P_{50}. HPLC might reveal the presence of a hemoglobin variant. Treatment is often not necessary.

ACQUIRED DISORDERS OF HEMOGLOBIN

CO binds hemoglobin with high affinity forming carboxyhemoglobin. Carboxyhemoglobin levels can be accurately measured by co-oximetry of arterial blood. Standard pulse oximeters cannot accurately make this measurement. Some newly developed pulse oximeters are able to measure both carboxyhemoglobin and methemoglobin. Bound CO inhibits the transport of O_2; the hemoglobin-O_2 binding curve is left-shifted. Acute and chronic CO intoxication, caused by occupational exposure and other sources of incomplete combustion of hydrocarbons, presents with headache, altered mental status, and other constitutional symptoms. High-flow O_2 via facemask is the preferred treatment; criteria have been developed to guide the use of hyperbaric O_2.

Acquired methemoglobinemia and methemoglobinemia due to deficiency of *CYB5R3* are more common than the M hemoglobins. *CYB5R3* is required for the reduction of methemoglobin by NADH. Affected individuals with "toxic" methemoglobinemia can be cyanotic and symptomatic. As in carboxyhemoglobinemia, O_2 transport is reduced and reflected by the left-shift in the hemoglobin-O_2 binding curve. *CYB5R3* deficiency usually affects only erythrocytes (type I), causing a mild disorder; when all cells are affected (type II), a severe disease results. Intravenous methylene blue is the preferred treatment in symptomatic patients with acquired methemoglobinemia and 40–60% methemoglobin. The usual dose is 1–2 mg/kg. Alternative treatment with ascorbic acid is preferable in people who are glucose-6-phosphate dehydrogenase deficient. Methylene blue interferes with co-oximetry, reducing the value of co-oximetry for monitoring treatment.

Many drugs and chemicals can induce methemoglobin in the absence of *CYB5R3* deficiency. Dapsone and topical anesthetics such as benzocaine are the most common offending agents.

99 Megaloblastic Anemias

A. Victor Hoffbrand

The megaloblastic anemias are a group of disorders characterized by the presence of distinctive morphologic appearances of the developing red cells in the bone marrow. The marrow is usually hypercellular, and the anemia is based on ineffective erythropoiesis. The cause is usually a deficiency of either cobalamin (vitamin B_{12}) or folate, but megaloblastic anemia may occur because of genetic or acquired abnormalities that affect the metabolism of these vitamins or because of defects in DNA synthesis not related to cobalamin or folate (Table 99-1).

COBALAMIN

Cobalamin (vitamin B_{12}) exists in a number of different chemical forms. All have a cobalt atom at the center of a corrin ring. In nature, the vitamin is mainly in the 2-deoxyadenosyl (ado) form, which is located in mitochondria. It is the cofactor for the enzyme L-methylmalonyl coenzyme A (CoA) mutase. The other major natural cobalamin is methylcobalamin, the form in human plasma and in cell cytoplasm. It is the cofactor for methionine synthase. Minor amounts of hydroxocobalamin are also present to which methyl- and adocobalamin are converted rapidly by exposure to light.

DIETARY SOURCES AND REQUIREMENTS

Cobalamin is synthesized solely by microorganisms. Ruminants obtain cobalamin from the foregut, but the only source for humans is food of animal origin, for example, meat, fish, and dairy products. Vegetables, fruits, and other foods of nonanimal origin are free from cobalamin unless they are contaminated by bacteria. A normal Western diet contains 5–30 μg of cobalamin daily. Adult daily losses (mainly in the urine and feces) are 1–3 μg (~0.1% of body stores), and because the body does not have the ability to degrade cobalamin, daily requirements are also about 1–3 μg. Body stores are of the order of 2–3 mg, sufficient for 3–4 years if supplies are completely cut off.

TABLE 99-1 Causes of Megaloblastic Anemia

Cobalamin deficiency or abnormalities of cobalamin metabolism (see Tables 99-3, 99-4)
Folate deficiency or abnormalities of folate metabolism (see Table 99-5)
Therapy with antifolate drugs (e.g., methotrexate)
Independent of either cobalamin or folate deficiency and refractory to cobalamin and folate therapy:
Some cases of acute myeloid leukemia, myelodysplasia
Therapy with drugs interfering with synthesis of DNA (e.g., cytosine arabinoside, hydroxyurea, 6-mercaptopurine, azidothymidine [AZT])
Orotic aciduria (responds to uridine)
Thiamine-responsive

ABSORPTION

Two mechanisms exist for cobalamin absorption. One is passive, occurring equally through buccal, duodenal, and ileal mucosa; it is rapid but extremely inefficient, with <1% of an oral dose being absorbed by this process. The normal physiologic mechanism is active; it occurs through the ileum and is efficient for small (a few micrograms) oral doses of cobalamin, and it is mediated by gastric intrinsic factor (IF). Dietary cobalamin is released from protein complexes by enzymes in the stomach, duodenum, and jejunum; it combines rapidly with a salivary glycoprotein that belongs to the family of cobalamin-binding proteins known as haptocorrins (HCs). In the intestine, the HC is digested by pancreatic trypsin and the cobalamin is transferred to IF.

IF (gene at chromosome 11q13) is produced in the gastric parietal cells of the fundus and body of the stomach, and its secretion parallels that of hydrochloric acid. Normally, a vast excess of IF is available. The IF-cobalamin complex passes to the ileum, where IF attaches to a specific receptor (cubilin) on the microvillus membrane of the enterocytes. Cubilin also is present in yolk sac and renal proximal tubular epithelium. Cubilin appears to traffic by means of amnionless (AMN), an endocytic receptor protein that directs sublocalization and endocytosis of cubilin with its ligand IF-cobalamin complex. The cobalamin-IF complex enters the ileal cell, where IF is destroyed. After a delay of about 6 h, the cobalamin appears in portal blood attached to transcobalamin (TC) II.

Between 0.5 and 5 μg of cobalamin enter the bile each day. This binds to IF, and a major portion of biliary cobalamin normally is reabsorbed together with cobalamin derived from sloughed intestinal cells. Because of the appreciable amount of cobalamin undergoing enterohepatic circulation, cobalamin deficiency develops more rapidly in individuals who malabsorb cobalamin than it does in vegans, in whom reabsorption of biliary cobalamin is intact.

TRANSPORT

Two main cobalamin transport proteins exist in human plasma; they both bind cobalamin—one molecule for one molecule. One HC, also known as TC I, is closely related to other cobalamin-binding HCs in milk, gastric juice, bile, saliva, and other fluids. The gene *TCNL* is at chromosome 11q11-q12.3. These HCs differ from each other only in the carbohydrate moiety of the molecule. TC I is derived primarily from the specific granules in neutrophils. Normally, it is about two-thirds saturated with cobalamin, which it binds tightly. TC I does not enhance cobalamin entry into tissues. Glycoprotein receptors on liver cells are involved in the removal of TC I from plasma, and TC I may play a role in the transport of cobalamin analogues (which it binds more effectively than IF) to the liver for excretion in bile.

The other major cobalamin transport protein in plasma is transcobalamin, also known as TC II. The gene is on chromosome 22q11-q13.1. As for IF and HC, there are nine exons. The three proteins are likely to have a common ancestral origin. TC II is synthesized by liver and by other tissues, including macrophages, ileum, and vascular endothelium. It normally carries only 20–60 ng of cobalamin per liter of plasma and readily gives up cobalamin to marrow, placenta, and other tissues, which it enters by receptor-mediated endocytosis involving the TC II receptor and megalin (encoded by the *LRP-2* gene). The TC II cobalamin is internalized by endocytosis via clathrin-coated pits; the complex is degraded, but the receptor probably is recycled to the cell membrane as is the case for transferrin. Export of "free" cobalamin is via the ATP-binding cassette drug transporter alias multidrug resistance protein 1.

FOLATE

DIETARY FOLATE

Folic (pteroylglutamic) acid is a yellow, crystalline, water-soluble substance. It is the parent compound of a large family of natural folate compounds, which differ from it in three respects: (1) they are partly or

TABLE 99-2 Biochemical Reactions of Folate Coenzymes

REACTION	COENZYME FORM OF FOLATE INVOLVED	SINGLE CARBON UNIT TRANSFERRED	IMPORTANCE
Formate activation	THF	–CHO	Generation of 10-formyl-THF
Purine synthesis			
Formation of glycinamide ribonucleotide	5,10-Methylene-THF	–CHO	Formation of purines needed for DNA, RNA synthesis, but reactions probably not rate-limiting
Formylation of aminoimidazole carboxamide ribonucleotide (AICAR)	10-Formyl (CHO)THF		
Pyrimidine synthesis			
Methylation of deoxyuridine monophosphate (dUMP) to thymidine monophosphate (dTMP)	5,10-Methylene-THF	$-CH_3$	Rate limiting in DNA synthesis Oxidizes THF to DHF Some breakdown of folate at the C-9–N-10 bond
Amino acid interconversion			
Serine-glycine interconversion	THF	$=CH_2$	Entry of single carbon units into active pool
Homocysteine to methionine	5-Methyl(M)THF	$-CH_3$	Demethylation of 5-MTHF to THF; also requires cobalamin, flavine adenine dinucleotide, ATP, and adenosylmethionine
Forminoglutamic acid to glutamic acid in histidine catabolism	THF	–HN–CH=	

Abbreviations: DHF, dihydrofolate; THF, tetrahydrofolate.

completely reduced to dihydrofolate (DHF) or tetrahydrofolate (THF) derivatives, (2) they usually contain a single carbon unit (Table 99-2), and (3) 70–90% of natural folates are folate-polyglutamates.

Most foods contain some folate. The highest concentrations are found in liver, yeast, spinach, other greens, and nuts (>100 μg/100 g). The total folate content of an average Western diet is ~250 μg daily, but the amount varies widely according to the type of food eaten and the method of cooking. Folate is easily destroyed by heating, particularly in large volumes of water. Total-body folate in the adult is ~10 mg, with the liver containing the largest store. Daily adult requirements are ~100 μg, and so stores are sufficient for only 3–4 months in normal adults, and severe folate deficiency may develop rapidly.

ABSORPTION

Folates are absorbed rapidly from the upper small intestine. The absorption of folate polyglutamates is less efficient than that of monoglutamates; on average, ~50% of food folate is absorbed. Polyglutamate forms are hydrolyzed to the monoglutamate derivatives either in the lumen of the intestine or within the mucosa. All dietary folates are converted to 5-methyl-THF (5-MTHF) within the small intestinal mucosa before entering portal plasma. The monoglutamates are actively transported across the enterocyte by a proton-coupled folate transporter (PCFT, SCL46A1). This is situated at the apical brush border and is most active at pH 5.5, which is about the pH of the duodenal and jejunal surface. Genetic mutations of this protein underlie hereditary malabsorption of folate (see below). Pteroylglutamic acid at doses >400 μg is absorbed largely unchanged and converted to natural folates in the liver. Lower doses are converted to 5-MTHF during absorption through the intestine.

About 60–90 μg of folate enter the bile each day and are excreted into the small intestine. Loss of this folate, together with the folate of sloughed intestinal cells, accelerates the speed with which folate deficiency develops in malabsorption conditions.

TRANSPORT

Folate is transported in plasma; about one-third is loosely bound to albumin, and two-thirds are unbound. In all body fluids (plasma, cerebrospinal fluid, milk, bile), folate is largely, if not entirely, 5-MTHF in the monoglutamate form. Three types of folate-binding protein are involved. A reduced folate transporter (RFC, SLC19A1) is the major route of delivery of plasma folate (5-MTHF) to cells. Two folate receptors, FR2 and FR3 embedded in the cell membrane by a glycosyl phosphatidylinositol anchor, transport folate into the cell via receptor-mediated endocytosis. The third protein, proton-coupled folate transporter (PCFT), transports folate at low pH from the vesicle to the cell cytoplasm. The reduced folate transporter also mediates uptake of methotrexate by cells.

BIOCHEMICAL FUNCTIONS

Folates (as the intracellular polyglutamate derivatives) act as coenzymes in the transfer of single-carbon units (Fig. 99-1 and Table 99-2). Two of these reactions are involved in purine synthesis and one in pyrimidine synthesis necessary for DNA and RNA replication. Folate is also a coenzyme for methionine synthesis, in which methylcobalamin is also involved and in which THF is regenerated. THF is the acceptor of single carbon units newly entering the active pool via conversion of serine to glycine. Methionine, the other product of the methionine synthase reaction, is the precursor for *S*-adenosylmethionine (SAM), the universal methyl donor involved in >100 methyltransferase reactions (Fig. 99-1).

During thymidylate synthesis, 5,10-methylene-THF is oxidized to DHF. The enzyme DHF reductase converts this to THF. The drugs methotrexate, pyrimethamine, and (mainly in bacteria) trimethoprim inhibit DHF reductase and so prevent formation of active THF coenzymes from DHF. A small fraction of the folate coenzyme is not recycled during thymidylate synthesis but is degraded at the C9-N10 bond.

BIOCHEMICAL BASIS OF MEGALOBLASTIC ANEMIA

The common feature of all megaloblastic anemias is a defect in DNA synthesis that affects rapidly dividing cells in the bone marrow. All conditions that give rise to megaloblastic changes have in common a disparity in the rate of synthesis or availability of the four immediate precursors of DNA: the deoxyribonucleoside triphosphates (dNTPs)—dA(adenine)TP and dG(guanine)TP (purines), dT(thymine)TP, and dC(cytosine)TP (pyrimidines). In deficiencies of either folate or cobalamin, there is failure to convert deoxyuridine monophosphate (dUMP) to deoxythymidine monophosphate (dTMP), the precursor of dTTP (Fig. 99-1). This is the case because folate is needed as the coenzyme 5,10-methylene-THF polyglutamate for conversion of dUMP to dTMP; the availability of 5,10-methylene-THF is reduced in either cobalamin or folate deficiency. DNA replication from multiple origins along the chromosome is slower than normal during mitosis, and there is failure of joining up the incomplete replicons with resulting single-stranded DNA breaks. An alternative theory for megaloblastic anemia in cobalamin or folate deficiency is misincorporation of uracil into DNA because of the accumulation of deoxyuridine triphosphate (dUTP) at

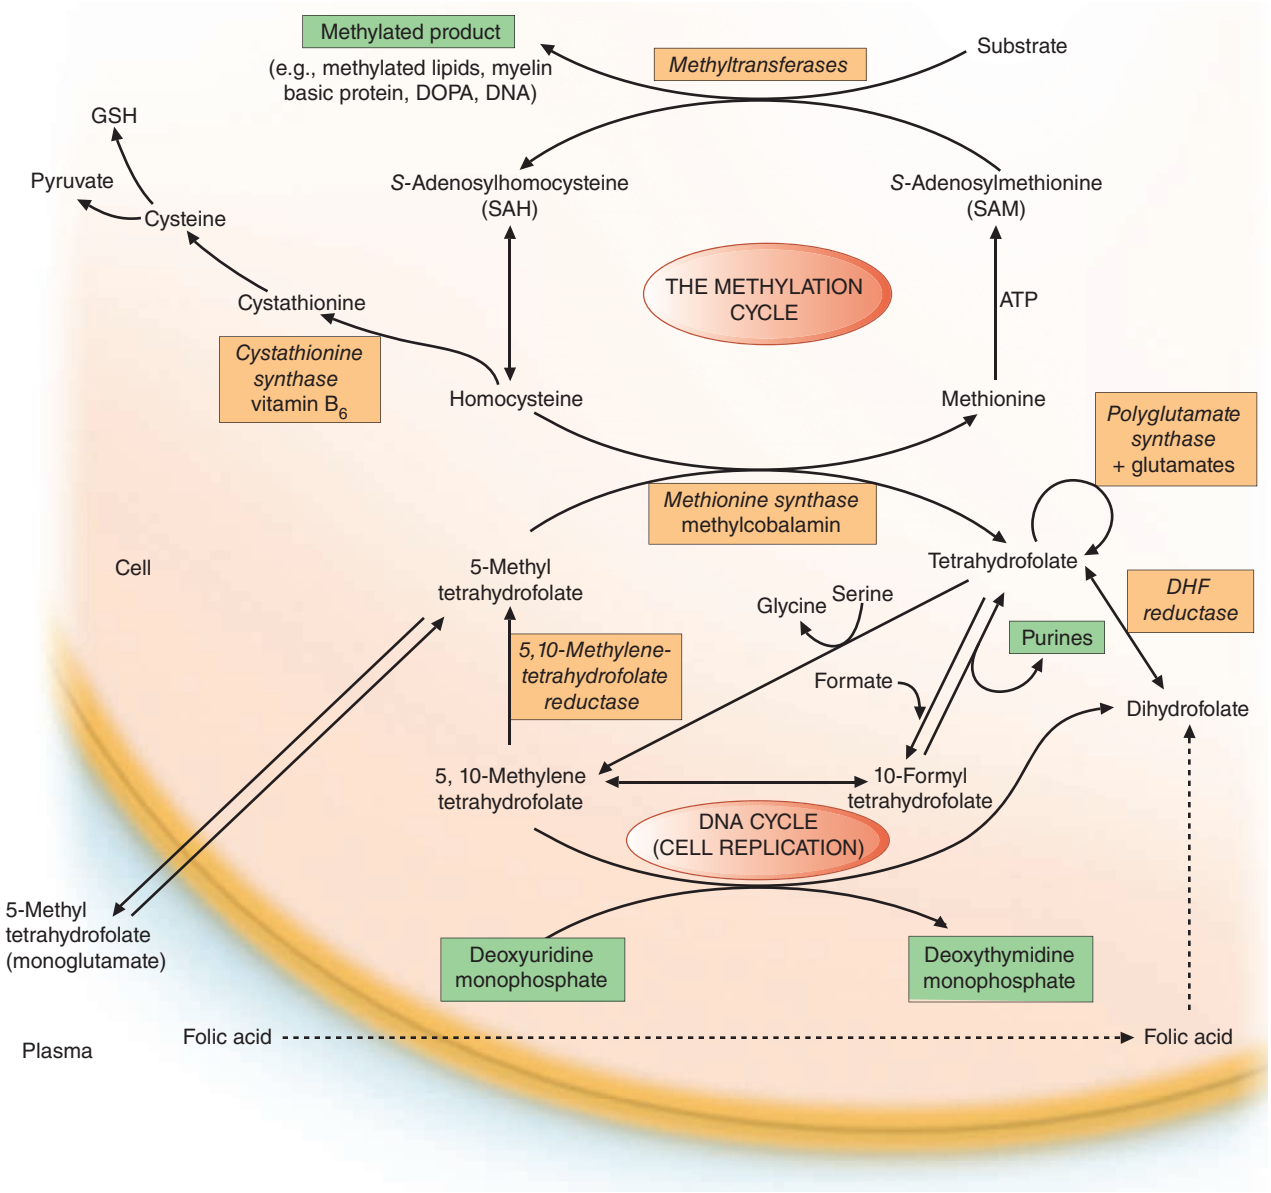

FIGURE 99-1 The role of folates in DNA synthesis and in formation of *S*-adenosylmethionine (SAM), which is involved in numerous methylation reactions. DHF, dihydrofolate; GSH, glutathione. *(Reproduced with permission from AV Hoffbrand et al [eds]: Postgraduate Haematology, 5th ed. Oxford, UK, Blackwell Publishing, 2005.)*

the DNA replication fork as a consequence of the block in conversion of dUMP to dTMP.

COBALAMIN-FOLATE RELATIONS

Folate is required for many reactions in mammalian tissues. Only two reactions in the body are known to require cobalamin. Methylmalonyl-CoA isomerization requires adocobalamin, and the methylation of homocysteine to methionine requires both methylcobalamin and 5-MTHF (Fig. 99-1). This reaction is the first step in the pathway by which 5-MTHF, which enters bone marrow and other cells from plasma, is converted into all the intracellular folate coenzymes. The coenzymes are all polyglutamated (the larger size aiding retention in the cell), but the enzyme folate polyglutamate synthase can use only THF, not MTHF, as substrate. In cobalamin deficiency, MTHF accumulates in plasma, and intracellular folate concentrations fall due to failure of formation of THF, the substrate on which folate polyglutamates are built. This has been termed *THF starvation*, or the *methylfolate trap*.

This theory explains the abnormalities of folate metabolism that occur in cobalamin deficiency (high serum folate, low cell folate, positive purine precursor aminoimidazole carboxamide ribonucleotide [AICAR] excretion; Table 99-2) and also why the anemia of cobalamin deficiency responds to folic acid in large doses.

CLINICAL FEATURES

Many symptomless patients are detected through the finding of a raised mean corpuscular volume (MCV) on a routine blood count. The main clinical features in more severe cases are those of anemia. Anorexia is usually marked, and there may be weight loss, diarrhea, or constipation. Glossitis, angular cheilosis, a mild fever in more severely anemic patients, jaundice (unconjugated), and reversible melanin skin hyperpigmentation also may occur with a deficiency of either folate or cobalamin. Thrombocytopenia sometimes leads to bruising, and this may be aggravated by vitamin C deficiency or alcohol in malnourished patients. The anemia and low leukocyte count may predispose to infections, particularly of the respiratory and urinary tracts. Cobalamin deficiency has also been associated in a few studies with impaired bactericidal function of phagocytes and with osteoporosis.

Neurologic Manifestations Vitamin B_{12} is needed for the myelination of the central nervous system. Its deficiency may cause a bilateral peripheral neuropathy or degeneration (demyelination) of the cervical and thoracic posterior and lateral (pyramidal) tracts of the spinal cord and, less frequently, of the cranial nerves and of the white matter of the brain. Optic atrophy and cerebral symptoms including dementia, depression, psychotic symptoms, and cognitive impairment may be

prominent. There may also be anosmia and loss of taste. MRI may show the "spongy" degeneration of the cord.

The patient, more frequently male, typically presents with paresthesias, muscle weakness, or difficulty in walking but sometimes may present with dementia, psychotic disturbances, or visual impairment. There is usually loss of proprioception and vibration sensation with positive Romberg and Lhermitte signs. Gait may be ataxic with spasticity (hyperreflexia). Autonomic nervous dysfunction can result in postural hypotension, impotence, and incontinence.

Long-term nutritional cobalamin deficiency in infancy leads to poor brain development and impaired intellectual development. In infancy, there may be feeding difficulties, lethargy, and coma. Convulsions and myoclonus have been described. An important clinical problem is the nonanemic patient with neurologic or psychiatric abnormalities and a low or borderline serum cobalamin level. In such patients, it is necessary to try to establish whether there is significant cobalamin deficiency, for example, by careful examination of the blood film, tests for pernicious anemia (PA) by serum gastrin level and for antibodies to IF or parietal cells, along with serum methylmalonic acid (MMA) measurement if available. A trial of cobalamin therapy for at least 3 months will usually also be needed to determine whether the symptoms improve.

The biochemical basis for cobalamin neuropathy remains obscure. Its occurrence in the absence of methylmalonic aciduria in TC II deficiency suggests that the neuropathy is related to the defect in homocysteine-methionine conversion. Accumulation of *S*-adenosylhomocysteine in the brain, resulting in inhibition of transmethylation reactions, has been suggested. Folate deficiency has been suggested to cause organic nervous disease, but this is uncertain, although methotrexate injected into the cerebrospinal fluid may cause brain or spinal cord damage.

Psychiatric disturbance as discussed above is common in both folate and cobalamin deficiencies. This, like the neuropathy, has been attributed to a failure of the synthesis of SAM, which is needed in methylation of biogenic amines (e.g., dopamine) as well as that of proteins, phospholipids, and neurotransmitters in the brain (Fig. 99-1). Associations between lower serum folate or cobalamin levels and higher homocysteine levels and the development of decreased cognitive function and dementia in Alzheimer's disease have been reported. A meta-analysis of randomized, placebo-controlled trials of homocysteine-lowering B-vitamin supplementation of individuals with and without cognitive impairment, however, showed that supplementation with vitamin B_{12}, vitamin B_6, and folic acid alone or in combination did not improve cognitive function. Some studies done in China suggest some cognitive improvement with supplements of both vitamins. It is unknown whether prolonged treatment with these B vitamins can reduce the risk of dementia in later life.

GENERAL TISSUE EFFECTS OF COBALAMIN AND FOLATE DEFICIENCIES

Epithelial Surfaces After the marrow, the next most frequently affected tissues are the epithelial cell surfaces of the mouth (with glossitis), stomach, and small intestine and the respiratory, urinary, and female genital tracts. The cells show macrocytosis, with increased numbers of multinucleate and dying cells. The deficiencies may cause cervical smear abnormalities.

Complications of Pregnancy The gonads are also affected, and infertility is common in both men and women with severe deficiency of either vitamin. Maternal folate deficiency has been implicated as a cause of prematurity, and both folate deficiency and cobalamin deficiency have been implicated in recurrent fetal loss and neural tube defects, as discussed below.

Neural Tube Defects Folic acid supplements at the time of conception and in the first 12 weeks of pregnancy reduce by ~70% the incidence of neural tube defects (NTDs) (anencephaly, meningomyelocele, encephalocele, and spina bifida) in the fetus. Most of this protective effect can be achieved by taking folic acid, 0.4 mg daily, at the time of conception.

The incidence of cleft palate and harelip also can be reduced by prophylactic folic acid. There is no clear simple relationship between maternal folate status and these fetal abnormalities, although overall, the lower the maternal folate, the greater is the risk to the fetus. NTDs also can be caused by antifolate and antiepileptic drugs.

An underlying maternal folate metabolic abnormality has also been postulated. One abnormality has been identified: reduced activity of the enzyme 5,10-methylene-THF reductase (MTHFR) (Fig. 99-1) caused by a common C677T polymorphism in the *MTHFR* gene. In one study, the prevalence of this polymorphism was found to be higher than in controls in the parents of NTD fetuses and in the fetuses themselves: homozygosity for the TT mutation was found in 13% of cases compared with 5% of control subjects. The polymorphism codes for a thermolabile form of MTHFR. The homozygous state results in a lower mean serum and red cell folate level compared with control subjects, as well as significantly higher serum homocysteine levels. Tests for mutations in other enzymes possibly associated with NTDs, for example, methionine synthase and serine–glycine hydroxymethylase, have been negative. Serum vitamin B_{12} levels are also lower in the sera of mothers of NTD infants than in controls. In addition, maternal TC II receptor polymorphisms are associated with increased risk of NTD births. However, no studies show that dietary fortification with vitamin B_{12} reduces the incidence of NTDs.

Cardiovascular Disease Children with severe homocystinuria (blood levels ≥100 μmol/L) due to deficiency of one of three enzymes (methionine synthase, MTHFR, or cystathionine synthase; Fig. 99-1) have vascular disease, for example, ischemic heart disease, cerebrovascular disease, or pulmonary embolus, as teenagers or in young adulthood. Lesser degrees of raised serum homocysteine and low levels of serum folate and homozygous inherited mutations of *MTHFR* have been found to be associated with cerebrovascular, peripheral vascular, and coronary heart disease and with deep vein thrombosis. Prospective randomized trials of lowering homocysteine levels with supplements of folic acid, vitamin B_{12}, and vitamin B_6 against placebo over a 5-year period in patients with vascular disease or diabetes have not, however, shown a reduction of first event fatal or nonfatal myocardial infarction, nor have these supplements reduced the risk of recurrent cardiovascular disease after an acute myocardial infarct. Meta-analysis showed an 18% reduction in strokes. The benefit for stroke prevention has been confirmed by a large (>20,000 subjects) randomized prospective study in hypertensive subjects in China. This showed a significant reduction in the first incidence of stroke in subjects receiving enalapril and folic acid compared to enalapril alone. The effect was especially marked in the subjects commencing the prospective trial with the lowest serum folate levels. Venous thrombosis has been reported to be more frequent in folate-deficient or vitamin B_{12}–deficient subjects than in controls and to occur at unusual sites such as cerebral venous sinuses. This tendency was ascribed to raised plasma homocysteine levels in folate or vitamin B_{12} deficiency.

Malignancy Prophylactic folic acid in pregnancy has been found in some but not all studies to reduce the subsequent incidence of acute lymphoblastic leukemia (ALL) in childhood. A significant negative association has also been found with the *MTHFR* C677T polymorphism and leukemias with mixed lineage leukemia (MLL) translocations, but a positive association was found with hyperdiploidy in infants with ALL or acute myeloid leukemia or with childhood ALL. A second polymorphism in the *MTHFR* gene, A1298C, is also strongly associated with hyperdiploid leukemia. Various positive and negative associations are noted between polymorphisms in folate-dependent enzymes and the incidence of adult ALL. The C677T polymorphism is thought to lead to increased thymidine pools and "better quality" of DNA synthesis by shunting one-carbon groups toward thymidine and purine synthesis. This may explain its reported association with a lower risk for colorectal cancer. Most but not all studies suggest that prophylactic folic acid also protects against colon adenomas. Other tumors that have been associated with folate polymorphisms or status include follicular lymphoma, breast cancer, and gastric cancer. A meta-analysis of 50,000 individuals given folic acid (0.5–40 mg daily) or placebo in cardiovascular or colon

adenoma prevention trials found that folic acid supplementation did not significantly increase or decrease the overall incidence of cancer or of any site-specific cancer during a weighted average scheduled treatment duration of 5.7 years. Because folic acid may "feed" tumors, it probably should be avoided in those with established tumors unless there is severe megaloblastic anemia due to folate deficiency.

HEMATOLOGIC FINDINGS

PERIPHERAL BLOOD

Oval macrocytes, usually with considerable anisocytosis and poikilocytosis, are the main feature **(Fig. 99-2*A*)**. The MCV is usually >100 fL unless a cause of microcytosis (e.g., iron deficiency or thalassemia trait) is present. Some of the neutrophils are hypersegmented (more than five nuclear lobes). There may be leukopenia due to a reduction in granulocytes and lymphocytes, but this is usually $>1.5 \times 10^9$/L; the platelet count may be moderately reduced, rarely to $<40 \times 10^9$/L. The severity of all these changes parallels the degree of anemia. In a nonanemic patient, the presence of a few macrocytes and hypersegmented neutrophils in the peripheral blood may be the only indication of the underlying disorder.

BONE MARROW

In a severely anemic patient, the marrow is hypercellular with an accumulation of primitive cells due to selective death by apoptosis of more mature forms. The erythroblast nucleus maintains a primitive appearance despite maturation and hemoglobinization of the cytoplasm. The cells are larger than normoblasts, and an increased number of cells with eccentric lobulated nuclei or nuclear fragments may be present **(Fig. 99-2*B*)**. Giant and abnormally shaped metamyelocytes and enlarged hyperpolyploid megakaryocytes are characteristic. In severe cases, the accumulation of primitive cells may mimic acute myeloid leukemia, whereas in less anemic patients, the changes in the marrow may be difficult to recognize. The terms *intermediate*, *mild*, and *early* have been used. The term *megaloblastoid* does not mean mildly megaloblastic. It is used to describe cells with both immature-appearing nuclei and defective hemoglobinization and is usually seen in myelodysplasia.

CHROMOSOMES

Bone marrow cells, transformed lymphocytes, and other proliferating cells in the body show a variety of changes, including random breaks, reduced contraction, spreading of the centromere, and exaggeration of secondary chromosomal constrictions and overprominent satellites. Similar abnormalities may be produced by antimetabolite drugs (e.g., cytosine arabinoside, hydroxyurea, and methotrexate) that interfere with either DNA replication or folate metabolism and that also cause megaloblastic appearances.

INEFFECTIVE HEMATOPOIESIS

Unconjugated bilirubin accumulates in plasma due to the death of nucleated red cells in the marrow (ineffective erythropoiesis). Other evidence for this includes raised urine urobilinogen, reduced haptoglobins and positive urine hemosiderin, and a raised serum lactate dehydrogenase. A weakly positive direct antiglobulin test due to complement can lead to a false diagnosis of autoimmune hemolytic anemia.

CAUSES OF COBALAMIN DEFICIENCY

Cobalamin deficiency is usually due to malabsorption. The only other cause is inadequate dietary intake.

INADEQUATE DIETARY INTAKE

Adults Dietary cobalamin deficiency arises in vegans who omit meat, fish, eggs, cheese, and other animal products from their diet. The largest group in the world consists of Hindus, and it is likely that many millions of Indians are at risk of deficiency of cobalamin on a nutritional basis. Subnormal serum cobalamin levels are found in up to 50% of randomly selected, young, adult Indian vegans, but the deficiency usually does not progress to megaloblastic anemia since the diet of most vegans is not totally lacking in cobalamin and the enterohepatic circulation of cobalamin is intact. Dietary cobalamin deficiency may also arise rarely in nonvegetarian individuals who exist on grossly inadequate diets because of poverty or psychiatric disturbance.

Infants Cobalamin deficiency has been described in infants born to severely cobalamin-deficient mothers. These infants develop megaloblastic anemia at about 3–6 months of age, presumably because they are born with low stores of cobalamin and because they are fed breast milk with low cobalamin content. The babies have also shown growth retardation, impaired psychomotor development, and other neurologic sequelae. MRI shows delayed myelination and atrophy.

GASTRIC CAUSES OF COBALAMIN MALABSORPTION

See **Tables 99-3** and **99-4**.

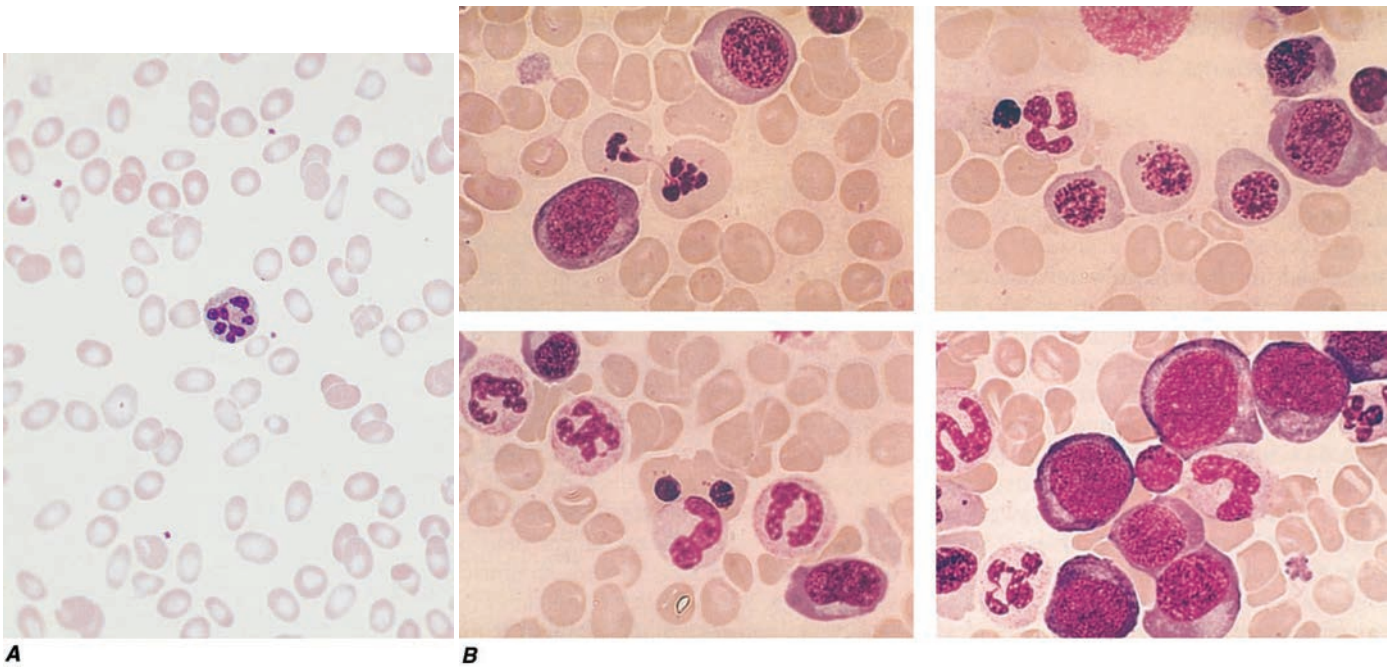

FIGURE 99-2 ***A.*** The peripheral blood in severe megaloblastic anemia. ***B.*** The bone marrow in severe megaloblastic anemia. *(Reprinted from AV Hoffbrand et al [eds]: Postgraduate Haematology, 5th ed. Oxford, UK, Blackwell Publishing, 2005; with permission.)*

TABLE 99-3 Causes of Cobalamin Deficiency Sufficiently Severe to Cause Megaloblastic Anemia

NUTRITIONAL	VEGANS
Malabsorption	Pernicious anemia
Gastric causes	Congenital absence of intrinsic factor or functional abnormality
	Total or partial gastrectomy
Intestinal causes	Intestinal stagnant loop syndrome: jejunal diverticulosis, ileocolic fistula, anatomic blind loop, intestinal stricture, etc.
	Ileal resection and Crohn's disease
	Selective malabsorption with proteinuria
	Tropical sprue
	Transcobalamin II deficiency
	Fish tapeworm

Formerly, the pathogenesis of B_{12} malabsorption was distinguishable based on the results of a Schilling test in which a radioactive form of B_{12} was administered orally and its appearance in the urine was a sign of absorption. Radioactive B_{12} is no longer available, and Schilling tests are no longer performed. Other approaches to the differential diagnosis of B_{12} malabsorption are now employed.

Pernicious Anemia PA may be defined as a severe lack of IF due to gastric atrophy. It is a common disease in northern Europeans but occurs in all countries and ethnic groups. It is more frequent in people of African than Asian ancestry. The overall incidence is about 120 per 100,000 population in the United Kingdom (UK). The ratio of incidence in men and women among whites is ~1:1.6, and the median age of onset is 70–80 years, with only 10% of patients being <40 years of age. However, in some ethnic groups, notably blacks and Latin Americans, the age at onset of PA is generally lower. The disease occurs more commonly than by chance in close relatives and in persons with other organ-specific autoimmune diseases, for example, thyroid diseases, vitiligo, hypoparathyroidism, type 1 diabetes, and Addison's disease. It is also associated with hypogammaglobulinemia, premature graying or blue eyes, and persons of blood group A. An association with human leukocyte antigen (HLA) 3 has been reported in some but not all series and, in those with endocrine disease, with HLA-B8, -B_{12}, and -BW15. Life expectancy is normal in women once regular treatment has begun. Men had a slightly subnormal life expectancy as a result of a higher incidence of carcinoma of the stomach than in control subjects, but current data on their life expectancy are unavailable. Gastric output of hydrochloric acid, pepsin, and IF is severely reduced. The serum gastrin level is raised, and serum pepsinogen I levels are low.

TABLE 99-4 Malabsorption of Cobalamin May Occur in the Following Conditions but Is Not Usually Sufficiently Severe and Prolonged to Cause Megaloblastic Anemia

Gastric causes
Simple atrophic gastritis (food cobalamin malabsorption)
Zollinger-Ellison syndrome
Gastric bypass or bariatric surgery
Use of proton pump inhibitors
Intestinal causes
Gluten-induced enteropathy
Severe pancreatitis
HIV infection
Radiotherapy
Graft-versus-host disease
Deficiencies of cobalamin, folate, protein, ?riboflavin, ?nicotinic acid
Therapy with colchicine, para-aminosalicylate, neomycin, slow-release potassium chloride, anticonvulsant drugs, metformin,[a] cytotoxic drugs
Alcohol

[a]It is now thought that metformin lowers serum vitamin B_{12} level by lowering the level of transcobalamin I.

Gastric Biopsy A single endoscopic examination is recommended if PA is diagnosed. Gastric biopsy usually shows atrophy of all layers of the body and fundus, with loss of glandular elements, an absence of parietal and chief cells and replacement by mucous cells, a mixed inflammatory cell infiltrate, and perhaps intestinal metaplasia. The infiltrate of plasma cells and lymphocytes contains an excess of CD4 cells. These are directed against gastric H/K-ATPase. The antral mucosa is usually well preserved. *Helicobacter pylori* infection occurs infrequently in PA, but it has been suggested that *H. pylori* gastritis occurs at an early phase of atrophic gastritis and presents in younger patients as iron-deficiency anemia but in older patients as PA. *H. pylori* is suggested to stimulate an autoimmune process directed against parietal cells, with the *H. pylori* infection then being gradually replaced, in some individuals, by an autoimmune process.

Serum Antibodies Two types of IF immunoglobulin G antibody may be found in the sera of patients with PA. The "blocking," or type I, antibody prevents the combination of IF and cobalamin, whereas the "binding," or type II, antibody prevents attachment of IF to ileal mucosa. Type I occurs in the sera of ~55% of patients, and type II in 35%. IF antibodies cross the placenta and may cause temporary IF deficiency in a newborn infant. Patients with PA also show cell-mediated immunity to IF. Type I antibody has been detected rarely in the sera of patients without PA but with thyrotoxicosis, myxedema, Hashimoto's disease, or diabetes mellitus and in relatives of PA patients. IF antibodies also have been detected in gastric juice in ~80% of PA patients. These gastric antibodies may reduce absorption of dietary cobalamin by combining with small amounts of remaining IF.

Parietal cell antibody is present in the sera of almost 90% of adult patients with PA but is frequently present in other subjects. Thus, it occurs in as many as 16% of randomly selected female subjects age >60 years. The parietal cell antibody is directed against the α and β subunits of the gastric proton pump (H^+, K^+-ATPase).

JUVENILE PERNICIOUS ANEMIA

This usually occurs in older children and resembles PA of adults. Gastric atrophy, achlorhydria, and serum IF antibodies are all present, although parietal cell antibodies are usually absent. About one-half of these patients show an associated endocrinopathy such as autoimmune thyroiditis, Addison's disease, or hypoparathyroidism; in some, mucocutaneous candidiasis occurs.

CONGENITAL INTRINSIC FACTOR DEFICIENCY OR FUNCTIONAL ABNORMALITY

An affected child usually presents with megaloblastic anemia in the first to third year of life; a few have presented as late as the second decade. The child usually has no demonstrable IF but has a normal gastric mucosa and normal secretion of acid. The inheritance is autosomal recessive. Parietal cell and IF antibodies are absent. Variants have been described in which the child is born with IF that can be detected immunologically but is unstable or functionally inactive, unable to bind cobalamin or to facilitate its uptake by ileal receptors.

GASTRECTOMY

After total gastrectomy, cobalamin deficiency is inevitable, and prophylactic cobalamin therapy should be commenced immediately after the operation. After partial gastrectomy, 10–15% of patients also develop this deficiency. The exact incidence and time of onset are most influenced by the size of the resection and the preexisting size of cobalamin body stores.

FOOD COBALAMIN MALABSORPTION

Failure of release of cobalamin from binding proteins in food is believed to be responsible for this condition, which is more common in the elderly. It is associated with low serum cobalamin levels, with or without raised serum levels of MMA and homocysteine. Typically,

these patients have normal cobalamin absorption, as measured with crystalline cobalamin, but show malabsorption when a modified test using food-bound cobalamin is used. It is usually due to mild forms of atrophic gastritis or therapy with proton pump inhibitors. Bariatric surgery is likely to be an increasing cause of this form of B_{12} malabsorption and deficiency. The frequency of progression to severe cobalamin deficiency and the reasons for this progression are not clear.

INTESTINAL CAUSES OF COBALAMIN MALABSORPTION

Intestinal Stagnant Loop Syndrome Malabsorption of cobalamin occurs in a variety of intestinal lesions in which there is colonization of the upper small intestine by fecal organisms. This may occur in patients with jejunal diverticulosis, enteroanastomosis, or an intestinal stricture or fistula or with an anatomic blind loop due to Crohn's disease, tuberculosis, or an operative procedure.

Ileal Resection Removal of ≥1.2 m of terminal ileum causes malabsorption of cobalamin. In some patients after ileal resection, particularly if the ileocecal valve is incompetent, colonic bacteria may contribute further to the onset of cobalamin deficiency.

Selective Malabsorption of Cobalamin with Proteinuria (Imerslund's Syndrome; Imerslund-Gräsbeck Syndrome; Congenital Cobalamin Malabsorption; Autosomal Recessive Megaloblastic Anemia; MGA1) This autosomal recessive disease is the most common cause of megaloblastic anemia due to cobalamin deficiency in infancy in Western countries. More than 200 cases have been reported with familial clusters in Finland, Norway, the Middle East, and North Africa. The patients secrete normal amounts of IF and gastric acid but are unable to absorb cobalamin. In Finland, impaired synthesis, processing, or ligand binding of cubilin due to inherited mutations is found. In Norway, mutation of the gene for *AMN* has been reported. Other tests of intestinal absorption are normal. Over 90% of these patients show nonspecific proteinuria, but renal function is otherwise normal, and renal biopsy has not shown any consistent renal defect. A few have shown aminoaciduria and congenital renal abnormalities, such as duplication of the renal pelvis.

Tropical Sprue Nearly all patients with acute and subacute tropical sprue show malabsorption of cobalamin; this may persist as the principal abnormality in the chronic form of the disease, when the patient may present with megaloblastic anemia or neuropathy due to cobalamin deficiency. Absorption of cobalamin usually improves after antibiotic therapy and, in the early stages, folic acid therapy.

Fish Tapeworm Infestation The fish tapeworm (*Diphyllobothrium latum*) lives in the small intestine of humans and accumulates cobalamin from food, rendering the cobalamin unavailable for absorption. Individuals acquire the worm by eating raw or partly cooked fish. Infestation is common around the lakes of Scandinavia, Germany, Japan, North America, and Russia. Megaloblastic anemia or cobalamin neuropathy occurs only in those with a heavy infestation.

Gluten-Induced Enteropathy Malabsorption of cobalamin occurs in ~30% of untreated patients (presumably those in whom the disease extends to the ileum). Cobalamin deficiency is not severe in these patients and is corrected with a gluten-free diet.

Severe Chronic Pancreatitis In this condition, lack of trypsin is thought to cause dietary cobalamin attached to gastric non-IF (R) binder to be unavailable for absorption. It also has been proposed that in pancreatitis, the concentration of calcium ions in the ileum falls below the level needed to maintain normal cobalamin absorption.

HIV Infection Serum cobalamin levels tend to fall in patients with HIV infection and are subnormal in 10–35% of those with AIDS. Malabsorption of cobalamin not corrected by IF has been shown in some, but not all, patients with subnormal serum cobalamin levels. Cobalamin deficiency sufficiently severe to cause megaloblastic anemia or neuropathy is rare.

Zollinger-Ellison Syndrome Malabsorption of cobalamin has been reported in the Zollinger-Ellison syndrome. It is thought that there is a failure to release cobalamin from R-binding protein due to inactivation of pancreatic trypsin by high acidity, as well as interference with IF binding of cobalamin.

Radiotherapy Both total-body irradiation and local radiotherapy to the ileum (e.g., as a complication of radiotherapy for carcinoma of the cervix) may cause malabsorption of cobalamin.

Graft-versus-Host Disease This commonly affects the small intestine. Malabsorption of cobalamin due to abnormal gut flora, as well as damage to ileal mucosa, is common.

Drugs The drugs that have been reported to cause malabsorption of cobalamin are listed in Table 99-4. However, megaloblastic anemia due to these drugs is rare. It has been suggested that metformin lowers serum B_{12} by lowering TC I level rather than causing malabsorption of B_{12}.

ABNORMALITIES OF COBALAMIN METABOLISM

Congenital Transcobalamin II Deficiency or Abnormality Infants with TC II deficiency usually present with megaloblastic anemia within a few weeks of birth. Serum cobalamin and folate levels are normal, but the anemia responds to massive (e.g., 1 mg three times weekly) injections of cobalamin. Some cases show neurologic complications. The protein may be present but functionally inert. Genetic abnormalities found include mutations of an intraexonic cryptic splice site, extensive deletion, single nucleotide deletion, nonsense mutation, and an RNA editing defect. Malabsorption of cobalamin occurs in all cases, and serum immunoglobulins are usually reduced. Failure to institute adequate cobalamin therapy or treatment with folic acid may lead to neurologic damage.

Congenital Methylmalonic Acidemia and Aciduria Infants with this abnormality are ill from birth with vomiting, failure to thrive, severe metabolic acidosis, ketosis, and mental retardation. Anemia, if present, is normocytic and normoblastic. The condition may be due to a functional defect in either mitochondrial methylmalonyl-CoA mutase or its cofactor adocobalamin. Mutations in the methylmalonyl-CoA mutase are not responsive or are only poorly responsive to treatment with cobalamin. A proportion of infants with failure of adocobalamin synthesis respond to cobalamin in large doses. Some children have combined methylmalonic aciduria and homocystinuria due to defective formation of both cobalamin coenzymes. This usually presents in the first year of life with feeding difficulties, developmental delay, microcephaly, seizures, hypotonia, and megaloblastic anemia.

Acquired Abnormality of Cobalamin Metabolism: Nitrous Oxide Inhalation Nitrous oxide (N_2O) irreversibly oxidizes methylcobalamin to an inactive precursor; this inactivates methionine synthase. Megaloblastic anemia has occurred in patients undergoing prolonged N_2O anesthesia (e.g., in intensive care units). A neuropathy resembling cobalamin neuropathy has been described in dentists and anesthetists who are exposed repeatedly to N_2O. Methylmalonic aciduria does not occur as adocobalamin is not inactivated by N_2O.

CAUSES OF FOLATE DEFICIENCY
(Table 99-5)

NUTRITIONAL

Dietary folate deficiency is common. Indeed, in most patients with folate deficiency, a nutritional element is present. Certain individuals are particularly prone to have diets containing inadequate amounts of folate (Table 99-5). In the United States and other countries where fortification of the diet with folic acid has been adopted, the prevalence of folate deficiency has dropped dramatically and is now almost restricted to high-risk groups with increased folate needs. Nutritional folate deficiency occurs in kwashiorkor and scurvy and in infants with repeated infections or those who are fed solely on goats' milk, which has a low folate content.

TABLE 99-5 Causes of Folate Deficiency

Dietary[a]
Particularly in: old age, infancy, poverty, alcoholism, chronic invalids, and the psychiatrically disturbed; may be associated with scurvy or kwashiorkor
Malabsorption
Major causes of deficiency
Tropical sprue, gluten-induced enteropathy in children and adults, and in association with dermatitis herpetiformis, specific malabsorption of folate, intestinal megaloblastosis caused by severe cobalamin or folate deficiency
Minor causes of deficiency
Extensive jejunal resection, Crohn's disease, partial gastrectomy, congestive heart failure, Whipple's disease, scleroderma, amyloid, diabetic enteropathy, systemic bacterial infection, lymphoma, sulfasalazine (Salazopyrin)
Excess utilization or loss
Physiologic
Pregnancy and lactation, prematurity
Pathologic
Hematologic diseases: chronic hemolytic anemias, sickle cell anemia, thalassemia major, myelofibrosis
Malignant diseases: carcinoma, lymphoma, leukemia, myeloma
Inflammatory diseases: tuberculosis, Crohn's disease, psoriasis, exfoliative dermatitis, malaria
Metabolic disease: homocystinuria
Excess urinary loss: congestive heart failure, active liver disease
Hemodialysis, peritoneal dialysis
Antifolate drugs[b]
Anticonvulsant drugs (phenytoin, primidone, barbiturates), sulfasalazine
Nitrofurantoin, tetracycline, antituberculosis (less well documented)
Mixed causes
Liver diseases, alcoholism, intensive care units

[a]In severely folate-deficient patients with causes other than those listed under Dietary, poor dietary intake is often present. [b]Drugs inhibiting dihydrofolate reductase are discussed in the text.

MALABSORPTION

Malabsorption of dietary folate occurs in tropical sprue and in gluten-induced enteropathy. In the rare congenital recessive syndrome of selective malabsorption of folate due to mutation of the PCFT, there is an associated defect of folate transport into the cerebrospinal fluid, and these patients show megaloblastic anemia, which responds to physiologic doses of folic acid given parenterally but not orally. They also show mental retardation, convulsions, and other central nervous system abnormalities. Minor degrees of malabsorption may also occur after jejunal resection or partial gastrectomy, in Crohn's disease, and in systemic infections, but in these conditions, if severe deficiency occurs, it is usually largely due to poor nutrition. Malabsorption of folate has been described in patients receiving sulfasalazine (Salazopyrin), cholestyramine, and triamterene.

EXCESS UTILIZATION OR LOSS

Pregnancy Folate requirements are increased by 200–300 μg to ~400 μg daily in a normal pregnancy, partly because of transfer of the vitamin to the fetus but mainly because of increased folate catabolism due to cleavage of folate coenzymes in rapidly proliferating tissues. Megaloblastic anemia due to this deficiency is prevented by prophylactic folic acid therapy. It occurred in 0.5% of pregnancies in the UK and other Western countries before prophylaxis with folic acid, but the incidence is much higher in countries where the general nutritional status is poor.

Prematurity A newborn infant, whether full term or premature, has higher serum and red cell folate concentrations than does an adult. However, a newborn infant's demand for folate has been estimated to be up to 10 times that of adults on a weight basis, and the neonatal folate level falls rapidly to the lowest values at about 6 weeks of age. The falls are steepest and are liable to reach subnormal levels in premature babies, a number of whom develop megaloblastic anemia responsive to folic acid at about 4–6 weeks of age. This occurs particularly in the smallest babies (<1500 g birth weight) and those who have feeding difficulties or infections or have undergone multiple exchange transfusions. In these babies, prophylactic folic acid should be given.

Hematologic Disorders Folate deficiency frequently occurs in chronic hemolytic anemia, particularly in sickle cell disease, autoimmune hemolytic anemia, and congenital spherocytosis. In these and other conditions of increased cell turnover (e.g., myelofibrosis, malignancies), folate deficiency arises because it is not completely reutilized after performing coenzyme functions.

Inflammatory Conditions Chronic inflammatory diseases such as tuberculosis, rheumatoid arthritis, Crohn's disease, psoriasis, exfoliative dermatitis, bacterial endocarditis, and chronic bacterial infections cause deficiency by reducing the appetite and increasing the demand for folate. Systemic infections also may cause malabsorption of folate. Severe deficiency is virtually confined to the patients with the most active disease and the poorest diet.

Homocystinuria This is a rare metabolic defect in the conversion of homocysteine to cystathionine. Folate deficiency occurring in most of these patients may be due to excessive utilization because of compensatory increased conversion of homocysteine to methionine.

Long-Term Dialysis Because folate is only loosely bound to plasma proteins, it is easily removed from plasma by dialysis. In patients with anorexia, vomiting, infections, and hemolysis, folate stores are particularly likely to become depleted. Routine folate prophylaxis is now given.

Congestive Heart Failure and Liver Disease Excess urinary folate losses of >100 μg per day may occur in some of these patients. The explanation appears to be release of folate from damaged liver cells.

ANTIFOLATE DRUGS

A large number of epileptics who are receiving long-term therapy with phenytoin or primidone, with or without barbiturates, develop low serum and red cell folate levels. The exact mechanism is unclear. Alcohol may also be a folate antagonist, as patients who are drinking spirits may develop megaloblastic anemia that will respond to normal quantities of dietary folate or to physiologic doses of folic acid only if alcohol is withdrawn. Macrocytosis of red cells is associated with chronic alcohol intake even when folate levels are normal. Inadequate folate intake is the major factor in the development of deficiency in spirit-drinking alcoholics. Beer is relatively folate-rich in some countries, depending on the technique used for brewing.

The drugs that inhibit DHF reductase include methotrexate, pyrimethamine, and trimethoprim. Methotrexate has the most powerful action against the human enzyme, whereas trimethoprim is most active against the bacterial enzyme and is likely to cause megaloblastic anemia only when used in conjunction with sulfamethoxazole in patients with preexisting folate or cobalamin deficiency. The activity of pyrimethamine is intermediate. The antidote to these drugs is folinic acid (5-formyl-THF).

CONGENITAL ABNORMALITIES OF FOLATE METABOLISM

Some infants with congenital defects of folate enzymes (e.g., cyclohydrolase or methionine synthase) have had megaloblastic anemia.

DIAGNOSIS OF COBALAMIN AND FOLATE DEFICIENCIES

The diagnosis of cobalamin or folate deficiency has traditionally depended on the recognition of the relevant abnormalities in the peripheral blood and analysis of the blood levels of the vitamins.

COBALAMIN DEFICIENCY

Serum Cobalamin This is measured by an automated enzyme-linked immunosorbent assay (ELISA) or competitive-binding luminescence assay (CBLA). Normal serum levels range from 118–148 pmol/L (160–200 ng/L) to ~738 pmol/L (1000 ng/L). In patients with megaloblastic anemia due to cobalamin deficiency, the level is usually <74 pmol/L (100 ng/L). In general, the more severe the deficiency, the lower is the serum cobalamin level. In patients with spinal cord damage due to the deficiency, levels are very low even in the absence of anemia. Values between 74 and 148 pmol/L (100 and 200 ng/L) are regarded as borderline. They may occur, for instance, in pregnancy, in patients with megaloblastic anemia due to folate deficiency. They may also be due to heterozygous, homozygous, or compound heterozygous mutations of the gene *TCN1* that codes for HC (TC I). There is then no clinical or hematologic abnormality. The serum cobalamin level is sufficiently robust, cost-effective, and most convenient to rule out cobalamin deficiency in the vast majority of patients suspected of having this problem. However, problems have arisen with commercial CBLA assays involving IF in PA patients with intrinsic antibodies in serum. These antibodies may cause false normal serum vitamin B_{12} levels in up to 50% of cases tested. Where clinical indications of PA are strong, a normal serum vitamin B_{12} does not rule out the diagnosis. Serum MMA levels will be elevated in untreated PA (see below).

Folate deficiency, TC I (HC) deficiency, oral contraceptives, and multiple myeloma have all been associated with low serum B_{12} levels that do not indicate B_{12} deficiency. On the other hand, high serum B_{12} levels are usually due to raised serum TC I levels and can be due to the presence of liver, renal, or myeloproliferative diseases or to cancer of the breast, colon, or liver.

Serum Methylmalonate and Homocysteine In patients with cobalamin deficiency sufficient to cause anemia or neuropathy, the serum MMA level is raised. Sensitive methods for measuring MMA and homocysteine in serum have been introduced and recommended for the early diagnosis of cobalamin deficiency, even in the absence of hematologic abnormalities or subnormal levels of serum cobalamin. Serum MMA levels fluctuate, however, in patients with renal failure. Mildly elevated serum MMA and/or homocysteine levels occur in up to 30% of apparently healthy volunteers, with serum cobalamin levels up to 258 pmol/L (350 ng/L) and normal serum folate levels; 15% of elderly subjects, even with cobalamin levels >258 pmol/L (>350 ng/L), have this pattern of raised metabolite levels. These findings bring into question the exact cutoff points for normal MMA and homocysteine levels. It is also unclear at present whether these mildly raised metabolite levels have clinical consequences.

Serum homocysteine is raised in both early cobalamin and folate deficiency but may be raised in other conditions, for example, chronic renal disease, alcoholism, smoking, pyridoxine deficiency, hypothyroidism, and therapy with steroids, cyclosporine, and other drugs. Levels are also higher in serum than in plasma, in men than in premenopausal women, in women taking hormone replacement therapy or in oral contraceptive users, and in elderly persons and patients with several inborn errors of metabolism affecting enzymes in transsulfuration pathways of homocysteine metabolism. Thus, homocysteine levels must be carefully interpreted for diagnosis of cobalamin or folate deficiency.

Tests for the Cause of Cobalamin Deficiency Only vegans, strict vegetarians, or people living on a totally inadequate diet will become vitamin B_{12} deficient because of inadequate intake. Studies of cobalamin absorption once were widely used, but difficulty in obtaining radioactive cobalamin and ensuring that IF preparations are free of viruses has made these tests obsolete. Tests to diagnose PA include serum gastrin, which is raised; serum pepsinogen I, which is low in PA (90–92%) but also in other conditions; and gastric endoscopy. Tests for IF and parietal cell antibodies are also used, as well as tests for individual intestinal diseases.

Patients with atrophic gastritis may also have sufficient occult gastrointestinal blood loss to have iron deficiency as well as vitamin B_{12} deficiency. Iron deficiency may blunt the development of macrocytosis when iron deficiency and B_{12} deficiency coexist. Iron deficiency is much more common than B_{12} deficiency, and in people older than age 60 years, B_{12} deficiency may accompany iron deficiency in 15–20% of cases. Thus, patients diagnosed with iron-deficiency anemia should have B_{12} levels assessed, and those diagnosed with B_{12} deficiency should have their iron status assessed.

FOLATE DEFICIENCY

Serum Folate This is also measured by an ELISA technique. In most laboratories, the normal range is from 11 nmol/L (2 μg/L) to ~82 nmol/L (15 μg/L). The serum folate level is low in all folate-deficient patients. It also reflects recent diet. Because of this, serum folate may be low before there is hematologic or biochemical evidence of deficiency. Serum folate rises in severe cobalamin deficiency because of the block in conversion of MTHF to THF inside cells; raised levels have also been reported in the intestinal stagnant loop syndrome due to absorption of bacterially synthesized folate.

Red Cell Folate The red cell folate assay is a valuable test of body folate stores. It is less affected than the serum assay by recent diet and traces of hemolysis. In normal adults, concentrations range from 880 to 3520 μmol/L (160–640 μg/L) of packed red cells. Subnormal levels occur in patients with megaloblastic anemia due to folate deficiency but also in nearly two-thirds of patients with severe cobalamin deficiency. False-normal results may occur if a folate-deficient patient has received a recent blood transfusion or if a patient has a raised reticulocyte count. Serum homocysteine assay is discussed earlier.

Tests for the Cause of Folate Deficiency The diet history is important. Tests for transglutaminase antibodies are performed to confirm or exclude celiac disease. If positive, duodenal biopsy is needed. An underlying disease causing increased folate breakdown should also be excluded.

TREATMENT

Cobalamin and Folate Deficiency

It is usually possible to establish which of the two deficiencies, folate or cobalamin, is the cause of the anemia and to treat only with the appropriate vitamin. In patients who enter the hospital severely ill, however, it may be necessary to treat with both vitamins in large doses once blood samples have been taken for cobalamin and folate assays and a bone marrow biopsy has been performed (if deemed necessary). Transfusion is usually unnecessary and inadvisable. If it is essential, packed red cells should be given slowly, one or two units only, with the usual treatment for heart failure if present. Potassium supplements have been recommended to obviate the danger of the hypokalemia but are not necessary. Occasionally, an excessive rise in platelets occurs after 1–2 weeks of therapy. Antiplatelet therapy, for example, aspirin, should be considered if the platelet count rises to $>800 \times 10^9$/L.

COBALAMIN DEFICIENCY

It is usually necessary to treat patients who have developed cobalamin deficiency with lifelong regular cobalamin injections. In the UK, the form used is hydroxocobalamin; in the United States, cyanocobalamin. In a few instances, the underlying cause of cobalamin deficiency can be permanently corrected, for example, fish tapeworm, tropical sprue, or an intestinal stagnant loop that is amenable to surgery. The indications for starting cobalamin therapy are a well-documented megaloblastic anemia or other hematologic abnormalities and neuropathy due to the deficiency. Patients with borderline serum cobalamin levels but no hematologic or other abnormality may be followed to make sure that the cobalamin deficiency does not progress (see below). If malabsorption of cobalamin or rises in serum MMA levels have been demonstrated, however, these patients also should be given regular maintenance cobalamin

therapy. Cobalamin should be given routinely to all patients who have had a total gastrectomy or ileal resection. Patients who have undergone gastric reduction for control of obesity or who are receiving long-term treatment with proton pump inhibitors should be screened and, if necessary, given cobalamin replacement.

Replenishment of body stores should be complete with six 1000-μg IM injections of hydroxocobalamin given at 3- to 7-day intervals. More frequent doses are usually used in patients with cobalamin neuropathy, but there is no evidence that they produce a better response. Allergic reactions are rare and may require desensitization or antihistamine or glucocorticoid cover. For maintenance therapy, 1000 μg hydroxocobalamin IM once every 3 months is satisfactory. Because of the poorer retention of cyanocobalamin, protocols generally use higher and more frequent doses, for example, 1000 μg IM, monthly, for maintenance treatment.

Because a small fraction of cobalamin can be absorbed passively through mucous membranes even when there is complete failure of physiologic IF-dependent absorption, large daily oral doses (1000–2000 μg) of cyanocobalamin are used in PA for replacement (especially in Canada and Sweden) and maintenance of normal cobalamin status in, for example, food malabsorption of cobalamin. Sublingual therapy has also been proposed for those in whom injections are difficult because of a bleeding tendency and who may not tolerate oral therapy. If oral therapy is used, it is important to monitor compliance, particularly with elderly, forgetful patients. This author prefers parenteral therapy for initial treatment, particularly in severe anemia or if a neuropathy is present, and for maintenance in PA. Oral B_{12} therapy even with low doses of 50 μg daily may have a larger role in treating food malabsorption of B_{12}.

For treatment of patients with subnormal serum vitamin B_{12} levels with a normal MCV and no hypersegmentation of neutrophils, a negative IF antibody test in the absence of tests of B_{12} absorption is problematic. Some (perhaps 15%) cases may be due to TC I (HC) deficiency. Homocysteine and/or MMA measurements may help, but in the absence of these tests and with otherwise normal gastrointestinal function, repeat serum B_{12} assay after 6–12 months may help one decide whether to start cobalamin therapy.

Vitamin B_{12} injections are used in a wide variety of diseases, often neurologic, despite normal serum B_{12} and folate levels and a normal blood count and in the absence of randomized, double-blind, controlled trials. These conditions include multiple sclerosis and chronic fatigue syndrome/myalgic encephalomyelitis (ME). It seems probable that any benefit is due to the placebo effect of a usually painless, pink injection. In ME, oral B_{12} therapy, despite providing equally large amounts of B_{12}, has not been beneficial, supporting the view of the effect of the injections being placebo only.

FOLATE DEFICIENCY

Oral doses of 5–15 mg of folic acid daily are satisfactory, as sufficient folate is absorbed from these extremely large doses even in patients with severe malabsorption. The length of time therapy must be continued depends on the underlying disease. It is customary to continue therapy for about 4 months, when all folate-deficient red cells will have been eliminated and replaced by new folate-replete populations.

Before large doses of folic acid are given, cobalamin deficiency must be excluded and, if present, corrected; otherwise, cobalamin neuropathy may develop despite a response of the anemia of cobalamin deficiency to folate therapy. Studies in the United States, however, suggest that there is no increase in the proportion of individuals with low serum cobalamin levels and no anemia since food fortification with folic acid, but it is unknown if there has been a change in incidence of cobalamin neuropathy.

Long-term folic acid therapy is required when the underlying cause of the deficiency cannot be corrected and the deficiency is likely to recur, for example, in chronic dialysis or hemolytic anemias. It may also be necessary in gluten-induced enteropathy that does not respond to a gluten-free diet. Where mild but chronic folate deficiency occurs, it is preferable to encourage improvement in the diet after correcting the deficiency with a short course of folic acid. In any patient receiving long-term folic acid therapy, it is important to measure the serum cobalamin level at regular (e.g., once-yearly) intervals to exclude the coincidental development of cobalamin deficiency.

Folinic Acid (5-Formyl-THF) This is a stable form of fully reduced folate. It is given orally or parenterally to overcome the toxic effects of methotrexate or other DHF reductase inhibitors, for example, trimethoprim or cotrimoxazole.

PROPHYLACTIC FOLIC ACID

Prophylactic folic acid is used in chronic dialysis patients and in parenteral feeds. Prophylactic folic acid has been used to reduce homocysteine levels to prevent cardiovascular disease and for cognitive function in the elderly, but there are no firm data to show any benefit.

Pregnancy In over 70 countries (but none in Europe), food is fortified with folic acid (in grain or flour) to reduce the risk of NTDs. Nevertheless, folic acid, 400 μg daily, should be given as a supplement before and throughout pregnancy to prevent megaloblastic anemia and reduce the incidence of NTDs, even in countries with fortification of the diet. The levels of fortification provide up to 400 μg daily on average in Chile, but in most countries, it is nearer to 200 μg, so periconceptual folic acid is still needed. Most if not all the folic acid used in fortification and eaten over three meals a day will be converted during absorption to methyltetrahydrofolate. This compound will not correct the anemia in B_{12} deficiency. Studies in early pregnancy show significant lack of compliance with the folic acid supplements, emphasizing the benefit of food fortification. Supplemental folic acid reduces the incidence of birth defects in babies born to diabetic mothers. In women who have had a previous fetus with an NTD, a dose of 5 mg daily is recommended when pregnancy is contemplated and throughout the subsequent pregnancy.

Infancy and Childhood The incidence of folate deficiency is so high in the smallest premature babies during the first 6 weeks of life that folic acid (e.g., 1 mg daily) should be given routinely to those weighing <1500 g at birth and to larger premature babies who require exchange transfusions or develop feeding difficulties, infections, or vomiting and diarrhea.

The World Health Organization currently recommends routine supplementation with iron and folic acid in children in countries where iron deficiency is common and child mortality, largely due to infectious diseases, is high. However, some studies suggest that in areas where malaria rates are high, this approach may increase the incidence of severe illness and death. Even where malaria is rare, there appears to be no survival benefit.

MEGALOBLASTIC ANEMIA NOT DUE TO COBALAMIN OR FOLATE DEFICIENCY OR ALTERED METABOLISM

This may occur with many antimetabolic drugs (e.g., hydroxyurea, cytosine arabinoside, 6-mercaptopurine) that inhibit DNA replication. Antiviral nucleoside analogues used in treatment of HIV infection may also cause macrocytosis and megaloblastic marrow changes. In the rare disease orotic aciduria, two consecutive enzymes in purine synthesis are defective. The condition responds to therapy with uridine, which bypasses the block. In thiamine-responsive megaloblastic anemia, there is a genetic defect in the high-affinity thiamine transport (*SLC19A2*) gene. This causes defective RNA ribose synthesis through impaired activity of transketolase, a thiamine-dependent enzyme in the pentose cycle. This leads to reduced nucleic acid production. It may be associated with diabetes mellitus and deafness and the presence of many ringed sideroblasts in the marrow. The explanation is unclear for megaloblastic changes in the marrow in some patients with acute myeloid leukemia and myelodysplasia.

100 Hemolytic Anemias

Lucio Luzzatto, Lucia De Franceschi

DEFINITIONS

A finite life span is a distinct characteristic of red cells. Hence, a logical, time-honored classification of anemias is in three groups: (1) decreased production of red cells, (2) increased destruction of red cells, and (3) acute blood loss. Decreased production is covered in **Chaps. 97**, **98**, and **102**; acute blood loss in **Chap. 101**; increased destruction is covered in this chapter.

All patients who are anemic as a result of either increased destruction of red cells or acute blood loss have one important element in common: the anemia results from overconsumption of red cells from the peripheral blood, whereas the supply of cells from the bone marrow is normal (indeed, it is usually increased). However, with blood loss, as in acute hemorrhage, the red cells are physically lost *from* the body itself; this is fundamentally different from destruction of red cells *within* the body, as in hemolytic anemias (HAs).

With respect to primary etiology, HAs may be *inherited* or *acquired*; from a clinical point of view, they may be more *acute* or more *chronic*, and they may vary from mild to very severe; the site of hemolysis may be predominantly *intravascular* or *extravascular*. With respect to mechanisms, HAs may be due to *intracorpuscular* causes or to *extracorpuscular* causes **(Table 100-1)**. But before reviewing the individual types of HA, it is appropriate to consider what general features they have in common, in terms of clinical aspects and pathophysiology.

TABLE 100-1 Classification of Hemolytic Anemias[a]

	INTRACORPUSCULAR DEFECTS	EXTRACORPUSCULAR FACTORS
Inherited	Hemoglobinopathies Enzymopathies Membrane-cytoskeletal defects	Familial (atypical) hemolytic-uremic syndrome
Acquired	Paroxysmal nocturnal hemoglobinuria (PNH)	Mechanical destruction (microangiopathic) Toxic agents Drugs Infectious Autoimmune

[a]Hereditary causes correlate with intracorpuscular defects because these defects are due to inherited mutations; the one exception is PNH because the defect is due to an acquired somatic mutation. Conversely, acquired causes correlate with extracorpuscular factors because mostly these factors are exogenous; the one exception is familial hemolytic-uremic syndrome (HUS; often referred to as atypical HUS) because here an inherited abnormality permits complement activation triggered by exogenous factors, to become excessive, with bouts of production of membrane attack complex capable of destroying normal red cells. Interestingly, in both PNH and aHUS hemolysis is complement-mediated.

GENERAL CLINICAL AND LABORATORY FEATURES

The clinical presentation of a patient with anemia is greatly influenced in the first place by whether the onset is abrupt or gradual and HAs are no exception. A patient with autoimmune HA or with favism may be a medical emergency, whereas a patient with mild hereditary spherocytosis (HS) or with cold agglutinin disease (CAD) may be diagnosed after years. This is due in large measure to the remarkable ability of the body to adapt to anemia when it is slowly progressing **(Chap. 63)**.

What differentiates HAs from other anemias is that the patient has signs and symptoms arising directly from hemolysis **(Table 100-2)**. At the clinical level, the main sign is *jaundice*; in addition, the patient may report discoloration of the urine. In many cases of HA, the spleen is enlarged because it is a preferential site of hemolysis; and in some cases, the liver may be enlarged as well. In all severe congenital forms of HA, there may also be skeletal changes due to overactivity of the bone marrow: they are never as severe as in thalassemia major because there is less ineffective erythropoiesis, or none at all.

The laboratory features of HA are related to (i) hemolysis per se, and (ii) the erythropoietic response of the bone marrow. In most cases hemolysis is largely extravascular, and it produces an increase in unconjugated bilirubin and aspartate aminotransferase (AST) in the serum; urobilinogen will be increased in both urine and stool. If hemolysis is mainly intravascular, the telltale sign is hemoglobinuria (often associated with hemosiderinuria); in the serum there is free hemoglobin, lactate dehydrogenase (LDH) is increased, and haptoglobin is reduced. In contrast, the serum bilirubin level may be normal

TABLE 100-2 Features Common to Most Patients with a Hemolytic Disorder

General examination	Jaundice, pallor
Other physical findings	Spleen may be enlarged; bossing of skull in severe congenital cases
Hemoglobin level	From normal to severely reduced
MCV, MCH	Usually increased
Reticulocytes	Usually increased
Bilirubin	Almost always increased (mostly unconjugated)
LDH	Increased (up to 10× normal with intravascular hemolysis)
Haptoglobin	Reduced to absent if hemolysis is at least in part intravascular

Abbreviations: LDH, lactate dehydrogenase; MCH, mean corpuscular hemoglobin; MCV, mean corpuscular volume.

or only mildly elevated. The main sign of the erythropoietic response by the bone marrow is an increase in reticulocytes (a test all too often neglected in the initial workup of a patient with anemia). Usually the increase will be reflected in both the percentage of reticulocytes (the more commonly quoted figure) and in the absolute reticulocyte count (the more definitive parameter). The increased number of reticulocytes is associated with an increased mean corpuscular volume (MCV) in the blood count. On the blood smear, this is reflected in the presence of macrocytes; there is also polychromasia, and sometimes one sees nucleated red cells. In most cases, a bone marrow aspirate is not necessary in the diagnostic workup; if it is done, it will show erythroid hyperplasia. In practice, once an HA is suspected, specific tests will usually be required for a definitive diagnosis of a specific type of HA.

GENERAL PATHOPHYSIOLOGY

The mature red cell is the product of a developmental pathway that brings the phenomenon of differentiation to an extreme. An orderly sequence of events produces synchronous changes, whereby the gradual accumulation of a huge amount of hemoglobin in the cytoplasm (to a final level of 340 g/L, i.e., about 5 m*M*) goes hand in hand with the gradual loss of cellular organelles and of biosynthetic abilities. In the end, the erythroid cell undergoes a process that has features of apoptosis, including nuclear pyknosis and eventually extrusion of the nucleus. However, the final result is more altruistic than suicidal; the cytoplasmic body, instead of disintegrating, is now able to provide oxygen to all cells in the human organism for some remaining 120 days of the red cell life span.

As a result of this unique process of differentiation and maturation, intermediary metabolism is drastically curtailed in mature red cells **(Fig. 100-1)**; for instance, cytochrome-mediated oxidative phosphorylation has been lost with the loss of mitochondria (through a process of physiologic autophagy); therefore, there is no backup to anaerobic glycolysis, which in the red cell is the only provider of adenosine triphosphate (ATP). Also, the capacity of making protein has been lost with the loss of ribosomes. This places the cell's limited metabolic apparatus at risk, because if any protein component deteriorates, it cannot be replaced, as it would be in most other cells; and in fact, the activity of most enzymes gradually decreases as red cells age. At the same time, during their long time in circulation, various red cell components inevitably accumulate damage and become physically denser. The anion exchanger known as band 3 is the most abundant protein in the red cell membrane (Fig. 100-2 and Table 100-3), with about 1.2 million molecules per red cell. As red cells age and become denser, probability is increased that a region of the band 3 molecule becomes exposed on the cell surface and contributes to creating an antigenic site recognizable by low-avidity naturally occurring anti-band 3 IgG antibodies. This process might be enhanced by the clustering of band 3 molecules favored by the antibody itself and by the binding of hemichromes arising from hemoglobin degradation. Senescent red cells thus become opsonized, and this is the signal for phagocytosis by macrophages in the spleen, in the liver, and elsewhere. This process may become accelerated in various ways in HA.

Another consequence of the relative simplicity of red cells is that they have a limited range of ways to manifest distress under hardship; in essence, any sort of metabolic failure will eventually lead either to structural damage to the membrane or to failure of the cation pump. In either case, the life span of the red cell is reduced, which is the definition of a *hemolytic disorder*. If the rate of red cell destruction exceeds the capacity of the bone marrow to produce more red cells, the hemolytic disorder will manifest as HA.

Thus, the essential pathophysiologic process common to all HAs is an increased red cell turnover; in many HAs, this is due at least in part to an acceleration of the senescence process described above. The gold standard for proving that the life span of red cells is reduced (compared to the normal value of about 120 days) is a *red cell survival* study, which can be carried out by labeling the red cells with ^{51}Cr and measuring the fall in radioactivity over several days or weeks (this classic test can now be replaced by a methodology using the nonradioactive isotope ^{15}N). If the hemolytic event is transient, it does not usually cause any long-term

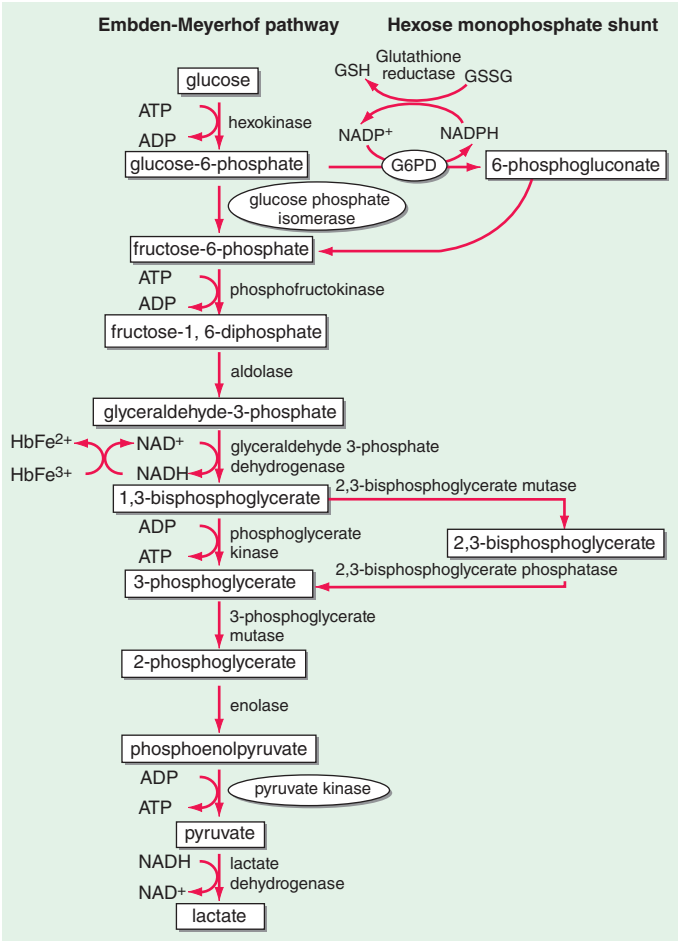

FIGURE 100-1 Red blood cell (RBC) metabolism. The Embden-Meyerhof pathway (glycolysis) generates ATP required for cation transport and for membrane maintenance. The generation of NADH maintains hemoglobin iron in a reduced state. The hexose monophosphate shunt generates NADPH that is used to reduce glutathione, which protects the red cell against oxidant stress; the 6-phosphogluconate, after decarboxylation, can be recycled via pentose sugars to glycolysis. Regulation of the 2,3-bisphosphoglycerate level is a critical determinant of oxygen affinity of hemoglobin. Enzyme deficiency states in order of prevalence: glucose-6-phosphate dehydrogenase (G6PD) > pyruvate kinase > glucose-6-phosphate isomerase > rare deficiencies of other enzymes in the pathway. The more common enzyme deficiencies are encircled.

consequences, except for an increased requirement for erythropoietic factors, particularly folic acid. However, if hemolysis is recurrent or persistent, the increased bilirubin production favors the formation of gallstones. If a considerable proportion of hemolysis takes place in the spleen, as is often the case, splenomegaly may become increasingly a feature, and hypersplenism may develop, with consequent neutropenia and/or thrombocytopenia.

The increased red cell turnover has important consequences. In normal subjects, the iron from effete red cells is very efficiently recycled by the body; however, with chronic intravascular hemolysis, the persistent hemoglobinuria will cause considerable iron loss, needing replacement. With chronic extravascular hemolysis, the opposite problem, iron overload, is more common, especially if the patient needs frequent blood transfusions. Even without blood transfusion, when erythropoiesis is massively increased, the release of erythroferrone from erythroid cells suppresses hepcidin, causing increased iron absorption. In the long run, in the absence of iron-chelation therapy, iron overload will cause secondary hemochromatosis; this will cause damage particularly to the liver, eventually leading to cirrhosis; and to the heart muscle, eventually causing heart failure.

Compensated Hemolysis versus Hemolytic Anemia Red cell destruction is a potent stimulus for erythropoiesis, which is mediated

by erythropoietin (EPO) produced by the kidney. This mechanism is so effective that in many cases the increased output of red cells from the bone marrow can fully balance an increased destruction of red cells. In such cases, we say that hemolysis is *compensated*. The pathophysiology of compensated hemolysis is similar to what we have just described, except there is no anemia. This notion is important from the diagnostic point of view, because a patient with a hemolytic condition, even an inherited one, may present without anemia; and it is also important from the point of view of management because compensated hemolysis may become "decompensated," i.e., anemia may suddenly appear in certain circumstances, for instance in pregnancy, folate deficiency, or renal failure interfering with adequate EPO production. Another general feature of chronic HAs is seen when any intercurrent condition, such as an acute infection, depresses erythropoiesis. When this happens, in view of the increased rate of red cell turnover, the effect will be predictably much more marked than in a person who does not have hemolysis. The most dramatic example is infection by parvovirus B19, which may cause a rather precipitous fall in hemoglobin—an occurrence sometimes referred to as *aplastic crisis*.

INHERITED HEMOLYTIC ANEMIAS

The red cell has three essential components: (1) hemoglobin, (2) the membrane-cytoskeleton complex, and (3) the metabolic machinery necessary to keep hemoglobin and the membrane-cytoskeleton complex in working order. Diseases caused by inherited abnormalities of hemoglobin, or hemoglobinopathies, are covered in **Chap. 98**. Here we will deal with diseases of the other two components.

Hemolytic Anemias due to Abnormalities of the Membrane-Cytoskeleton Complex The detailed architecture of the red cell membrane is complex, but its basic design is relatively simple **(Fig. 100-2)**. The lipid bilayer incorporates phospholipids and cholesterol, and it is spanned by a number of proteins that have their hydrophobic transmembrane domain(s) embedded in the membrane; most of these proteins also extend to both the outside (extracellular domains) and the inside of the cell (cytoplasmic domains). Other proteins are tethered to the membrane through a glycosylphosphatidylinositol (GPI) anchor; these have only an extracellular domain. Membrane proteins include energy-dependent ion transporters, ion channels, receptors for complement components, and receptors for other ligands. The most abundant red cell membrane proteins are glycophorins and the so-called band 3, an anion transporter that is an integral membrane protein. The extracellular domains of many of these proteins are heavily glycosylated, and they carry antigenic determinants that correspond to blood groups. Underneath the membrane, and tangential to it, is a network of other proteins that make up the cytoskeleton. The main cytoskeletal protein is the spectrin tetramer, consisting of a head-to-head association of two α-spectrin-β-spectrin heterodimers. The cytoskeleton is linked to the membrane through the *ankyrin complex* (that includes also band 4.2) and the *junctional complex* (that includes adducin and band 4.1) (Fig. 100-2). These multiprotein complexes make membrane and cytoskeleton intimately connected to each other, thus supporting membrane stability and at the same time providing the erythrocyte with the important property of deformability.

The membrane-cytoskeleton complex has essentially three functions: It is an envelope for the red cell cytoplasm; it maintains the normal red cell shape; it provides cross-membrane transport of electrolytes and of metabolites such as glucose and amino acids. In the membrane-cytoskeleton complex, the individual components are so intimately associated with each other that an abnormality of almost any of them will be disturbing or disruptive, causing mechanical instability of the membrane and/or reduced red cell deformability, ultimately causing hemolysis. These abnormalities are almost invariably inherited mutations; thus diseases of the membrane-cytoskeleton complex belong to the category of inherited HAs. Before the red cells lyse, they often exhibit more or less specific changes that alter the normal biconcave disk shape. Thus, the majority of the diseases in this group have been known for over a century as hereditary spherocytosis (HS) and hereditary elliptocytosis (HE). More recently a third morphologic entity, whereby on a blood smear the round-shaped central pallor of a red cell is replaced by a linear-shaped central pale area, has earned the name *stomatocytosis*: because this abnormal shape is related to abnormalities of channel molecules, the underlying disorders are also referred to as channelopathies. From an understanding of the molecular basis of these disorders, it has emerged **(Table 100-3)** that, although these disorders are predominantly monogenic, no one-to-one correlation exists between a certain gene and a certain disorder. Rather, what has been regarded as a single disorder (e.g., HS) can arise through mutation of one of several genes; conversely, what have been regarded as different disorders can arise through different mutations of the very same gene **(Fig. 100-3)**.

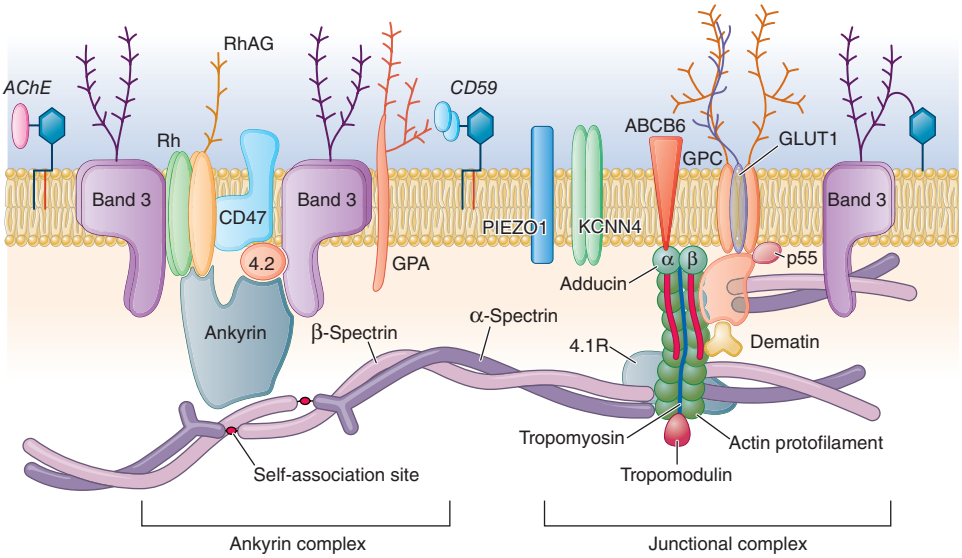

FIGURE 100-2 The red cell membrane and cytoskeleton. Within the membrane lipid bilayer several integral membrane proteins are shown: band 3 (anion exchanger 1 [AE1]) is the most abundant. *PIEZO1* is a mechanoreceptor, *KCNN4*, a Ca^{2+} activated K^+ channel, and *ABCB6* is an ion channel: they are important in the regulation of the red cell volume. Other proteins, e.g., acetylcholinesterase (AChE) and the two complement-regulatory proteins CD59 and CD55, are tethered to the membrane through the glycosylphosphatidylinositol (GPI) anchor: in these cases the entire polypeptide chain is extracellular. Many of the membrane proteins bear polypeptide and/or carbohydrate red cell antigens. Underneath the membrane, the α–β spectrin dimers, that associate head-to-head into tetramers, together with actin and other proteins, form most of the cytoskeleton. The *ankyrin complex*, that also involves the band 4.2 protein, and the *junctional complex*, that involves the band 4.1 protein and dematin, connect the membrane to the cytoskeleton. The ankyrin complex provides mainly radial (also called vertical) connections; the junctional complex provides mainly tangential (also called horizontal) connections: pathogenic changes in the former can cause spherocytosis, whereas pathogenic changes in the latter can cause elliptocytosis; pathogenic changes in spectrin can cause either. Branched lines symbolize carbohydrate moiety of proteins. The various molecules are obviously not drawn to the same scale. Additional explanations are found in the text. *(Reproduced with permission from N Young et al: Clinical Hematology. Philadelphia, Elsevier, 2006.)*

HEREDITARY SPHEROCYTOSIS This is most common among this group of HAs, with an estimated prevalence of 1:2000–1:5000 in populations of European ancestry. Its identification is credited to Minkowksy and Chauffard, who, at the end of the nineteenth century, reported families who had spherocytes in their peripheral blood **(Fig. 100-4*A*)**. In vitro studies revealed that the red cells were abnormally susceptible to lysis in hypotonic media; indeed, the presence of

TABLE 100-3 Inherited Diseases of the Red Cell Membrane-Cytoskeleton Complex

GENE	CHROMOSOMAL LOCATION	PROTEIN PRODUCED	DISEASE(S) WITH CERTAIN MUTATIONS (INHERITANCE)	COMMENTS
SPTA1	1q22-q23	α-Spectrin	HS (recessive) HE (dominant)	Rare Mutations of this gene account for about 65% of HE. More severe forms may be due to coexistence of an otherwise silent mutant allele.
SPTB	14q23-q24.1	β-Spectrin	HS (dominant) HE (dominant)	Rare Mutations of this gene account for about 30% of HE, including some severe forms.
ANK1	8p11.2	Ankyrin	HS (dominant)	May account for majority of HS.
SLC4A1	17q21	Band 3; also known as AE (anion exchanger) or AE1	HS (dominant) Southeast Asia ovalocytosis (dominant) Stomatocytosis (cryohydrocytosis)	Mutations of this gene may account for about 25% of HS. Polymorphic mutation (deletion of nine amino acids); in heterozygotes clinically asymptomatic and protective against *Plasmodium falciparum.* Certain specific missense mutations shift protein function from anion exchanger to cation conductance.
EPB41	1p33-p34.2	Band 4.1	HE (dominant)	Mutations of this gene account for about 5% of HE, mostly with prominent morphology but little/no hemolysis in heterozygotes; severe hemolysis in homozygotes.
EPB42	15q15-q21	Band 4.2	HS (recessive)	Mutations of this gene account for about 3% of HS.
RHAG	6p21.1-p11	Rhesus-associated glycoprotein	Chronic nonspherocytic hemolytic anemia (recessive)	Very rare; associated with total loss of all Rh antigens. One specific mutation in this gene entails loss of stomatin from the cell membrane, causing overhydrated stomatocytosis.
PIEZO1	16q23-q24	PIEZO1 (mechanosensitive ion channel component 1 channel)	Dehydrated hereditary stomatocytosis (dominant)	Also known as xerocytosis with pseudohyperkalemia. Patients may present with perinatal edema.
KCNN4	19q13.31	KCNN4 Intermediate conductance calcium-activated potassium channel protein 4 (Gardos channel)	Dehydrated hereditary stomatocytosis (dominant)	Clinical presentation similar to that of *PIEZO1* mutants.
ABCB6	2q35-q36	ATP-binding cassette subfamily B member 6	Familial pseudohyperkalemia (dominant)	Increased potassium leakage upon storage in blood bank condition: this can cause hyperkalemia in the recipient. ABCB6 mutation is present in 0.3% of blood donors.
SLC2A1	1p34.2	GLUT1 glucose transporter	Overhydrated hereditary stomatocytosis	Associated with serious neurological manifestations.

Note: PIEZO1, KCNN4, ABCB6, and *GLUT1* are channel molecules; conditions associated with mutations in the respective genes are appropriately named channelopathies.
Abbreviations: HE, hereditary elliptocytosis; HS, hereditary spherocytosis.

osmotic fragility became the main diagnostic test for HS. Today we know that HS, thus defined, is genetically heterogeneous; i.e., it can arise from a variety of mutations in one of several genes (Table 100-3). It has been also recognized that the inheritance of HS is not always autosomal dominant (with the patient being heterozygous); indeed, some of the most severe forms are instead autosomal recessive (with the patient being homozygous).

Clinical Presentation and Diagnosis The spectrum of clinical severity of HS is broad. Severe cases may present in infancy with severe anemia, whereas mild cases may present in young adults or even later in life. The main clinical findings are jaundice, an enlarged spleen, and often gallstones; indeed, it may be the finding of gallstones in a young person that triggers diagnostic investigations.

The variability in clinical manifestations that is observed among patients with HS is largely due to the different underlying molecular lesions (Table 100-3). Not only are mutations of several genes involved, even different mutations of the same gene can give very different clinical manifestations. In milder cases, hemolysis is often compensated (see above), but changes in clinical expression may be seen even in the same patient because intercurrent conditions (e.g., pregnancy, infection) may cause decompensation. The anemia is usually normocytic with the characteristic morphology that gives the disease its name. An increased mean corpuscular hemoglobin concentration (MCHC >34) and increased red cell distribution width (RDW >14%) associated with normal or slightly decreased MCV on an ordinary blood count report should raise the suspicion of HS. The spleen plays a key role in HS through a dual mechanism. On one hand, like in many other HAs, the spleen itself is a major site of destruction; on the other hand, because the red cells in HS are less deformable, transit through the splenic circulation makes them more prone to vesiculate, thus accelerating their demise.

When there is a family history, it is usually easy to make a diagnosis based on features of HA and typical red cell morphology. However, family history may be negative for at least two reasons. First, the patient may have a de novo mutation, i.e., a mutation that has taken place in a germ cell of one of the patient's parents or early after zygote formation. Second, the patient may have a recessive form of HS (Table 100-3). In such cases, more extensive laboratory investigations are required, including osmotic fragility, the acid glycerol lysis test, the eosin-5'-maleimide (EMA)–binding test, and SDS-gel electrophoresis of membrane proteins; these tests are usually carried out in laboratories with special expertise in this area. Sometimes a definitive diagnosis can be obtained only by molecular studies demonstrating a mutation in one of the genes underlying HS (Table 100-3).

TREATMENT

Hereditary Spherocytosis

We do not have a causal treatment for HS; i.e., no way has yet been found to correct the basic defect in the membrane-cytoskeleton structure. Given the special role of the spleen in HS (see above),

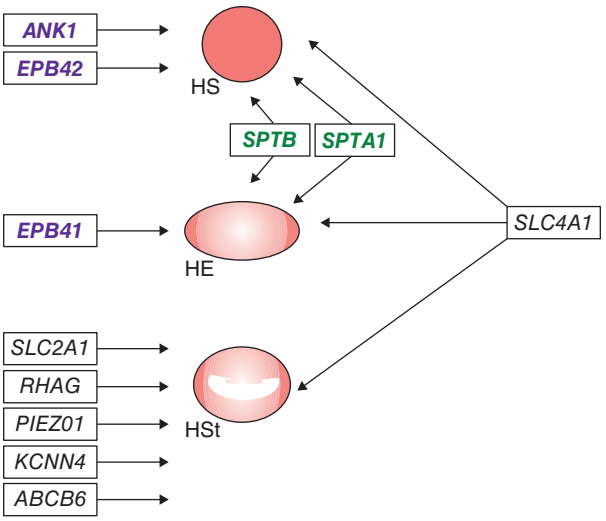

FIGURE 100-3 Hereditary spherocytosis (HS), hereditary elliptocytosis (HE), and hereditary stomatocytosis (HSt) are three morphologically distinct forms of congenital hemolytic anemia. It has emerged that each one can arise from mutation of one of several genes and that different mutations of the same gene can give one or another form. (See also Table 100-3.) Genes encoding membrane proteins are in *black*; genes encoding cytoskeleton proteins are in *green*; genes encoding proteins in the junctional and ankyrin complexes are in *purple*.

splenectomy is often beneficial. Current recommendations are to proceed with splenectomy at the age of 4–6 years in severe cases, to delay splenectomy until puberty in moderate cases, and to avoid splenectomy in mild cases. Partial splenectomy can be considered in certain cases; and it is helpful to know about the outcome of splenectomy in the patient's affected relatives. Before splenectomy, vaccination against encapsulated bacteria (*Neisseria meningitidis* and *Streptococcus pneumonia)* is imperative; penicillin prophylaxis after splenectomy is controversial. Along with splenectomy, cholecystectomy should not be carried out automatically; but it should be carried out, usually by the laparoscopic approach, whenever it is clinically indicated.

HEREDITARY ELLIPTOCYTOSIS HE is at least as heterogeneous as HS, both from the genetic point of view (Table 100-3, Fig. 100-3) and from the clinical point of view. The global incidence of HE is 1:2000–4000 subjects. Again, it is the shape of the red cells **(Fig. 100-4*B*)** that gives the name to the condition, but there is no direct correlation between the elliptocytic morphology and clinical severity. In fact, some mild or even asymptomatic cases may have nearly 100% elliptocytes (or ovalocytes). Indeed, the diagnosis of HE is generally incidental, because hemolysis may be compensated and there may be no anemia, although this may become evident in the course of infection. One particular in-frame deletion of nine amino acids in the *SLC4A1* gene encoding band 3 underlies the so-called Southeast Asia ovalocytosis (SAO): it is not a disease, but rather a polymorphism with a frequency of up to 5–7% in certain populations (e.g., Papua New Guinea, Indonesia, Malaysia, Philippines), presumably as a result of malaria selection; it is asymptomatic in heterozygotes and probably lethal in homozygotes. The cases of HE with the most severe HA are those with biallelic mutations of one of the genes involved (see Fig. 100-3), and these are said to have pyropoikilocytosis (HPP): here the instability of the cytoskeleton protein network may result from decreased tetramerization of spectrin dimers. The red cell volume is decreased (MCV: 50–60 fL), and all kinds of bizarre poikilocytes are seen on the blood smear **(Fig. 100-4*C*)**. HPP patients have splenomegaly and often benefit from splenectomy.

Channelopathies These rare conditions (see Fig. 100-3) are characterized by abnormalities in red cell ion content and alteration of erythrocyte volume. Cation leak can cause hyperkalemia; in some cases, this leak is accelerated in the cold (the resulting spuriously high serum K^+ is then referred to as pseudo-hyperkalemia). The less rare form, dehydrated stomatocytosis (DHS; also referred to as xerocytosis) is a (usually compensated) macrocytic hemolytic disorder, with increased MCHC (generally higher than 36 g/dL) associated with mild jaundice. Mutations in either *PIEZO1*, encoding an ion channel activated by

FIGURE 100-4 Peripheral blood smear from patients with membrane-cytoskeleton abnormalities. *A.* Hereditary spherocytosis. ***B.*** Hereditary elliptocytosis, heterozygote. ***C.*** Pyropoikilocytosis, with both alleles of the α-spectrin gene mutated.

pressure (mechanoreceptor), or in *KCCN4*, encoding the Ca^{2+} activated K^+ channel (Gardos channel) have been recognized to cause DHS (see Table 100-3).

Another form is overhydrated stomatocytosis (OHS): this too is macrocytic (MCV >110 fL), but the MCHC is low (<30 g/dL). The underlying mutation is in the Rhesus gene *RHAG*, which encodes an ammonia channel. Yet other patients with stomatocytosis (Table 100-3) have mutations in *SLC4A1* (encoding band 3) and *SLC2A1* (encoding the glucose transporter GLUT1). Mutations of the latter are responsible for *cryohydrocytosis*, a channelopathy in which the red cells swell and burst when they are cooled. In vivo hemolysis can vary from relatively mild to quite severe. Familial hyperkalemia has been recently linked to mutations in *ABCB6*, resulting in abnormal cation leak with extracellular release of a large amount of K+ (hyperkaliemia). Mutations in *ABCB6* have been identified in almost 0.3% of blood donors. However, splenectomy is contraindicated in stomatocytosis due to the significant proportion of severe thromboembolic complications observed in splenectomized DHS patients.

A specialized technique to measure erythrocyte deformability through laser diffraction analysis is *ektacytometry*: this has been used extensively in order to investigate membrane-cytoskeleton abnormalities. For diagnostic purposes, systematic sequencing of a panel of genes in patients' DNA is a powerful approach already in use and destined to be used increasingly.

Enzyme Abnormalities When an important defect in a component of the membrane-cytoskeleton complex is present, hemolysis is a direct consequence of the fact that the very structure of the red cell is compromised. Instead, when one of the enzymes is defective, the consequences will depend on the precise role of that enzyme in the metabolic machinery of the red cell. This machinery has two main functions: (1) to provide energy in the form of ATP, and (2) to prevent oxidative damage to hemoglobin and to other proteins by providing sufficient reductive potential; the key molecule for this is NADPH.

ABNORMALITIES OF THE GLYCOLYTIC PATHWAY Because red cells, in the course of their differentiation, have sacrificed not only their nucleus and their ribosomes but also their mitochondria, they rely exclusively on the anaerobic portion of the glycolytic pathway for producing ATP, most of which is required by the red cell for cation transport against a concentration gradient across the membrane. If this fails due to a defect of any of the enzymes of the glycolytic pathway **(Table 100-4)**, the result will be hemolytic disease.

Pyruvate Kinase Deficiency Abnormalities of the glycolytic pathway are all inherited and all rare. Among them, deficiency of pyruvate kinase (PK) is the least rare, with an estimated prevalence in most populations of 1:10,000. However, recently, a polymorphic PK mutation (E277K) was found in some African populations with heterozygote frequencies of 1–7%, suggesting that this may be another malaria-related polymorphism. HA secondary to PK deficiency is an autosomal recessive disease **(Fig. 100-5)**.

The clinical picture of homozygous (or biallelic) PK deficiency is that of an HA that often presents in the newborn with neonatal jaundice, requiring nearly always phototherapy and frequently exchange transfusion; the jaundice persists, and it is often associated with reticulocytosis. The anemia is of variable severity; sometimes it is so severe as to require regular blood transfusion treatment, whereas sometimes it is mild, bordering on a nearly compensated hemolytic disorder. As a result, the diagnosis may be delayed: in some cases, it is made, for instance, in a young woman during her first pregnancy, when the anemia may get worse. The delay in diagnosis may be caused in part by the fact that the anemia is often remarkably well tolerated because

TABLE 100-4 Red Cell Enzyme Abnormalities Causing Hemolysis

	ENZYME (ACRONYM)	GENE SYMBOL; CHROMOSOMAL LOCATION	PREVALENCE OF ENZYME DEFICIENCY (RANK)	CLINICAL MANIFESTATIONS EXTRA-RED CELL	COMMENTS
Glycolytic Pathway					
	Hexokinase (HK)	*HK1*; 10q22	Very rare		May benefit from splenectomy; BMT[c]
	Glucose 6-phosphate isomerase (G6PI)	*GPI*; 19q31.1	Rare (4); at least 60 cases reported[a]	NM, CNS	May benefit from splenectomy
	Phosphofructokinase (PFK)[b]	*PFKM*; 12q13	Very rare	Myopathy; myoglobinuria	
	Aldolase	*ALDOA*; 16q22-24	Very rare	Myopathy	
	Triose phosphate isomerase (TPI)	*TPI1*; 12p13.31	Very rare	CNS (severe), NM	
	Glyceraldehyde 3-phosphate dehydrogenase (GAPD)	*GAPDH*; 12p13.31	Very rare	Myopathy	
	Bisphosphoglycerate mutase (BPGM)	*BPGM*; 7q33	Very rare		Erythrocytosis rather than hemolysis; some of the rare mutations are in the enzyme active site
	Phosphoglycerate kinase (PGK)	*PGK1*; Xq21.1	Very rare	CNS, NM	May benefit from splenectomy; BMT[c]
	Pyruvate kinase (PK)	*PKLR*; 1q22	Rare (2)[a]		May benefit from splenectomy; BMT[c]
Redox					
	Glucose 6-phosphate dehydrogenase (G6PD)	*G6PD*; Xq28	Common (1)[a]	Very rarely granulocytes	In almost all cases, only AHA from exogenous trigger
	Glutathione synthase	*GSS*; 20q11.22	Very rare	CNS	
	Glutathione reductase	*GSR;* 8p12	Very rare	Cataracts	AHA from exogenous trigger (favism)
	γ-Glutamylcysteine synthase	*GCLC*; 6p12.1	Very rare	CNS	Mutations affect catalytic subunit
	Cytochrome b5 reductase	*CYB5R3*; 22q13.2	Rare	CNS	Methemoglobinemia rather than hemolysis
Nucleotide Metabolism					
	Adenylate kinase (AK)	*AK1*; 9q34.11	Very rare	CNS	May benefit from splenectomy
	Pyrimidine 5′ nucleotidase (P5N)	*NTSC3A*; 7p14.3	Rare (3)[a]		May benefit from splenectomy

[a]The numbers from (1) to (4) indicate the ranking order of these enzymopathies in terms of frequency. [b]PFK deficiency is associated with increased glycogen in muscle, and it is also known as glycogen storage disease type VII or Tarui's disease. [c]Occasional report of successful treatment of the hematologic manifestations by BMT.

Abbreviations: AHA, acquired hemolytic anemia; BMT, bone marrow transplantation; CNS, central nervous system; NM, neuromuscular.

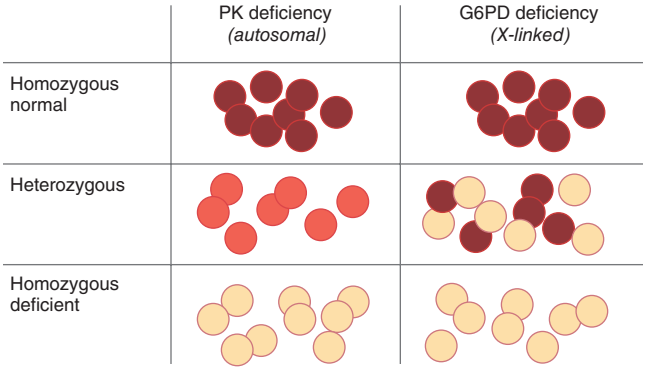

FIGURE 100-5 Different phenotypes of heterozygotes for red cell enzymopathies. In a heterozygote for deficiency of PK, encoded by an autosomal gene (see Table 100-4), the level of enzyme is about one-half of normal in all red cells. Because this level of enzyme is sufficient, there are no clinical consequences, i.e., PK deficiency is recessive. In a heterozygote for deficiency of G6PD, encoded by an X-linked gene, the situation is quite different: X-chromosome inactivation generates red cell mosaicism, whereby some red cells are entirely normal and others are G6PD deficient. Therefore, G6PD deficiency is expressed in heterozygotes: it is not recessive.

the metabolic block at the last step in glycolysis causes an increase in 2,3-bisphosphoglycerate (or DPG; Fig. 100-1), a major effector of the hemoglobin-oxygen dissociation curve; thus the oxygen delivery to the tissues is enhanced, a remarkable compensatory feat.

TREATMENT

Pyruvate Kinase Deficiency

The management of PK deficiency is mainly supportive. In view of the marked increase in red cell turnover, oral folic acid supplements should be given constantly. Blood transfusion should be used as necessary, and iron chelation may be required even in some patients who, though not receiving blood transfusion, may be developing iron overload (see "General Pathophysiology" above). About one-half of patients sooner or later undergo splenectomy, which usually provides a modest but significant increase in hemoglobin (paradoxically, often reticulocytes also increase considerably). Cholecystectomy may also be required. Some patients with severe disease have received bone marrow transplantation (BMT) from an HLA-identical PK-normal sibling. Prenatal diagnosis has been carried out in a mother who had already had an affected child. A clinical trial of a small molecule that is a specific PK ligand and may increase the stability and/or catalytic efficiency of mutant PK is currently ongoing. Rescue of inherited PK deficiency through lentiviral-mediated human PK gene transfer has been successful in mice. An oral small molecule allosteric activator of PK called *mitapivat* raised hemoglobin levels in about half of PK deficient patients in a small phase 2 study.

Other Glycolytic Enzyme Abnormalities All of these defects are rare to very rare (Table 100-4), and most of them cause HA with varying degrees of severity. It is not unusual for the presentation to be in the guise of severe neonatal jaundice, which may require exchange transfusion; if the anemia is less severe, it may present later in life, or it may even remain asymptomatic and be detected incidentally when a blood count is done for unrelated reasons. The spleen is often enlarged. When other systemic manifestations occur, they can involve the central nervous system (sometimes entailing severe mental retardation, particularly in the case of triose phosphate isomerase deficiency), the neuromuscular system, or both (see Table 100-4). This is not altogether surprising if we consider that these are housekeeping genes, i.e., expressed in all tissues. The diagnosis of HA is usually not difficult, thanks to the triad of normo-macrocytic anemia, reticulocytosis, and hyperbilirubinemia. Enzymopathies should be considered in the differential diagnosis of any chronic Coombs-negative HA. Unlike with membrane disorders, in most cases of glycolytic enzymopathies, morphologic abnormalities are conspicuous by their absence. A definitive diagnosis can be made only by demonstrating the deficiency of an individual enzyme by quantitative assays; these are carried out in only a few specialized laboratories. If a particular molecular abnormality is already known in the family, then one could test directly for that defect at the DNA level, thus bypassing the need for enzyme assays. Of course the time may be getting nearer when a patient will present with her or his exome already sequenced, and we will need to concentrate on which genes to look up within the file. The principles for the management of these conditions are similar as for PK deficiency. In isolated cases of glycolytic enzyme abnormalities, BMT has been carried out successfully, although unfortunately nonhematologic manifestations, if any, are not reversed.

ABNORMALITIES OF REDOX METABOLISM • Glucose-6-phosphate Dehydrogenase (G6PD) Deficiency G6PD is a housekeeping enzyme critical in the redox metabolism of all aerobic cells (Fig. 100-1). In red cells, its role is even more critical because it is the only source of NADPH, which directly and via glutathione (GSH) defends these cells against oxidative stress **(Fig. 100-6)**. G6PD deficiency-related HA is a prime example of an HA due to interaction between an intracorpuscular cause and an extracorpuscular cause: indeed, in the vast majority of cases hemolysis is triggered by an exogenous agent. Although the G6PD activity is decreased in most tissues of G6PD-deficient subjects, in other cells the decrease is much less pronounced than in red cells, and it does not seem to impact on clinical expression.

GENETIC CONSIDERATIONS

The G6PD gene is X-linked, and this has important implications. First, because males have only one G6PD gene (i.e., they are hemizygous for this gene), they must be either normal or G6PD deficient. By contrast, females, who have two G6PD genes, can be either normal or deficient (homozygous) or intermediate (heterozygous). Second, as a result of the phenomenon of X chromosome inactivation, heterozygous females are genetic mosaics (see Fig. 100-5), with a highly variable ratio of G6PD-normal to G6PD-deficient cells and an equally variable degree of clinical expression; some heterozygotes can be just as affected as hemizygous males. The enzymatically active form of G6PD is either a dimer or a tetramer of a single protein subunit of 514 amino acids. G6PD-deficient subjects have been found invariably to have mutations in the coding region of the G6PD gene. Almost all of the 230 different mutations known are single missense point mutations, entailing single amino acid replacements in the G6PD protein. In most cases, these mutations cause G6PD deficiency by decreasing the in vivo stability of the protein; thus the physiologic decrease in G6PD activity that takes place with red cell aging is greatly accelerated. In some cases, an amino acid replacement can also affect the catalytic function of the enzyme.

Among these mutations, those underlying chronic nonspherocytic hemolytic anemia (CNSHA; see below) are a discrete subset. This much more severe clinical phenotype can be ascribed in some cases to adverse qualitative changes (for instance, a decreased affinity for the substrate glucose-6-phosphate) or simply to the fact that the enzyme deficit is more extreme because of a more severe instability of the enzyme. For instance, a cluster of mutations map at or near the dimer interface, and clearly they compromise severely the formation of the dimer.

Epidemiology G6PD deficiency is widely distributed in tropical and subtropical parts of the world (Africa, Southern Europe, the Middle East, Southeast Asia, and Oceania) **(Fig. 100-7)** and wherever people from those areas have migrated. A conservative estimate is that at least 500 million people have a G6PD deficiency gene. In several of these areas, the frequency of a G6PD deficiency gene may be as high as 20% or more. It would be quite extraordinary for a trait that causes significant pathology to spread widely and reach high frequencies in many populations without conferring some biologic advantage. Indeed, G6PD is one of the best-characterized examples of genetic polymorphisms in the human species. Clinical field studies and in

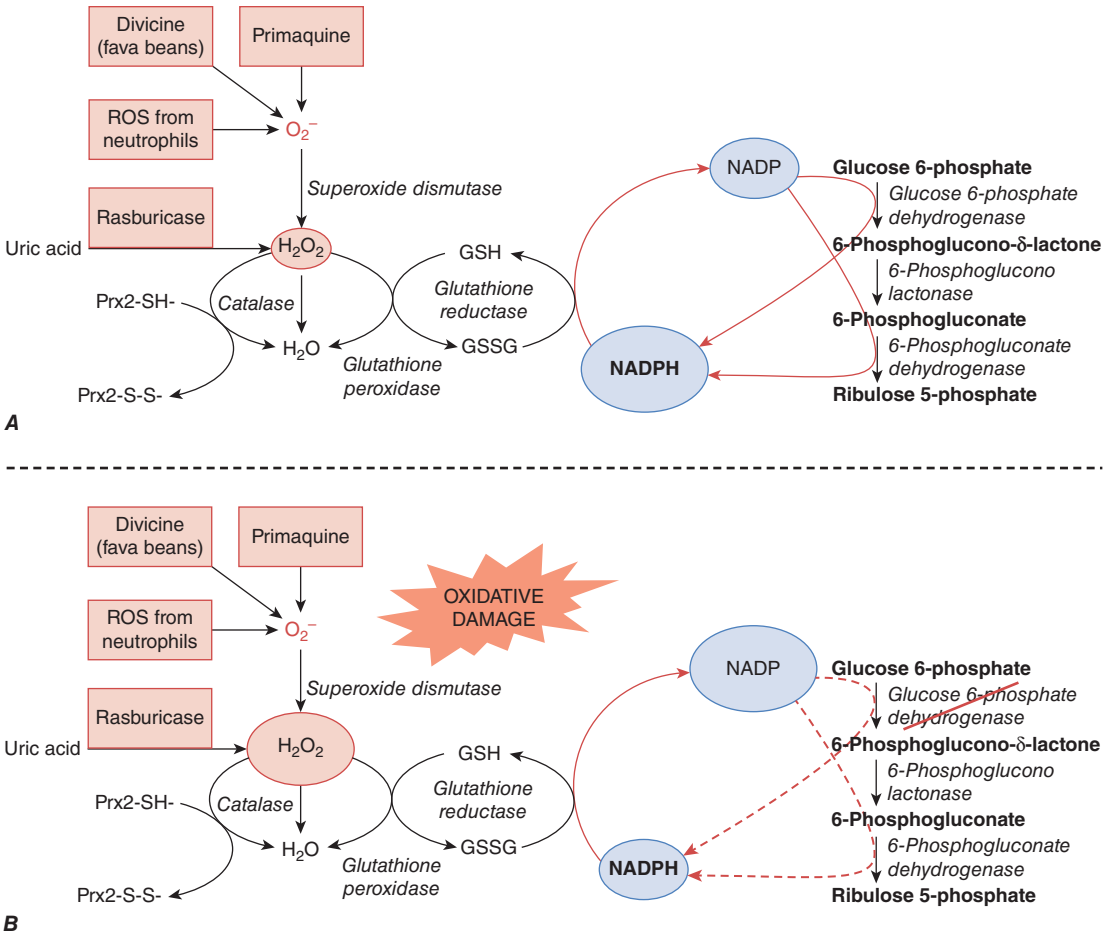

FIGURE 100-6 The role of G6PD in protecting red cells from oxidative damage. ***A.*** In G6PD-normal red cells, G6PD and 6-phosphogluconate dehydrogenase—two of the enzymes of the pentose phosphate pathway—provide ample supply of NADPH, which in turn regenerates GSH when this is oxidized by reactive oxygen species (e.g., O_2^- and H_2O_2). Thus when O_2^- (meant here to represent itself and other reactive oxygen species or ROS) is produced by pro-oxidant compounds such as primaquine, or the glucosides in fava beans (divicine), or the oxidative burst of neutrophils, these ROS are rapidly neutralized; similarly, when rasburicase administered to degrade uric acid produces an equimolar amount of hydrogen peroxide, this is rapidly degraded by the combined action of glutathione peroxidase, catalase, and Prx2 (peroxiredoxin-2: all three mechanisms are NADPH dependent). ***B.*** In G6PD-deficient red cells, where the enzyme activity is reduced, NADPH production is limited, and it may not be sufficient to cope with the excess ROS generated by pro-oxidant compounds, and the consequent excess hydrogen peroxide. This diagram also explains why a defect in glutathione reductase has very similar consequences to G6PD deficiency.

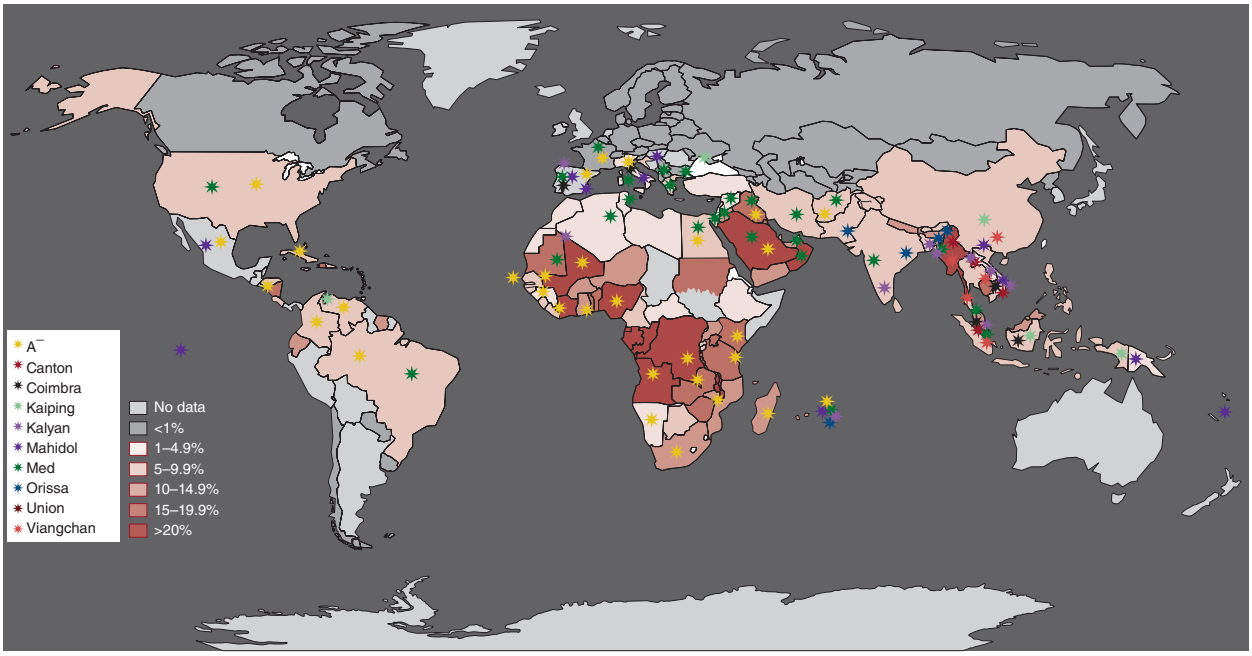

FIGURE 100-7 Epidemiology of G6PD deficiency throughout the world. Each country on the map is shaded in a color based on the best estimate of the mean frequency of G6PD deficiency allele(s) in that country (this is the same as the frequency of G6PD deficient males). The small panel on the left gives the key to color shadings corresponding to each country. The larger panel gives a color-coded list of ten common G6PD variants associated with G6PD deficiency: asterisk-shaped symbols in the corresponding colors are shown in the countries where these variants have been observed (for graphic reasons symbols could not be inserted in all countries). *(Republished with permission of American Society of Hematology, from Glucose-6-phosphate dehydrogenase deficiency, L Luzzatto et al. 136:1225, 2020 permission conveyed through Copyright Clearance Center, Inc.)*

vitro experiments strongly support the view that G6PD deficiency has been selected by *Plasmodium falciparum* malaria because it confers a relative resistance against this highly lethal infection. As in other cases of balanced polymorphism, it is heterozygotes, therefore females, who are protected. Different G6PD variants underlie G6PD deficiency in different parts of the world. Examples of widespread variants are G6PD Mediterranean on the shores of that sea, in the Middle East, and elsewhere; G6PD A– in Africa, in the Middle East, and in Southern Europe; G6PD Orissa in India; G6PD Viangchan and G6PD Mahidol in Southeast Asia; G6PD Kaiping and G6PD Canton in China; and G6PD Union worldwide. The heterogeneity of polymorphic G6PD variants is proof of their independent origin, further supporting the notion of selection by a common environmental agent, namely malaria, in keeping with the concept of convergent evolution (Fig. 100-7).

Clinical Manifestations The vast majority of people with G6PD deficiency remain clinically asymptomatic throughout their lifetime; however, all of them have an increased risk of developing neonatal jaundice (NNJ) and a risk of developing acute HA (AHA) when challenged by a number of oxidative agents. NNJ related to G6PD deficiency is rarely present at birth; the peak incidence of clinical onset is between day 2 and day 3, and in most cases the anemia is not severe. However, NNJ can be very severe in some G6PD-deficient babies, especially in association with prematurity, infection, and/or environmental factors (such as naphthalene-camphor balls, which may be used in babies' bedding and clothing); and the risk of severe NNJ is also increased by the coexistence of a monoallelic or biallelic mutation in the uridyl transferase gene (*UGT1A1*; the same mutations are associated with Gilbert's syndrome). It is imperative to manage promptly NNJ associated with G6PD deficiency, because it can produce kernicterus and permanent neurologic damage.

AHA can develop as a result of three types of triggers: (1) fava beans, (2) infections, and (3) drugs **(Table 100-5)**. Typically, a hemolytic attack starts with malaise, weakness, and abdominal or lumbar pain. Within a timeframe of several hours to 2–3 days, the patient develops jaundice and often dark urine. The onset can be extremely abrupt, especially with favism in children. The anemia is moderate to extremely severe, usually normocytic and normochromic, and due partly to intravascular hemolysis; hence, it is associated with hemoglobinemia, hemoglobinuria, high LDH, and low or absent plasma haptoglobin. The blood film shows anisocytosis, polychromasia, and spherocytes; in addition, the most typical feature of G6PD deficiency is the presence of bizarre poikilocytes, with red cells that appear to have unevenly distributed hemoglobin ("hemighosts") and red cells that appear to have had parts of them bitten away ("bite cells" or "blister cells") **(Fig. 100-8)**. A classical test, now rarely carried out, is supravital staining with methyl violet, which, if done promptly, reveals the presence of Heinz bodies (consisting of precipitates of denatured hemoglobin and hemichromes), which are regarded as a signature of oxidative damage to red cells (they are also seen with unstable hemoglobins). Since there is also a substantial component of extravascular hemolysis, unconjugated bilirubin is high and there is often clinical icterus. The most serious threat from AHA in adults is the development of acute renal failure (this is exceedingly rare in children). Once the threat of acute anemia is over and in the absence of comorbidity, full recovery from AHA associated with G6PD deficiency is the rule.

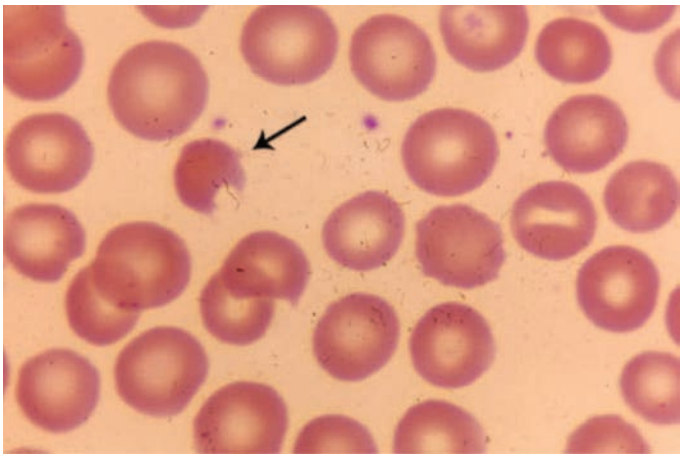

FIGURE 100-8 Peripheral blood smear from a glucose-6-phosphate dehydrogenase (G6PD)-deficient boy experiencing hemolysis. Note the red cells that are misshapen and called "bite" cells. *(From MA Lichtman et al: Lichtman's Atlas of Hematology: http://www.accessmedicine.com. Copyright © The McGraw-Hill Companies, Inc. All rights reserved.)*

It was primaquine (PQ)-induced AHA that led to the discovery of G6PD deficiency, but this drug has not been very prominent subsequently because it is not necessary for the treatment of life-threatening *P. falciparum* malaria. Today there is a revival in the use of PQ for two reasons. First, it is the only effective agent for eliminating the gametocytes of *P. falciparum* (thus preventing further transmission): a small single dose (0.25 mg/kg) is required, and it is safe for G6PD-deficient persons. Second, a 14-day course of PQ is needed for eliminating the hypnozoites of *Plasmodium vivax* (thus preventing endogenous relapse). In countries aiming to eliminate malaria, there may be a call for mass administration of PQ; this ought to be associated with G6PD testing. At the other end of the historic spectrum, the latest additions to the list of potentially hemolytic drugs (Table 100-5) are rasburicase and pegloticase; again G6PD testing ought to be made mandatory before giving either of these drugs, because fatal cases have been reported upon using one of these drugs, which generate hydrogen peroxide, in newborns with kidney injury and in adults with tumor lysis syndrome.

Although drug-induced AHA has been prominent in the study of G6PD deficiency, the most common clinical manifestations are in fact NNJ and favism, both of which are of public health importance in many populations. Contrary to beliefs that are still widespread, fava bean pollen inhalation does not cause favism, and other beans are safe.

A very small minority of subjects with G6PD deficiency have CNSHA of variable severity. The patient is nearly always a male, usually with a history of NNJ, who may present with anemia, unexplained jaundice, or gallstones later in life. The spleen may be enlarged. The severity of anemia ranges in different patients from borderline to transfusion dependent. The anemia is usually normo-macrocytic, with reticulocytosis. Bilirubin and LDH are increased. Although hemolysis is, by definition, chronic in these patients, they are also vulnerable to acute oxidative damage, and therefore the same agents that can cause AHA in people with the ordinary type of G6PD deficiency will cause

TABLE 100-5 Drugs That Carry Risk of Clinical Hemolysis in Persons with Glucose 6-Phosphate Dehydrogenase Deficiency

	DEFINITE RISK	POSSIBLE RISK	DOUBTFUL RISK
Antimalarials	Primaquine Dapsone/ chlorproguanil[a]	Chloroquine; hydroxychloroquine	Quinine
Sulphonamides/ sulphones	Dapsone	Sulfamethoxazole Sulfasalazine Sulfadimidine	Sulfisoxazole Sulfadiazine

severe exacerbations in people with CNSHA associated with G6PD deficiency. In some cases of CNSHA, the deficiency of G6PD is so severe in granulocytes that it limits their capacity to produce an oxidative burst, with consequent increased susceptibility to some bacterial infections.

Laboratory Diagnosis The suspicion of G6PD deficiency can be confirmed by semiquantitative methods often referred to as screening tests, which are suitable for population studies and can correctly classify male subjects, in the steady state, as G6PD normal or G6PD deficient. However, in clinical practice, a diagnostic test is usually needed when the patient has had a hemolytic attack: whereby the oldest, most G6PD-deficient red cells have been selectively destroyed, and young red cells, having higher G6PD activity, are being released into the circulation. Under these conditions, only a quantitative test can give a definitive result. In males, this test will identify normal hemizygotes and G6PD-deficient hemizygotes; among females, some heterozygotes will be missed, but those who are at most risk of hemolysis will be identified. Of course, G6PD deficiency also can be diagnosed by DNA testing. Currently easy-to-use "point of care" tests for G6PD deficiency are becoming available, geared especially to the prospect of mass administration of PQ or of the newly introduced derivative tafenoquine.

TREATMENT

G6PD Deficiency

The AHA of G6PD deficiency is largely preventable by avoiding exposure to triggering factors of previously screened subjects. Of course, the practicability and cost-effectiveness of screening depend on the prevalence of G6PD deficiency in each individual community. Favism is entirely preventable in G6PD-deficient subjects by not eating fava beans. Drug-induced hemolysis can be prevented by testing for G6PD deficiency before prescribing; in many cases one can use alternative drugs. When AHA develops and once its cause is recognized, no specific treatment is needed in most cases. However, if the anemia is severe, it may be a medical emergency, especially in children, requiring immediate action, including blood transfusion. This has been the case with an antimalarial drug combination containing dapsone (called Lapdap, introduced in 2003) that has caused severe acute hemolytic episodes in children with malaria in several African countries; after a few years, the drug was taken off the market. If there is acute renal failure, hemodialysis may be necessary, but if there is no previous kidney disease, recovery is the rule. The management of NNJ associated with G6PD deficiency is no different from that of NNJ due to other causes.

In cases with CNSHA, if the anemia is not severe, regular folic acid supplements and regular hematologic surveillance will suffice. It will be important to avoid exposure to potentially hemolytic drugs, and blood transfusion may be indicated when exacerbations occur, mostly in concomitance with intercurrent infection. In rare patients, regular blood transfusions may be required, in which case appropriate iron chelation should be instituted. Unlike in HS, there is no evidence of selective red cell destruction in the spleen; however, in practice, splenectomy has proven beneficial in severe cases.

Other Abnormalities of the Redox System As mentioned previously, GSH is a key player in the defense against oxidative stress. Inherited defects of GSH metabolism are exceedingly rare, but each one can give rise to chronic HA (Table 100-4). A rare, peculiar, and severe but usually self-limited HA occurring in the first month of life, called *infantile poikilocytosis*, may be associated with deficiency of glutathione peroxidase (GSHPX) due not to an inherited abnormality, but to transient nutritional deficiency of selenium, an element essential for the activity of GSHPX.

PYRIMIDINE 5'-NUCLEOTIDASE (P5N) DEFICIENCY P5N is a key enzyme in the catabolism of nucleotides arising from the degradation of nucleic acids that takes place in the final stages of erythroid cell maturation. How exactly its deficiency causes HA is not well understood, but a highly distinctive feature of this condition is a morphologic abnormality of the red cells known as *basophilic stippling*. The condition is rare, but it probably ranks third in frequency among red cell enzyme defects (after G6PD deficiency and PK deficiency). The anemia is lifelong, of variable severity, and may benefit from splenectomy.

Familial (Atypical) Hemolytic-Uremic Syndrome (aHUS) This term is used to designate a group of rare disorders, mostly affecting children, characterized by microangiopathic HA with presence of fragmented erythrocytes in the peripheral blood smear, thrombocytopenia (usually mild), and acute renal failure. (The word *atypical* in this phrase should be consigned to history: it was introduced originally to distinguish this condition from the hemolytic-uremic syndrome [HUS] caused by infection with *Escherichia coli* producing the Shiga toxin, regarded as *typical*.) The genetic basis of atypical HUS (aHUS) has been elucidated. Studies of >100 families have revealed that those family members who developed HUS had mutations in any one of several genes encoding complement regulatory proteins: complement factor H (*CFH*), CD46 or membrane cofactor protein (*MCP*), complement factor I (*CFI*), complement component C3, complement factor B (*CFB*), thrombomodulin, and others. Thus, whereas all other inherited HAs are due to intrinsic red cell abnormalities, this group is unique in that hemolysis results from an inherited defect external to red cells (Table 100-1). Because the regulation of the complement cascade has considerable redundancy, in the steady state any of the above abnormalities can be tolerated. However, when an intercurrent infection or some other trigger briskly activates complement the deficiency of one of the complement regulators becomes critical. Endothelial cells get damaged, especially in the kidney; at the same time, and partly as a result of this, there will be brisk hemolysis (thus, the more common Shiga toxin–related HUS **(Chap. 166)** can be regarded as a phenocopy of aHUS). aHUS is a severe disease, with up to 15% mortality in the acute phase and up to 50% of cases progressing to end-stage renal disease (ESRD). Not infrequently, aHUS undergoes spontaneous remission. Because it is an inherited abnormality, it is not surprising that, given renewed exposure to a trigger, the syndrome will tend to recur; when it does, the prognosis is always serious. The traditional treatment has been plasma exchange, which will supply the deficient complement regulator. This has changed since the introduction of the anti-C5 complement inhibitor eculizumab (see "Paroxysmal Nocturnal Hemoglobinuria") was found to greatly ameliorate the microangiopathic picture, with improvement in platelet counts and in renal function, thus abrogating the need for plasma exchange, which is not always effective and not free of complications. Because the basis of aHUS is genetic, and relapses are always possible even after complete remission, there is a rationale for continuing eculizumab indefinitely, especially in order to prevent ESRD. Patients who relapsed after discontinuing eculizumab have responded again. Discontinuation of eculizumab might be reasonable especially in patients heterozygous for a MCP mutation. However, there is no evidence base at the moment for balancing the pros and cons of lifetime eculizumab (a very expensive drug).

ACQUIRED HEMOLYTIC ANEMIA

Mechanical Destruction of Red Cells Although red cells are characterized by the remarkable deformability that enables them to squeeze through capillaries narrower than themselves for thousands of times in their lifetime, there are at least two situations in which they succumb to shear, if not to wear and tear; the result is intravascular hemolysis, resulting in hemoglobinuria **(Table 100-6)**. One situation is acute and self-inflicted, *march hemoglobinuria*. Why sometimes a marathon runner may develop this complication, whereas on another occasion, this does not happen, we do not know (perhaps her or his footwear needs attention). A similar syndrome may develop after prolonged barefoot ritual dancing or intense playing of bongo drums. The other situation is chronic and iatrogenic (it has been called *microangiopathic hemolytic anemia*). It takes place in patients with prosthetic heart valves, especially when paraprosthetic regurgitation is present. If the hemolysis consequent on mechanical trauma to the red cells is mild, and if the supply of iron is adequate, the loss may be largely

TABLE 100-6 Diseases and Clinical Situations in Which Hemolysis Is Largely Intravascular

	ONSET/TIME COURSE	MAIN MECHANISM	APPROPRIATE DIAGNOSTIC PROCEDURE	COMMENTS
Mismatched blood transfusion	Abrupt	Nearly always ABO incompatibility	Repeat cross-match	
Paroxysmal nocturnal hemoglobinuria (PNH)	Chronic with acute exacerbations	Complement (C)-mediated destruction of CD59(–) red cells	Flow cytometry to display a CD59(–) red cell population	Exacerbations due to C activation through any pathway
Paroxysmal cold hemoglobinuria (PCH)	Acute	Immune lysis of normal red cells	Test for Donath-Landsteiner antibody	Often triggered by viral infection
Septicemia	Very acute	Exotoxins produced by *Clostridium perfringens*	Blood cultures	Other organisms may be responsible
Microangiopathic	Acute or chronic	Red cell fragmentation	Red cell morphology on blood smear	Different causes ranging from endothelial damage to hemangioma to leaky prosthetic heart valve
March hemoglobinuria	Abrupt	Mechanical destruction	Targeted history taking	Has been reported after extreme ritual dancing
Favism	Acute	Destruction of older fraction of G6PD-deficient red cells	G6PD assay	Triggered by ingestion of large dish of fava beans[a]

[a]The trigger of acute hemolytic anemia, often with hemoglobinuria, can be infection or a drug (see Table 100-5) rather than fava beans. Hemoglobinuria may or may not be reported by patient; but it is often macroscopic, i.e., recognizable by simple inspection of urine.

Abbreviation: G6PD, glucose 6-phosphate dehydrogenase.

compensated; if more than mild anemia develops, reintervention to correct regurgitation may be required.

Infection By far the most frequent infectious cause of HA in endemic areas is malaria **(Chap. 224)**. In other parts of the world, the most frequent direct cause is probably Shiga toxin–producing *E. coli* O157:H7, now recognized as the main etiologic agent of HUS, which is more common in children than in adults **(Chap. 161)**. Life-threatening intravascular hemolysis, due to a toxin with lecithinase activity, occurs with *Clostridium perfringens* sepsis, particularly following open wounds, septic abortion, or as a disastrous accident due to a contaminated blood unit. Rarely, and if at all in children, HA is seen with sepsis or endocarditis from a variety of organisms. In addition, bacterial and viral infections can cause HA by indirect mechanisms (see Table 100-6).

Immune Hemolytic Anemias These can arise through at least two distinct mechanisms. First, when an antibody directed against a certain molecule (e.g., a drug) reacts with that molecule, red cells may get caught in the reaction (the so-called innocent bystander mechanism: see section below on Hemolytic Anemia from Toxic Agents and Drugs), whereby they are damaged or destroyed. Second, and more frequently, a true autoantibody is directed against a red cell antigen, i.e., a molecule present on the surface of red cells. Autoimmune hemolytic anemias have been originally classified into two types, depending on the thermal amplitude of the autoantibodies involved: this classification is valid, because the two types have different pathophysiological and clinical features.

AUTOIMMUNE HEMOLYTIC ANEMIA, WARM TYPE (WAIHA: FOR SIMPLICITY WE WILL USE THE ACRONYM AIHA) This type has an estimated incidence in the United States of about 1–3:100,000 per year, and a prevalence of 17:100,000. AIHA can be serious since even with appropriate management the mortality is of the order of 5–10%.

Clinical Features and Diagnosis The onset is often abrupt and can be dramatic. The hemoglobin level may drop, within days, to as low as 4 g/dL; the massive red cell removal will produce jaundice, and sometimes the spleen is enlarged. When this triad is present, the suspicion of AIHA must be high. The reticulocyte count is typically elevated, except when erythroid precursors are also targeted by the autoantibody attack. LDH may also be elevated. In some cases, AIHA can be associated, on first presentation or subsequently, with autoimmune thrombocytopenia. This double autoimmune condition, referred to as Evans syndrome, may be a manifestation of common variable immune deficiency, and in children it may suggest one of several primary immune deficiency syndromes. Evans syndrome signals high-risk disease. Other predictors of the outcome and of the probability of relapse of AIHA are severe anemia (Hb <6 g/dL), certain characteristics of the antibody, acute renal failure, and infection.

There are few situations in hematology where one laboratory test is as informative as the direct antiglobulin test developed in 1945 by R. R. A. Coombs and known since then by this name. The currently recommended version of this test uses in the first instance a "broad-spectrum" reagent, i.e., one that will detect not only immunoglobulins (Ig) but also complement (C) components (usually C3 fragments) bound to the surface of the patient's red cells. If the test is positive (and barring special circumstances such as previous blood transfusion), it is practically diagnostic of AIHA, and one can then determine, by using specific reagents, whether Ig or C or both are implicated. The sensitivity of the Coombs test varies depending on the techniques that are used: in general, the test is positive if there are an average of at least 400 molecules of Ig and/or C on each red cell; but with more advanced techniques involving flow cytometry analysis or enzyme-linked radiolabeled tests allowing the detection of ~30–40 antibody molecules per erythrocyte, the sensitivity can be pushed to as low as 30–40 molecules per red cell. Therefore liaison with a specialized laboratory is desirable; a dual direct antiglobulin test has also been developed. In the past the diagnosis of "Coombs-negative AIHA" was regarded as a last resort, but it is important to know that a patient with this label may have severe AIHA, because if the antibody is powerful (high affinity/avidity), few molecules may be sufficient to opsonize red cells. Based on the Coombs test findings as well as on the thermal characteristics and the antigenic specificities of the autoantibodies **(Table 100-7)**, AIHA has been classified into subtypes.

In AIHA the autoantibody reacts best at 37°C and it is usually Rhesus-specific (sometimes specifically anti-e). The main mechanism of hemolysis in AIHA is that the Fc portion of the IgG antibody bound to red cells is recognized by the Fc receptor of macrophages: this will trigger erythrophagocytosis wherever macrophages are abundant, i.e., in the liver, in the bone marrow, but especially in red pulp of the spleen (see **Fig. 100-9**) that, also because of its special anatomy, is often the predominant site of red cell destruction.

AIHA may be seen in isolation (and it is then called *idiopathic*) or as secondary to other disorders such as systemic autoimmune disorders (systemic lupus erythematosus [SLE]: sometimes AIHA may be the first manifestation that leads to a diagnosis of SLE) or lymphoproliferative disorders (Table 100-7). Like all autoimmune diseases, AIHA must arise from a dysregulation of immunity. It is therefore not surprising that it is increasingly being recognized in chronic lymphocytic leukemia (CLL), whether treated or untreated; after BMT; and after solid organ transplantation entailing immunosuppressive treatment. Recently, warm antibody AIHA has also occurred as a side effect of the use of immune checkpoint inhibitors, such as nivolumab, in patients with various types of cancer.

TABLE 100-7 Classification of Acquired Immune Hemolytic Anemias

CLINICAL SETTING	TYPE OF ANTIBODY: COLD, MOSTLY IgM, OPTIMAL TEMPERATURE 4°C–30°C	TYPE OF ANTIBODY: WARM, MOSTLY IgG, OPTIMAL TEMPERATURE 37°C; OR MIXED
Primary	CAD	AIHA (idiopathic)
Secondary to viral infection	EBV CMV Other	Parvovirus B19 HIV HCV EBV Viral vaccines
Secondary to other infection	Mycoplasma infection: paroxysmal cold hemoglobinuria	Babesia
Secondary to/ associated with other disease	CAD in: Waldenström's disease Lymphoma	AIHA in: SLE, scleroderma, RA CLL Lymphoproliferative disorders Multiple myeloma Other malignancy Chronic inflammatory disorders (e.g., IBD) Thyroiditis (including Hashimoto) After allogeneic HSCT Common variable immunodeficiency After immune checkpoint modulating drugs
Secondary to drugs: drug-induced immune hemolytic anemia	Small minority (e.g., with lenalidomide)	Majority: currently most common culprit drugs are cefotetan, ceftriaxone, piperacillin, methyldopa, fludarabine
	Drug-dependent: antibody destroys red cells only when drug present (e.g., rarely penicillin) Drug-independent: antibody can destroy red cells even when drug no longer present (e.g., methyldopa)	
Associated with	Pregnancy	

Abbreviations: AIHA, autoimmune hemolytic anemia; CAD, cold agglutinin disease; CLL, chronic lymphocytic leukemia; CMV, cytomegalovirus; EBV, Epstein-Barr virus; HCV, hepatitis C virus; HIV, human immunodeficiency virus; HSCT, hematopoietic stem cell transplantation; IBD, inflammatory bowel disease; SLE, systemic lupus erythematosus; RA: rheumatoid arthritis.

TREATMENT

Warm Antibody Autoimmune Hemolytic Anemia

Severe acute AIHA can be a medical emergency. The immediate treatment almost invariably includes transfusion of red cells. This may pose a special problem because many or all of the blood units cross-matched may be incompatible. In these cases, it is often correct, if paradoxical, to transfuse ABO-matched but incompatible blood: the rationale being that the transfused red cells will be destroyed no less—but no more—than the patient's own red cells, and in the meantime the patient stays alive. A situation like this requires close liaison and understanding between the clinical unit treating the patient and the blood transfusion/serology lab. Whenever the anemia is not immediately life-threatening, blood transfusion should be withheld (because compatibility problems may increase with each unit of blood transfused), and medical treatment started immediately with prednisone (1 mg/kg per day), which will produce a remission promptly in at least one-half of patients. Rituximab (anti-CD20), previously regarded as second-line treatment, is increasingly being used at a relatively low dose (100 mg/week × 4), together with prednisone as part of first-line treatment. It is especially encouraging that this approach seems to reduce the rate of relapse, a common occurrence in AIHA.

For patients who do relapse or are refractory to medical treatment, additional therapeutic strategies are now available. Splenectomy does not cure the disease, but it can produce significant benefit by removing a major site of hemolysis, thus improving the anemia and/or reducing the need for other therapies (e.g., the dose of prednisone); of course, splenectomy is not free of risk, as it entails increased risk of sepsis and of thrombosis. The response rate to splenectomy and to rituximab are similar. Since the introduction of rituximab, azathioprine, cyclophosphamide, cyclosporine, mycophenolate and intravenous immunoglobulin have become second- or third-line agents. In very rare severe refractory cases, one may have to consider a high dose of cyclophosphamide (50 mg/kg/d for 4 days) followed by a myelo-stimulating agent to support bone marrow or the anti-CD52 agent, alemtuzumab. When severe anemia is associated with reticulocytopenia, the use of erythropoietin may help to reduce or avoid the requirement for transfusion of red cells.

PAROXYSMAL COLD HEMOGLOBINURIA (PCH) PCH is a rare form of AIHA occurring mostly in children, usually triggered by a viral infection, usually self-limited, and characterized by the so-called Donath-Landsteiner antibody. In vitro, this antibody has unique serologic features; it has usually anti-P specificity and it binds to red cells only at a low temperature (optimally at 4°C), but when the temperature is shifted to 37°C, lysis of red cells takes place in the presence of complement. Consequently, in vivo there is intravascular hemolysis, resulting in hemoglobinuria. Clinically the differential diagnosis must include other causes of hemoglobinuria (Table 100-6), but the presence of the Donath-Landsteiner antibody will prove PCH. Active supportive treatment, including blood transfusion, may be needed to control the anemia; subsequently, recovery is the rule.

COLD AGGLUTININ DISEASE This designation indicates the other main type of AIHA, which has quite different features when compared with wAIHA. First, cold agglutinin disease (CAD) is a chronic and more frequently indolent condition—in contrast to the abrupt onset of warm antibody AIHA. Second, the term *cold* refers to the fact that the autoantibody involved reacts with red cells poorly or not at all at 37°C, whereas it reacts strongly at lower temperatures. As a result, hemolysis is more prominent the more the body is exposed to the cold. Third, the antibody is produced by a clone of autoreactive B lymphocytes. Sometimes the antibody concentration in the serum is high enough to show up as a spike in plasma protein electrophoresis, thus qualifying CAD as an IgM monoclonal gammopathy; however, it differs from Waldenström macroglobulinemia by not having the characteristic *MYD88* mutation (see **Chap. 111**): there is instead, in the B-cell clone of a majority of CAD patients, a somatic mutation in the *KMT2D* gene, encoding a lysine histone methylase that seems to favor proliferation. The antibody produced by the B-cell clone is IgM; usually it has an anti-I specificity (the I antigen is present on the red cells of almost everybody), and it may have a very high titer (1:100,000 or more has been observed). IgM, when bound to red cells, is a powerful activator of the complement cascade, with ultimate formation of the membrane attack complex (see Fig. 100-9): this will directly cause destruction of red cells (*intravascular hemolysis:* indeed, CAD patients may present with hemoglobinuria). In addition, once complement is activated C3b will bind to red cells that, thus opsonized, will be destroyed by macrophages (*extravascular hemolysis*); unlike in AIHA, there is no predominance of the spleen in this process.

In mild forms of CAD, avoidance of exposure to cold may be all that is needed to enable the patient to have a reasonably comfortable quality of life; but in more severe forms, the management of CAD is not easy. Plasma exchange will remove antibodies and is, therefore, in theory, a rational approach in severe cases. However, the management of CAD has changed significantly with the advent of the anti-CD20 antibody rituximab: up to 60% of patients respond. If remission is followed by relapse, a new course of rituximab may be again effective, and remissions may be more durable with a rituximab-fludarabine combination, in particular in CAD associated with lymphoproliferative disorders. Therefore, even

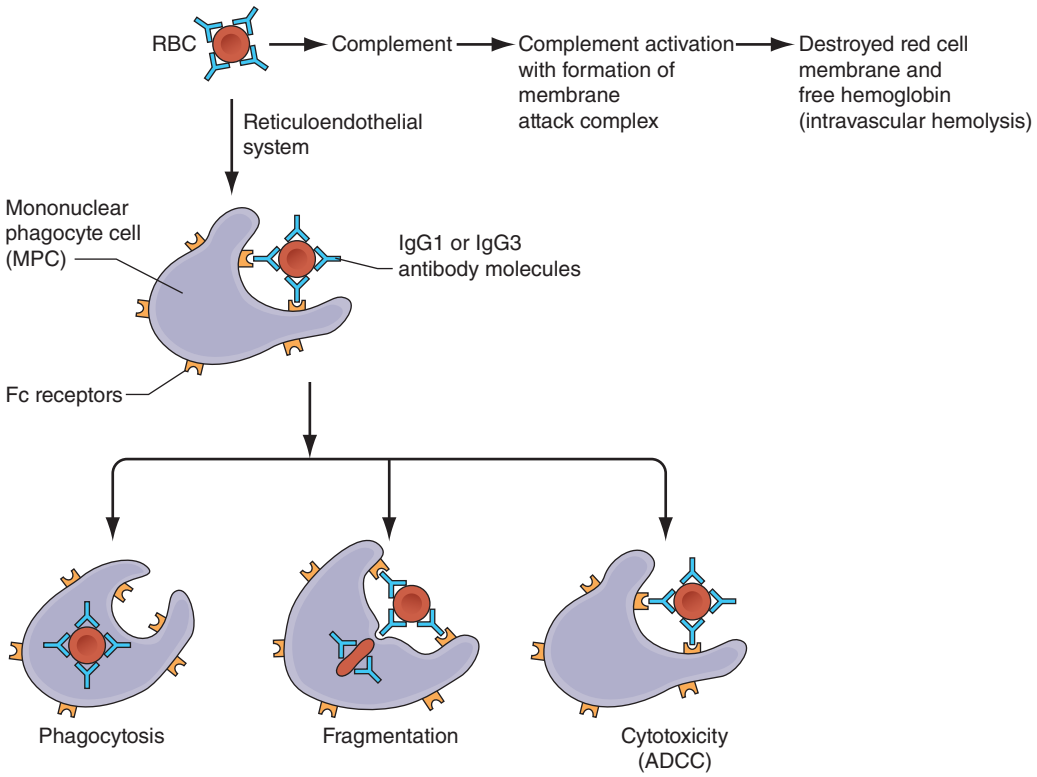

FIGURE 100-9 Mechanism of antibody-mediated immune destruction of red blood cells (RBCs). The three bottom images illustrate three different modalities of extravascular hemolysis. ADCC, antibody-dependent cell-mediated cytotoxicity. *(Reproduced with permission from N Young et al: Clinical Hematology. Philadelphia, Elsevier, 2006.)*

in the absence of a formal trial, rituximab has become de facto first-line treatment: especially since previously used immunosuppressive/cytotoxic agents, although they can reduce the antibody titer, have limited clinical efficacy and, in view of the chronic nature of CAD, their side effects may prove unacceptable. Unlike in AIHA, prednisone and splenectomy are ineffective. In the management of CAD in relapse, there is an emerging role for the B-cell receptor inhibitors venetoclax and ibrutinib, as well as for the proteasome inhibitor bortezomib. A different approach targeting complement inhibitors has been also explored by using eculizumab (anti-C5) or sutimlimab (anti-C1s): a limitation of this approach is that hemolysis will be curbed only for as long as these agents are administered.

In terms of supportive treatment, blood transfusion may be helpful—in spite of the fact that red cells from the donor, being I-positive, will survive no longer than those of the patient: both the blood bag and the patient's extremities must be kept warm during transfusion.

Hemolytic Anemia from Toxic Agents and Drugs A number of chemicals with oxidative potential, whether medicinal or not, can cause hemolysis even in people who are not G6PD deficient (for which, see above). Examples are hyperbaric oxygen (or 100% oxygen), nitrates, chlorates, methylene blue, dapsone, cisplatin, and numerous aromatic (cyclic) compounds. Other chemicals may be hemolytic through nonoxidative, largely unknown mechanisms; examples include arsine, stibine, copper, and lead. The HA caused by lead poisoning is characterized by basophilic stippling; it is in fact a phenocopy of that seen in P5N deficiency (see above), suggesting it is mediated at least in part by lead inhibiting this enzyme.

In these cases, hemolysis appears to be mediated by a direct chemical action on red cells. But drugs can cause hemolysis through at least two other mechanisms. (1) A drug can behave as a hapten and induce antibody production; in rare subjects, this happens, for instance, with penicillin. Upon a subsequent exposure, red cells are caught, as innocent bystanders, in the reaction between penicillin and antipenicillin antibodies. Hemolysis will subside as soon as penicillin administration is stopped. (2) A drug can trigger, perhaps through mimicry, the production of an antibody against a red cell antigen. The best-known example is methyldopa, an antihypertensive agent no longer in use, which in a small fraction of patients stimulated the production of the Rhesus antibody anti-e. In patients who have this antigen, the anti-e is a true autoantibody, which then causes true AIHA (see above). Usually this will gradually subside once methyldopa is discontinued.

Severe intravascular hemolysis can be caused by the venom of certain snakes (cobras and vipers), and HA can also follow spider bites.

Paroxysmal Nocturnal Hemoglobinuria (PNH) PNH is an acquired chronic HA characterized by persistent intravascular hemolysis with occasional or frequent recurrent exacerbations. In addition to (i) hemolysis, there may be (ii) pancytopenia and (iii) a distinct tendency to venous thrombosis. This triad makes PNH a truly unique clinical condition; however, when not all of these three features are manifest on presentation, the diagnosis is often delayed, although it can always be made by appropriate laboratory investigations (see below).

PNH is encountered in all populations throughout the world, but it is a rare disease, with an estimated prevalence of ~5 per million (it may be somewhat less rare in Southeast Asia and in the Far East). PNH has about the same frequency in men and women. PNH is not inherited, and it has never been reported as a congenital disease, but it can present in small children or as late as in the seventies, although most patients are young adults.

CLINICAL FEATURES When seeking medical attention, the patient may report that one morning, she or he "passed blood instead of urine." This distressing or frightening event may be regarded as the classic presentation; however, more frequently, this symptom is not noticed or not reported. Indeed, the patient often presents simply as a problem in the differential diagnosis of anemia, whether symptomatic or discovered incidentally. Sometimes the anemia is associated from the outset with neutropenia, thrombocytopenia, or both, thus signaling an element of bone marrow failure (see below). Some patients may present with recurrent attacks of severe abdominal pain eventually found to be related to thrombosis in abdominal veins, or attributable to NO depletion associated with intravascular hemolysis. When thrombosis affects the hepatic vein, it may produce acute hepatomegaly and ascites,

i.e., a full-fledged Budd-Chiari syndrome, which, in the absence of liver disease, ought to raise the suspicion of PNH.

The natural history of PNH can extend over decades. In the past, with supportive treatment only, the median survival was estimated to be about 10–20 years, with the most common cause of death being venous thrombosis, followed by infection secondary to severe neutropenia and hemorrhage secondary to severe thrombocytopenia. Rarely (estimated 1–2% of all cases), PNH may terminate in acute myeloid leukemia. On the other hand, full spontaneous recovery from PNH has been documented, albeit rarely.

LABORATORY INVESTIGATIONS AND DIAGNOSIS The most consistent blood finding is anemia, which may range from mild to moderate to very severe. The anemia is usually normo-macrocytic, with unremarkable red cell morphology. If the MCV is high, it is usually largely accounted for by reticulocytosis, which may be quite marked (up to 20%, or up to 400,000/μL). The anemia may become microcytic if the patient is allowed to become iron-deficient as a result of chronic iron loss through hemoglobinuria. Unconjugated bilirubin is mildly or moderately elevated; LDH is typically markedly elevated (values in the thousands are common); and haptoglobin is usually undetectable. All of these findings make the diagnosis of HA compelling. Hemoglobinuria may be overt in a random urine sample; if it is not, it may be helpful to obtain serial urine samples (Fig. 100-9) because hemoglobinuria can vary dramatically from day to day and even from hour to hour. The bone marrow is usually cellular, with marked to massive erythroid hyperplasia, often with mild to moderate dyserythropoietic features (these overlap with those seen in myelodysplastic syndromes, but PNH remains a separate entity). At some stage of the disease, the marrow may become hypocellular or even frankly aplastic (see below).

The definitive diagnosis of PNH must be based on the demonstration that a substantial proportion of the patient's red cells have an increased susceptibility to complement (C), due to the deficiency on their surface of proteins (particularly CD59 and CD55) that normally protect the red cells from activated C. The sucrose hemolysis test is unreliable; in contrast, the acidified serum (Ham) test is highly reliable but is carried out only in a few laboratories. The gold standard today is flow cytometry, which can be carried out on granulocytes as well as on red cells and has a very high sensitivity. In PNH, characteristically, one sees a bimodal distribution of cells, with a discrete population that is CD59 and CD55 negative. Although very small populations of CD59(–) cells are of interest in terms of pathophysiology (particularly of aplastic anemia [AA]), no patient should be diagnosed with PNH unless the proportion is substantial: in first approximation at least 5% of the total red cells and at least 20% of the total granulocytes.

PATHOPHYSIOLOGY Hemolysis in PNH is mainly intravascular and is due to an intrinsic abnormality of the red cell, which makes it exquisitely sensitive to activated C, whether C is activated through the alternative pathway or through an antigen-antibody reaction (classic pathway). The former mechanism is mainly responsible for chronic hemolysis in PNH; the latter explains why the hemolysis can be dramatically exacerbated in the course of a viral or bacterial infection. Hypersusceptibility to C is due to deficiency in the red cell membrane of several protective proteins **(Fig. 100-10)**, among which CD59 is the most important because it is able to hinder the insertion into the membrane of C9 polymers (the so-called membrane attack complex, or MAC). The molecular basis for the deficiency of these proteins has been pinpointed not to a defect in any of the respective genes, but rather to the shortage of a unique glycolipid molecule, GPI (Fig. 100-2), which, through a peptide bond, anchors these proteins to the surface membrane of cells. The shortage of GPI is due in turn to a somatic mutation in an X-linked gene, called *PIGA*, required for an early step in GPI biosynthesis. As a result, the patient's marrow is a mosaic of mutant and nonmutant cells, and the peripheral blood always contains both GPI-negative (PNH) cells and GPI-positive (non-PNH) cells: in most cases the former prevail. Thrombosis is one of the most immediately life-threatening complications of PNH, and yet one of the least understood in its pathogenesis. It could be that deficiency of CD59 on the PNH platelet causes inappropriate platelet activation; however, other mechanisms are possible. In very rare cases PNH can be caused by biallelic mutations of the *PIGT* gene, in the absence of a *PIGA* mutation. In these cases, because GPI is produced but cannot bind to proteins, the clinical picture is further complicated by the coexistence of a chronic inflammatory state.

BONE MARROW FAILURE (BMF) AND RELATIONSHIP BETWEEN PNH AND APLASTIC ANEMIA (AA) It is not unusual that patients with firmly established PNH have a previous history of AA, sometimes well documented; indeed, BMF preceding overt PNH is probably the rule rather than the exception. On the other hand, sometimes a patient with PNH becomes less hemolytic and more pancytopenic and ultimately has the clinical picture of AA. The relationship between PNH and AA manifested in the clinical course of patients may reflect a close link in pathogenesis. AA is thought to be an organ-specific autoimmune disease, in which T cells cause damage to hematopoietic stem cells via an as yet unidentified molecular target. The same may be true of PNH, and in this condition the target might be the GPI molecule itself. This would explain why GPI-negative (PNH) stem cells are spared; *PIGA* mutations can be demonstrated in normal people. Thus, PNH results from the combined action of two factors: failure of normal hematopoiesis and massive expansion of a PNH clone. There is evidence from mouse models that PNH stem cells do not expand on their own, and there is evidence from human patients that expansion is associated with negative selection against GPI-positive cells by GPI-specific T cells. Thus, PNH is a prime example of a clonal disease that is not malignant.

TREATMENT

Paroxysmal Nocturnal Hemoglobinuria

Until some 15 years ago there were essentially two treatment options for PNH: either allogeneic BMT, providing a definitive cure at the cost of nonnegligible risks; or continued supportive treatment for what, unlike other acquired HAs, may be a lifelong condition. A major advance has been the introduction in 2007 of a humanized monoclonal antibody, eculizumab, which binds to the complement component C5 near the site that, when cleaved, will trigger the distal part of the complement cascade leading to formation of the MAC. With C5 blocked by anti-C5, the patient is relieved of intravascular hemolysis and of its attendant consequences, including hemoglobinuria; with a substantial decrease in the rate of thrombosis. In the majority of those patients who needed regular blood transfusion, the transfusion requirement is either abolished or significantly reduced. For many PNH patients, eculizumab has meant a real improvement in the quality of life, as well as a decrease in complications, particularly thrombosis. At the same time, it is important to know that in patients on eculizumab the PNH red cells, now protected from being lysed through the MAC, do still bind C3 fragments and thus become opsonized. Therefore, hemolysis continues, but it is now extravascular. The extent to which this happens depends in part on a genetic polymorphism of the complement receptor CR1. Those patients who, on eculizumab, are still receiving blood transfusion are at risk of iron overload. Based on its half-life, eculizumab must be administered intravenously every 14 days. Ravulizumab, a long-lived anti-C5 derivative of eculizumab, is administered at 8-week rather than 2-week intervals: it provides similar benefit with obvious practical advantage.

Eculizumab and ravulizumab are very expensive and for this reason not accessible to patients in many parts of the world. Therefore, the management of PNH by supportive treatment is still very important. Folic acid supplements (at least 3 mg/d) are mandatory; the serum iron should be checked periodically, and iron supplements should be administered as appropriate. Transfusion of white cell-free red cells should be used whenever necessary, which, for some patients, means quite frequently. Long-term glucocorticoids are not indicated because there is no evidence that they have any effect on chronic hemolysis; in fact, they are contraindicated

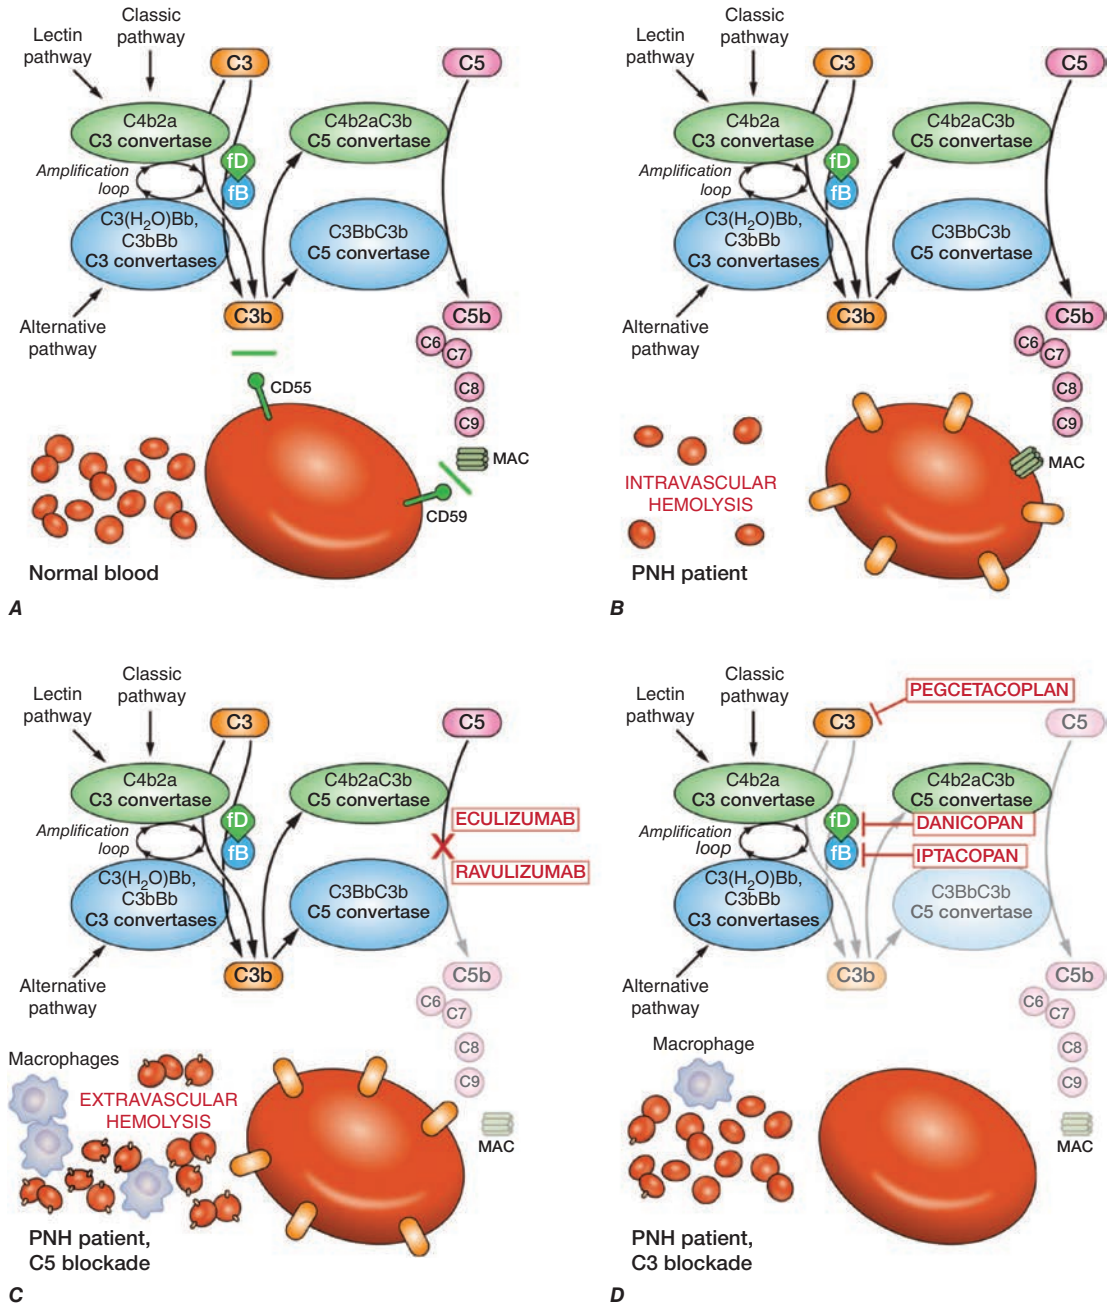

FIGURE 100-10 The complement cascade and the fate of red cells. ***A.*** In normal blood, when complement is activated, red cells are protected from lysis in several ways: primarily by the 2 glycosylphosphatidylinositol (GPI)-linked surface proteins CD55 (prevents binding of C3 fragments) and CD59 (prevents the membrane attack complex [MAC] from inserting into the membrane). ***B.*** PNH red cells are deficient in CD55 and CD59 because the GPI biosynthetic pathway is blocked as a result of a PIGA mutation; therefore, C3 fragments, particularly C3d, bind to their surface, and the red cells are rapidly lysed by the action of the MAC. ***C.*** With drugs (monoclonal antibodies) that bind to C5 and prevent it splitting into C5a and C5b, the entire distal pathway from C5 onward is blocked, MAC is not formed, and IVH is abrogated. However, red cells opsonized by C3d will be destroyed in the spleen and elsewhere; this drug-induced EVH varies in severity between patients. The Coombs test, which is characteristically negative in PNH, becomes positive (provided that a "broad spectrum" or an anticomplement reagent is used). ***D.*** With a drug that targets C3, C3b formation is inhibited, and the distal pathway is not triggered by C3b. Therefore, again, no MAC is formed (abrogating IVH), and, at the same time, opsonization of red cells by C3d is prevented, so that EVH is also curbed. The same is largely true for drugs that target factor B or factor D, although C3b can still be formed through the classical pathway. *(Reproduced with permission from L Luzzatto: Control of hemolysis in patients with PNH. Blood 138:1909, 2021.)*

because their side effects are considerable. A short course of prednisone may be useful when an inflammatory process exacerbates hemolysis. Any patient who has had venous thrombosis or who has a genetically determined thrombophilic state in addition to PNH should be on regular anticoagulant prophylaxis. With thrombotic complications that do not resolve otherwise, thrombolytic treatment with tissue plasminogen activator may be indicated.

Where anti-C5 therapy is available the proportion of PNH patients receiving BMT has decreased significantly. However, when an HLA-identical sibling is available, BMT should be taken into consideration for any young patient with severe PNH; and for patients with the so-called PNH-AA syndrome, since eculizumab has no effect on BMF. For these patients immunosuppressive treatment with antithymocyte globulin and cyclosporine A may be an alternative, and it may be compatible with concurrent administration of eculizumab.

In view of persistent extravascular hemolysis, and sometimes persistent blood transfusion requirement in PNH patients on C5 blockade therapy, there has been great stimulus to developing agents that may inhibit complement activation more upstream. Several compounds that inhibit either the convertase function of C3 or plasma factors required for this function are currently in clinical trials (see Fig. 100-11).

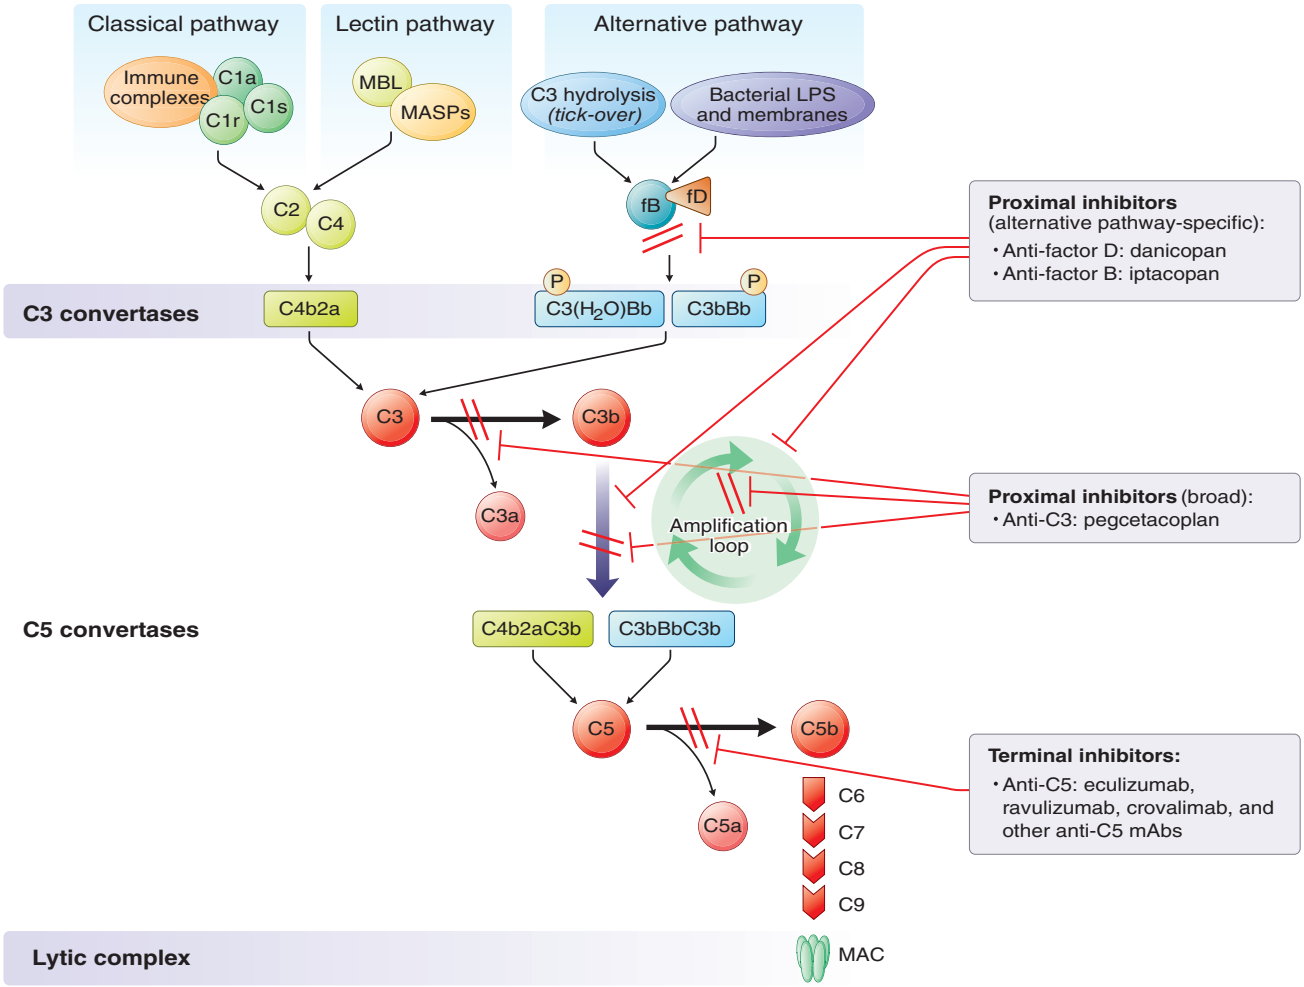

FIGURE 100-11 Monoclonal antibodies and small molecules in use or in development for the management of PNH and other complement-related disorders. Complement components are indicated by C followed by a number. MBL stands for mannose-binding lectin; MASP1 for mannose-binding lectin-associated serine protease 1. P is properdin. Of the inhibitors shown on the right, only eculizumab and ravulizumab, which bind to C5 and are therefore inhibitors of the distal pathway, are already licensed drugs: both effectively abrogate MAC formation but they do not interfere with the formation of either the C3 convertase or the C5 convertase: in contrast, this can be achieved with the upstream inhibitors danicopan, iptacopan, and pegcetacoplan.

101 Anemia Due to Acute Blood Loss

Dan L. Longo

Blood loss causes anemia by two main mechanisms: (1) by the direct loss of red cells; and (2) if the loss of blood is protracted, it will gradually deplete iron stores, eventually resulting in iron deficiency. The latter type of anemia is covered in **Chap. 97**. Here, we are concerned with the former type, that is, *posthemorrhagic anemia*, which follows *acute* blood loss. This can be *external* (e.g., after trauma or obstetric hemorrhage) or *internal* (e.g., from bleeding in the gastrointestinal tract, rupture of the spleen, rupture of an ectopic pregnancy, subarachnoid hemorrhage, leaking aneurysm). In any of these cases, after the sudden loss of a large amount of blood, there are three clinical/pathophysiologic stages. (1) At first, the dominant feature is hypovolemia, which poses a threat particularly to organs that normally have a high blood supply, like the brain and the kidneys; therefore, loss of consciousness and acute renal failure are major threats. It is important to note that at this stage an ordinary blood count will not show anemia because the hemoglobin concentration is not affected. On physical exam, tachycardia, tachypnea, decreased pulse pressure, cold skin that appears pale and mottled, and decreased urine output may be noted. (2) Next, as

an emergency response, baroreceptors and stretch receptors will cause release of vasopressin and other peptides, and the body will shift fluid from the extravascular to the intravascular compartment, producing hemodilution; thus, the hypovolemia gradually converts to anemia. The degree of anemia will reflect the amount of blood lost. If after 3 days the hemoglobin is, for example, 7 g/dL, it means that about half of the entire blood has been lost. (3) Provided bleeding does not continue, the bone marrow response will gradually ameliorate the anemia. In this phase of the process, the reticulocyte count and erythropoietin levels will be elevated. The physiologic increase in marrow red cell production reflected by the increase in reticulocytes is similar to the marrow response to hemolysis.

The diagnosis of acute posthemorrhagic anemia (APHA) is usually straightforward, although sometimes internal bleeding episodes (e.g., after a traumatic injury), even when large, may not be immediately obvious. Look for physical findings that may help localize the bleeding. Grey Turner sign (flank ecchymosis) may reflect retroperitoneal bleeding. Cullen sign (umbilical ecchymosis) may suggest intraperitoneal or retroperitoneal bleeding. Dullness to chest percussion may suggest intrapleural bleeding. Whenever an abrupt fall in hemoglobin has taken place, whatever history is given by the patient, APHA should be suspected. Supplementary history may have to be obtained by asking the appropriate questions, and appropriate investigations (e.g., a sonogram or an endoscopy) may have to be carried out.

TREATMENT

Anemia Due to Acute Blood Loss

In patients who are hemodynamically unstable, the usual airway, breathing, and circulation assessments take priority. In the face of bleeding associated with hypotension, pharmacologic support with vasopressors is critical. With respect to anemia treatment, a two-pronged approach is imperative. (1) In many cases, the blood lost needs to be replaced promptly. Unlike with many chronic anemias, when finding and correcting the cause of the anemia is the first priority and blood transfusion may not be even necessary because the body is adapted to the anemia, with acute blood loss, the reverse is true; because the body is not adapted to the anemia, blood transfusion takes priority. (2) While the emergency is being confronted, it is imperative to stop the hemorrhage and to eliminate its source.

In an acute hemorrhage situation, plasma may be preferred to saline for volume expansion since dilution of clotting factors with crystalloid may interfere with hemostasis.

A special type of APHA is blood loss during and immediately after surgery, which can be substantial (e.g., up to 2 L in the case of a radical prostatectomy). Of course with elective surgical procedures, the patient's own stored blood may be available (through preoperative autologous blood donation), and in any case, blood loss ought to have been carefully monitored/measured. The fact that this blood loss is iatrogenic dictates that ever more effort should be invested in optimizing its management. The special features of transfusion medicine are discussed in **Chap. 113**.

A Holy Grail of emergency medicine for a long time has been the idea of a blood substitute that would be universally available, suitable for all recipients, easy to store and to transport, safe, and as effective as blood itself. Two main paths have been pursued: (1) fluorocarbon synthetic chemicals that bind oxygen reversibly, and (2) artificially modified hemoglobins, known as hemoglobin-based oxygen carriers (HBOCs). Although there are numerous anecdotal reports of the use of both approaches in humans, and although HBOCs have reached the stage of phase 2–3 clinical trials, no "blood substitute" has yet become standard treatment.

102 Bone Marrow Failure Syndromes Including Aplastic Anemia and Myelodysplasia

Neal S. Young

Bone marrow failure diseases include aplastic anemia, myelodysplastic syndrome (MDS), pure red cell aplasia (PRCA), and myelophthisis. Hypoproliferative anemia is a cardinal feature of these disorders, but more frequent is *pancytopenia*: anemia, leukopenia, and thrombocytopenia. Low blood counts in marrow failure result from deficient hematopoiesis, as distinguished from blood count depression due to peripheral destruction of red cells (hemolytic anemias), platelets (idiopathic thrombocytopenic purpura [ITP] or due to splenomegaly), and granulocytes (as in the immune leukopenias). Marrow damage and dysfunction also may be secondary to infection, inflammation, or cancer.

Hematopoietic failure syndromes are classified by dominant morphologic features of the bone marrow **(Table 102-1)**. Although practical distinction among these syndromes usually is clear from the marrow pathology, some processes are so closely related that the diagnosis may be complex. Separation between aplastic anemia and hypocellular MDS can be particularly difficult. Mutations on genomic screens may be etiologic or interpreted as risk factors. Patients may seem to suffer from two or three related diseases simultaneously, or one diagnosis may appear to evolve into another. Many of these syndromes share an immune-mediated mechanism of marrow destruction and some element of genomic instability resulting in a higher rate of malignant transformation.

It is important that the internist and general practitioner recognize the marrow failure syndromes because quality of life and ultimate prognosis may be poor if the patient is untreated; effective therapies are often available but sufficiently complicated in their choice and delivery so as to warrant the care of a hematologist or oncologist. While the identification of pathogenic mutations on genomic screen, often on testing ordered by the internist and pediatrician, has revolutionized the diagnosis of the marrow failure syndromes, these results often require the interpretation of the hematologist and oncologist.

APLASTIC ANEMIA

DEFINITION

Aplastic anemia is pancytopenia with bone marrow hypocellularity. Acquired aplastic anemia is distinguished from iatrogenic aplasia, from marrow hypocellularity after intensive cytotoxic chemotherapy for cancer, and from usually accidental physical and chemical injury, as in radiation poisoning. Aplastic anemia can also be constitutional. Genetic diseases such as Fanconi anemia and dyskeratosis congenita usually (but not always) present in early childhood and have typical physical anomalies. Telomere diseases (see **Chap. 469**) and hematologic manifestations of mutations in genes such as *GATA2, RUNX1*, and *MPL* can present as marrow failure in normal-appearing adults.

TABLE 102-1 Differential Diagnosis of Pancytopenia

Pancytopenia with Hypocellular Bone Marrow	
Acquired aplastic anemia	
Constitutional aplastic anemia (Fanconi anemia, dyskeratosis congenita, and others)	
Hypocellular myelodysplastic syndrome	
Rare aleukemic leukemia	
Some acute lymphoid leukemia	
Rare lymphomas of bone marrow	
Copper deficiency	
Pancytopenia with Cellular Bone Marrow	
Primary bone marrow diseases	Secondary to systemic diseases
Myelodysplastic syndromes	Systemic lupus erythematosus
Paroxysmal nocturnal hemoglobinuria (PNH)	Hypersplenism
Myelofibrosis	B_{12}, folate deficiency
Aleukemic leukemia	Copper deficiency
Myelophthisis	Alcohol
Bone marrow lymphoma	HIV infection
Hairy cell leukemia	Brucellosis
	Sarcoidosis
	Tuberculosis
	Leishmaniasis
	Sepsis
Hypocellular Bone Marrow ± Pancytopenia	
Q fever	
Legionnaires' disease	
Anorexia nervosa, starvation	
Mycobacterium	

TABLE 102-2 Classification of Aplastic Anemia and Single Cytopenias

ACQUIRED	INHERITED/CONSTITUTIONAL
Aplastic Anemia	
Secondary	Fanconi anemia
Radiation	Dyskeratosis congenita/telomere disease
Drugs and chemicals	Shwachman-Diamond syndrome
Regular effects	Familial aplastic anemia/leukemia predisposition syndromes: *GATA2, RUNX1, CTLA4*, and others
Idiosyncratic reactions	
Viruses	
Epstein-Barr virus (infectious mononucleosis)	Nonhematologic syndromes (Down, Dubowitz, Seckel)
Hepatitis (non-A, non-B, non-C hepatitis)	
Parvovirus B19 (transient aplastic crisis, pure red cell aplasia [PRCA])	
HIV-1 (AIDS)	
Immune diseases	
Eosinophilic fasciitis	
Hypoimmunoglobulinemia	
Large granular lymphocytosis (LGL)	
Thymoma/thymic carcinoma	
Graft-versus-host disease in immunodeficiency	
Paroxysmal nocturnal hemoglobinuria (PNH)	
Pregnancy	
Idiopathic (immune)	
Cytopenias	
PRCA (see Table 102-4)	Congenital PRCA (Diamond-Blackfan anemia)
Neutropenia/agranulocytosis	
Idiopathic	Kostmann syndrome
Drugs, toxins	Shwachman-Diamond syndrome
LGL	Reticular dysgenesis
Pure white cell aplasia (+/– thymoma)	
Thrombocytopenia	
Drugs, toxins	Amegakaryocytic thrombocytopenia
Acquired amegakaryocytic thrombocytopenia	Thrombocytopenia with absent radii
	Other rare germline mutations

Acquired aplastic anemia is often stereotypical in its manifestations, with the abrupt onset of low blood counts in a previously well young adult; seronegative hepatitis or a course of an incriminated medical drug may precede the onset. The diagnosis in these instances is uncomplicated. Sometimes blood count depression is moderate or incomplete, resulting in anemia, leukopenia, and thrombocytopenia in some combination. Aplastic anemia is related to both paroxysmal nocturnal hemoglobinuria (PNH; **Chap. 100**) and to MDS, and a clear distinction among these disorders may not be possible.

EPIDEMIOLOGY

The incidence of acquired aplastic anemia in Europe and Israel is two cases per million persons annually. In Thailand and China, rates of five to seven per million have been established. Men and women are affected with equal frequency, but the age distribution is biphasic, with the major peak in the teens and twenties and a second rise in older adults.

ETIOLOGY

The origins of aplastic anemia have been inferred from several recurring clinical associations **(Table 102-2)**; unfortunately, these relationships are not reliable in an individual patient and may not be etiologic. In addition, although most cases of aplastic anemia are idiopathic, little other than history separates these cases from those with a presumed etiology such as a drug exposure.

Radiation Marrow aplasia is a major acute sequela of radiation. Radiation damages DNA; tissues dependent on active mitosis are particularly susceptible. Nuclear accidents involve not only power plant workers but also employees of hospitals, laboratories, and industry (food sterilization, metal radiography, etc.), as well as innocents exposed to stolen, misplaced, or misused sources. Whereas the radiation dose can be approximated from the rate and degree of decline in blood counts, dosimetry by reconstruction of the exposure can help to estimate the patient's prognosis and also to protect medical personnel from contact with radioactive tissue and excreta. MDS and leukemia, but probably not aplastic anemia, are late effects of radiation.

Chemicals Benzene is a notorious cause of bone marrow failure: epidemiologic, clinical, and laboratory data link benzene to aplastic anemia, acute leukemia, and blood and marrow abnormalities. For leukemia, incidence is correlated with cumulative exposure, but susceptibility must also be important because only a minority of even heavily exposed workers develop myelotoxicity. The employment history is important, especially in industries where benzene is used for a secondary purpose, usually as a solvent. Benzene-related blood diseases have declined with regulation of industrial exposure. Although benzene is no longer generally available as a household solvent, exposure to its metabolites occurs in the normal diet and in the environment. The association between marrow failure and other chemicals is much less well substantiated. Further, there is scant direct evidence of marrow failure as a late effect of exposure, even to benzene.

Drugs (Table 102-3) Many chemotherapeutic drugs have marrow suppression as a major toxicity; effects are dose dependent and will

TABLE 102-3 Some Drugs and Chemicals Associated with Aplastic Anemia

Agents that regularly produce marrow depression as major toxicity in commonly used doses or normal exposures:
Cytotoxic drugs used in cancer chemotherapy: *alkylating agents*, *antimetabolites*, *antimitotics*, some antibiotics
Agents that frequently but not inevitably produce marrow aplasia:
Benzene
Agents associated with aplastic anemia but with a relatively low probability:
Chloramphenicol
Insecticides
Antiprotozoals: *quinacrine* and chloroquine, mepacrine
Nonsteroidal anti-inflammatory drugs (including *phenylbutazone*, indomethacin, ibuprofen, sulindac, aspirin)
Anticonvulsants (*hydantoins*, *carbamazepine*, phenacemide, felbamate)
Heavy metals (*gold*, arsenic, bismuth, mercury)
Sulfonamides: some antibiotics, antithyroid drugs (methimazole, methylthiouracil, propylthiouracil), antidiabetes drugs (tolbutamide, chlorpropamide), carbonic anhydrase inhibitors (acetazolamide and methazolamide)
Antihistamines (*cimetidine*, chlorpheniramine)
D-Penicillamine
Estrogens (in pregnancy and in high doses in animals)
Agents whose association with aplastic anemia is more tenuous:
Other antibiotics (streptomycin, tetracycline, methicillin, mebendazole, trimethoprim/sulfamethoxazole, flucytosine)
Sedatives and tranquilizers (chlorpromazine, prochlorperazine, piperacetazine, chlordiazepoxide, meprobamate, methyprylon)
Allopurinol
Methyldopa
Quinidine
Lithium
Guanidine
Potassium perchlorate
Thiocyanate
Carbimazole

Note: Terms set in italics show the most consistent association with aplastic anemia.

occur in all recipients. In contrast, idiosyncratic reactions to a large and diverse group of drugs may lead to aplastic anemia without a clear dose-response relationship. A large international study in Europe in the 1980s quantitated drug relationships, especially for nonsteroidal analgesics, sulfonamides, thyrostatic drugs, some psychotropics, penicillamine, allopurinol, and gold. Association does not equal causation: a drug may have been used to treat the first symptoms of bone marrow failure (antibiotics for fever or a preceding viral illness) or provoked the first symptom of a preexisting disease (petechiae by nonsteroidal anti-inflammatory agents administered to the thrombocytopenic patient). In the context of total drug use, idiosyncratic reactions, although individually devastating, are rare events. Risk estimates are usually lower when determined in population-based studies. Furthermore, the low absolute risk is also made more obvious: even a 10- or 20-fold increase in risk translates, in a rare disease, to just a handful of drug-induced aplastic anemia cases among hundreds of thousands of exposed persons.

Infections Transient, mild blood count depression is frequent in the course of many viral and bacterial infections. Aplastic anemia can rarely follow infectious mononucleosis. Parvovirus B19 does not usually cause generalized bone marrow failure.

Immunologic Diseases Aplasia is a major consequence and the inevitable cause of death in *transfusion-associated graft-versus-host disease* (GVHD) that can occur after infusion of nonirradiated blood products to an immunodeficient recipient. Aplastic anemia is strongly associated with the rare collagen vascular syndrome eosinophilic fasciitis that is characterized by painful induration of subcutaneous tissues **(Chap. 360)**. Thymoma and hypoimmunoglobulinemia are occasional associations with aplastic anemia. Pancytopenia with marrow hypoplasia can also occur in systemic lupus erythematosus (SLE).

Hepatitis Posthepatitis marrow failure accounts for ~5% of etiologies in most series. Patients are usually young men who have recovered from a bout of liver inflammation 1–2 months earlier; the subsequent pancytopenia is very severe. The hepatitis is seronegative (non-A, non-B, non-C); intensive laboratory efforts including deep sequencing have not disclosed an infectious agent, and the hepatitis is presumed to be immune-mediated. Fulminant liver failure in childhood can follow seronegative hepatitis, and marrow failure occurs at a high rate in these patients.

Pregnancy Aplastic anemia very rarely may occur and recur during pregnancy and resolve with delivery or with spontaneous or induced abortion.

Paroxysmal Nocturnal Hemoglobinuria An acquired mutation in the *PIG-A* gene in a hematopoietic stem cell is required for the development of PNH, but *PIG-A* mutations probably occur commonly in normal individuals. If the PIG-A mutant stem cell proliferates, the result is a clone of progeny deficient in glycosylphosphatidylinositol-linked cell surface membrane proteins **(Chap. 100)**. Small clones of deficient cells can be detected by sensitive flow cytometry tests in one-half or more of patients with aplastic anemia at the time of presentation. Functional studies of bone marrow from PNH patients, even those with mainly hemolytic manifestations, show evidence of defective hematopoiesis. Patients with an initial clinical diagnosis of PNH, especially younger individuals, may later develop frank marrow aplasia and pancytopenia; patients with an initial diagnosis of aplastic anemia may suffer later from hemolytic PNH years after recovery of blood counts.

Constitutional Syndromes Fanconi anemia, an autosomal recessive disorder, manifests as congenital developmental anomalies, progressive pancytopenia, and an increased risk of malignancy. Chromosomes in Fanconi anemia are susceptible to DNA cross-linking agents, the basis for a diagnostic assay. Patients with Fanconi anemia typically have short stature, café au lait spots, and anomalies involving the thumb, radius, and genitourinary tract. At least 17 different genetic defects (all but one with an identified gene) have been defined; the most common, type A Fanconi anemia, is due to a mutation in *FANCA*. Most of the Fanconi anemia gene products form a protein complex that activates FANCD2 by monoubiquitination to play a role in the cellular response to DNA damage and especially interstrand cross-linking.

Diamond-Blackfan anemia (see below) and Shwachman-Diamond syndrome are ribosomopathies, genetic defects in ribosome assembly that are tissue specific. In Shwachman-Diamond syndrome, presentation is early in life with neutropenia, pancreatic insufficiency, and malabsorption; most patients have compound heterozygous mutations in *SBDS*.

In the telomeropathies, inherited genetic defects alter telomere repair or one of the shelterin protein components of the telomere. The pediatric syndrome dyskeratosis congenita is characterized by the triad of mucous membrane leukoplasia, dystrophic nails, reticular hyperpigmentation, and early development of aplastic anemia **(Chap. 469)**. Dyskeratosis congenita is due to mutations in genes of the telomere repair complex, which acts to maintain telomere length in replicating cells: the X-linked variety is due to mutations in the *DKC1* (*dyskerin*) gene; the more unusual autosomal dominant type is due to mutation in *TERC*, which encodes an RNA template. Rarely, mutations can also occur in genes such as *TNF2* that encode shelterin proteins, which bind telomere DNA.

Mutations in *TERC* and *TERT*, which encodes the catalytic reverse transcriptase telomerase, have subtle and milder effects on hematopoietic function, and presentation in adults is not unusual. It manifests as moderate aplastic anemia, which can be chronic and not progressive,

and isolated macrocytic anemia or thrombocytopenia. Physical anomalies are usually not present, but early hair graying is a clue to the diagnosis. A detailed personal and family history may disclose pulmonary fibrosis and hepatic cirrhosis. Variable penetrance means that *TERT* and *TERC* mutations represent risk factors for marrow failure, as family members with the same mutations may have normal or only slight hematologic abnormalities but more subtle evidence of (compensated) hematopoietic insufficiency. Measurement of telomere length of peripheral blood leukocytes is a commercially available functional test.

PATHOPHYSIOLOGY

Bone marrow failure results from severe damage to the hematopoietic cell compartment. In aplastic anemia, replacement of the bone marrow by fat is apparent in the morphology of the biopsy specimen (Fig. 102-1) and magnetic resonance imaging (MRI) of the spine. Cells bearing the CD34 antigen, a marker of early hematopoietic cells, are greatly diminished, and in functional studies, committed and primitive progenitor cells are virtually absent; in vitro assays have suggested that the stem cell pool is reduced to ≤1% of normal in severe disease at the time of presentation.

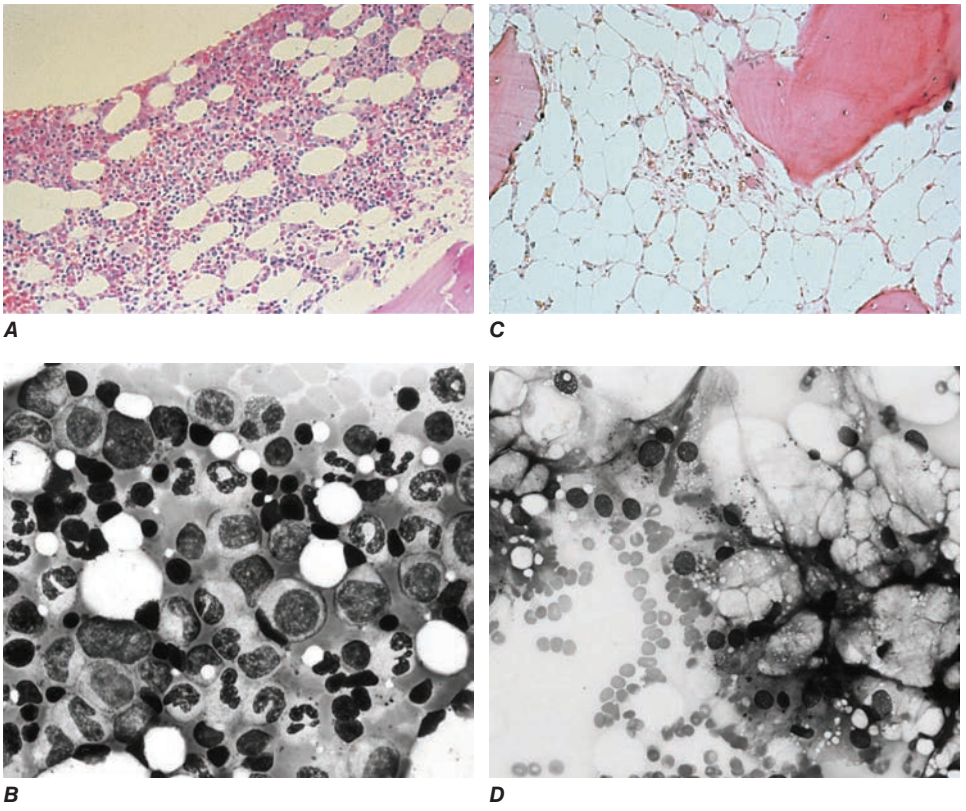

FIGURE 102-1 Normal and aplastic bone marrow. ***A.*** Normal bone marrow biopsy. ***B.*** Normal bone marrow aspirate smear. The marrow is normally 30–70% cellular, and there is a heterogeneous mix of myeloid, erythroid, and lymphoid cells. ***C.*** Aplastic anemia biopsy. ***D.*** Marrow smear in aplastic anemia. The marrow shows replacement of hematopoietic tissue by fat and only residual stromal and lymphoid cells.

Constitutional Genetic Syndromes

An intrinsic stem cell defect exists for the constitutional aplastic anemias: in a critical DNA repair pathway in Fanconi anemia, manifested in the laboratory as chromosome damage and cell death on exposure to certain chemical agents. In the telomeropathies, inability to repair telomeres or to protect chromosome ends is the result of mutations in genes of the telomerase complex or the shelterin proteins; telomere defects limit the cell's capacity to proliferate. Mutations in the *GATA* and *RUNX* genes affect signal transduction and transcriptional regulation in hematopoietic gene networks.

Chemical and Drug Injury Extrinsic damage to the marrow follows massive physical or chemical insults such as high doses of radiation and toxic chemicals. For the more common idiosyncratic reaction to modest doses of medical drugs, altered drug metabolism has been invoked as a mechanism. The metabolic pathways of many drugs and chemicals, especially if they are polar and have limited water solubility, involve enzymatic degradation to highly reactive electrophilic compounds; these intermediates are toxic because of their propensity to bind to cellular macromolecules. For example, derivative hydroquinones and quinolones are responsible for benzene-induced tissue injury. Excessive generation of toxic intermediates or failure to detoxify the intermediates may be genetically determined and apparent only on specific drug challenge; the complexity and specificity of the pathways imply multiple susceptibility loci and would provide an explanation for the rarity of idiosyncratic drug reactions.

Immune-Mediated Stem Cell Destruction The recovery of marrow function in some patients prepared for bone marrow transplantation with antilymphocyte globulin first suggested that aplastic anemia might be immune mediated. Laboratory data, including animal models, support an important role for the immune system in aplastic anemia. Blood and bone marrow cells of patients can suppress normal hematopoietic progenitor cell growth, and removal of T cells from aplastic anemia bone marrow improves hematopoiesis in vitro. Increased numbers of activated cytotoxic T-cell clones usually decline with successful immunosuppressive therapy; type 1 cytokines are implicated; and interferon γ (IFN-γ) induces Fas expression on CD34 cells, leading to apoptotic cell death. Hematopoietic stem cells that have lost human leukocyte antigen (HLA) expression may be selectively expanded. The rarity of aplastic anemia despite common exposures (medicines, seronegative hepatitis) suggests that genetically determined features of the immune response can convert a normal physiologic response into a sustained abnormal autoimmune process, including polymorphisms in histocompatibility antigens, cytokine genes, and genes that regulate T-cell polarization (maturation toward helper or cytotoxic phenotypes) and effector function.

CLINICAL FEATURES

History Aplastic anemia can appear abruptly or insidiously. Bleeding is the most common early symptom; a complaint of days to weeks of easy bruising, oozing from the gums, nose bleeds, heavy menstrual flow, and sometimes petechiae will have been noticed. With thrombocytopenia, massive hemorrhage is unusual, but small amounts of bleeding in the central nervous system can result in catastrophic intracranial or retinal hemorrhage. Symptoms of anemia are also frequent, including lassitude, weakness, shortness of breath, and a pounding sensation in the ears. Infection is an unusual first symptom in aplastic anemia (unlike in agranulocytosis, where pharyngitis, anorectal infection, or frank sepsis occurs early). Patients often feel and look remarkably well despite drastically reduced blood counts. Systemic complaints and weight loss should point to other etiologies of pancytopenia. Prior medical drug use, chemical exposure, and preceding viral illnesses must often be elicited with directed questioning. A family history of hematologic diseases or blood abnormalities, of pulmonary or liver fibrosis, or of early hair graying points to a telomeropathy; a family history of unusual infections and warts points to *GATA2* deficiency.

Physical Examination Petechiae and ecchymoses are typical, and retinal hemorrhages may be present. Pelvic and rectal examinations

can often be deferred but, when performed, should be undertaken with great gentleness to avoid trauma; these may show bleeding from the cervical os and blood in the stool. Pallor of the skin and mucous membranes is common. Infection on presentation is unusual but may occur if the patient has been symptomatic for a few weeks. Lymphadenopathy and splenomegaly are highly atypical of aplastic anemia. Café au lait spots and short stature suggest Fanconi anemia; peculiar nails and leukoplakia suggest dyskeratosis congenita; early graying (and use of hair dyes to mask it!) suggests a telomerase defect.

LABORATORY STUDIES

Blood The smear shows large erythrocytes and a paucity of platelets and granulocytes. Mean corpuscular volume (MCV) is commonly increased. Reticulocytes are absent or few, and lymphocyte numbers may be normal or reduced. The presence of immature myeloid forms suggests leukemia or MDS; nucleated red blood cells (RBCs) suggest marrow fibrosis or tumor invasion; abnormal platelets suggest either peripheral destruction or MDS.

Bone Marrow The bone marrow is usually readily aspirated but dilute on smear, and the fatty biopsy specimen may be grossly pale on withdrawal; a "dry tap" instead suggests fibrosis or myelophthisis. In severe aplasia, the smear of the aspirated specimen shows only red cells, residual lymphocytes, and stromal cells; the biopsy (which should be >1 cm in length) is superior for determination of cellularity and shows mainly fat under the microscope, with hematopoietic cells occupying <25% of the marrow space; sometimes, the biopsy is virtually all fat. The correlation between marrow cellularity and disease severity is imperfect; patients with moderate disease by blood counts can have empty iliac crest biopsies, whereas "hot spots" of hematopoiesis may be seen in severe cases. Residual hematopoietic cells should have normal morphology, except for mildly megaloblastic erythropoiesis; megakaryocytes are greatly reduced and usually absent. Granulomas may indicate an infectious etiology of the marrow failure.

Ancillary Studies Chromosome breakage studies of peripheral blood using diepoxybutane or mitomycin C should be performed on children and younger adults to exclude Fanconi anemia. Very short telomere length strongly suggests the presence of a telomerase or shelterin mutation, which can be pursued by family studies and nucleotide sequencing. Chromosome studies of bone marrow cells are often revealing in MDS but should be negative in typical aplastic anemia. Flow cytometry offers a sensitive diagnostic test for PNH. Serologic studies may show evidence of recent viral infection, such as Epstein-Barr virus and HIV. Posthepatitis aplastic anemia is seronegative.

Genomics Next-generation sequencing allows for large number of genes to be tested for the presence of pathogenic mutations. Panels are available commercially and in certified academic laboratories. While expensive, they are very useful and sometimes critical in establishing the correct diagnosis. Germline gene panels examine 50 or more genes etiologic in constitutional bone marrow failure, including many for which functional assays (described above) are not available. A germline panel should be considered for all children and those adults with suggestive clinical features or family histories. Somatic mutations are sought when MDS is suspected. Myeloid neoplasm gene panels can query about 100 genes that are recurrently mutated in MDS and acute myeloid leukemia (AML). Pathogenic mutations in spliceosome genes and genes in the cohesion family are frequent in MDS and unexpected in aplastic anemia.

DIAGNOSIS

The diagnosis of aplastic anemia is usually straightforward, based on the combination of pancytopenia with a fatty bone marrow. Aplastic anemia is a disease of the young and should be a leading diagnosis in the pancytopenic adolescent or young adult. When pancytopenia is secondary, the primary diagnosis is usually obvious from either history or physical examination: the massive spleen of alcoholic cirrhosis, the history of metastatic cancer or SLE, or miliary tuberculosis on chest radiograph (Table 102-1).

Diagnostic problems can occur with atypical presentations and among related hematologic diseases. Patients with bone marrow hypocellularity may have depression of only one or two of three blood lines, with later progression to pancytopenia. The most important differential diagnoses are between acquired and constitutional aplastic anemia, and between aplastic anemia and MDS. The bone marrow in constitutional aplastic anemia is usually morphologically indistinguishable from the aspirate in acquired disease (an exception is *GATA2* deficiency with its characteristic megakaryocyte atypia). The diagnosis can be suggested by family history, abnormal blood counts since childhood, or the presence of associated, sometimes subtle physical anomalies. Genomic testing for pathogenic mutations in genes etiologic in constitutional marrow failure syndromes can discriminate acquired from inherited aplastic anemia (but results may not return for several weeks, a problem in the severely pancytopenic patient). Acute myeloid leukemia (AML) and MDS in a pedigree should prompt screening for an inherited predispositon syndrome, such as RUNX1 mutations. Aplastic anemia may be difficult to distinguish from the hypocellular variety of MDS: MDS is favored by finding morphologic abnormalities, particularly of megakaryocytes and myeloid precursor cells, and typical cytogenetic abnormalities and somatic mutations on genomic screening of myeloid neoplasm genes (see above). There remains an unclear boundary between immune aplastic anemia and low-risk MDS: patients with deletion of 13q and 20q may respond well to immunosuppression, and mutations in genes such as *DNMT3A* and *ASXL1* occur in both diseases.

PROGNOSIS

The natural history of severe aplastic anemia is rapid deterioration and death. Historically, provision first of RBCs and later of platelet transfusions and effective antibiotics were of some benefit, but few patients show spontaneous recovery. The major prognostic determinant is the blood count. Severe disease historically has been defined by the presence of two of three parameters: absolute neutrophil count <500/μL, platelet count <20,000/μL, and corrected reticulocyte count <1% (or absolute reticulocyte count <60,000/μL). In the era of effective immunosuppressive therapies, absolute numbers of reticulocytes (>25,000/μL) and lymphocytes (>1000/μL) may be better predictors of response to treatment and long-term outcome.

Other prognostic factors include the presence of a PNH clone, short telomeres on presentation, and somatically mutated white cells. Even small PNH clones may indicate an immune pathophysiology and responsiveness to immunosuppressive therapies. Telomere shortening in most patients likely reflects stem cell reserve, regenerative stress, and susceptibility to chromosomal instability. Collectively, the presence of mutations in the same myeloid neoplasia genes that are mutated in clonal hematopoiesis of indeterminate potential (*ASXL1*, *DNMT3A*) is associated with worse prognosis and clonal evolution.

TREATMENT

Aplastic Anemia

Severe acquired aplastic anemia can be cured by replacement of the absent hematopoietic cells (and the immune system) by stem cell transplant, or it can be ameliorated by suppression of the immune system to allow recovery of the patient's residual bone marrow function. Glucocorticoids are not of value as primary therapy. Suspect exposures to drugs or chemicals should be discontinued; however, spontaneous recovery of severe blood count depression is rare, and a waiting period before beginning treatment may not be advisable unless the blood counts are only modestly depressed.

HEMATOPOIETIC STEM CELL TRANSPLANTATION

This is the first choice for the younger patient with a fully histocompatible sibling donor **(Chap. 114)**. HLA typing should be ordered as soon as the diagnosis of aplastic anemia is established in a child or younger adult. In transplant candidates, transfusion of blood from family members should be avoided so as to prevent sensitization to histocompatibility antigens. In general, limited numbers of blood

products probably do not greatly affect outcome, especially when blood products are depleted of leukocytes. For allogeneic transplant from fully matched siblings, long-term survival rates for children are ~90%. Transplant morbidity and mortality are increased among adults, due to the higher risk of chronic GVHD and infections. Nevertheless, transplant should be considered early in all but the most elderly, including from alternative donors.

Most patients do not have a suitable sibling donor. Occasionally, a full phenotypic match can be found within the family and serve as well. Matched unrelated donors in large registries are available for the majority of Caucasian patients. With high-resolution matching at HLA, outcomes are similar to those with sibling donors, although complications (mainly GVHD and infection) are more frequent. Cord blood also can be a source of stem cells, especially for children. Matched unrelated donor transplants are often considered as initial treatment in children and as salvage therapy for adults after failed immunosuppression. Transplantation from an HLA haploidentical family donor is increasingly popular, as a donor is almost always quickly available. There is large experience in China, where lymphocyte depletion is usually performed before donor cell infusion. Posttransplant cyclophosphamide appears effective in preventing GVHD. Transplant protocols for marrow failure now usually do not include radiation in order to avoid late occurrence of cancer.

IMMUNOSUPPRESSION

The standard regimen of antithymocyte globulin (ATG) in combination with cyclosporine induces hematologic recovery (independence from transfusion and a leukocyte count adequate to prevent infection) in 60–70% of patients. Children do especially well, whereas older adult patients can suffer complications due to the presence of comorbidities. An early robust hematologic response correlates with long-term survival. Improvement in granulocyte number is generally apparent within 2 months of treatment. Most recovered patients continue to have some degree of blood count depression, the MCV remains elevated, and bone marrow cellularity returns toward normal very slowly if at all. Relapse (recurrent pancytopenia) is frequent, often occurring as cyclosporine is tapered or discontinued; most, but not all, patients respond to reinstitution of immunosuppression, but some responders become dependent on continued cyclosporine administration. "Clonal evolution," isolated chromosomal abnormalities or the development of MDS, with typical cytogenetic aberrations and abnormal marrow morphology, occurs in ~15% of treated patients over a decade following initiation of ATG, usually but not invariably associated with a return of pancytopenia, and some patients develop leukemia. A laboratory diagnosis of PNH can generally be made at the time of presentation of aplastic anemia by flow cytometry; recovered patients may have frank hemolysis if the PNH clone expands. Bone marrow examinations should be performed if there is an unfavorable change in blood counts.

Horse ATG is administered as intravenous infusions and requires hospitalization. Rabbit ATG is much less effective, perhaps because it reduces T-regulatory cell numbers in patients. Serum sickness, a flulike illness with a characteristic cutaneous eruption and arthralgia, may develop ~10 days after initiating treatment. Methylprednisolone is administered with ATG to ameliorate the immune consequences of heterologous protein infusion. (Excessive or extended glucocorticoid therapy is associated with avascular joint necrosis.) Cyclosporine is administered orally at an initial high dose, with subsequent adjustment according to blood levels. Its most important side effects are nephrotoxicity, hypertension, and seizures.

Most patients with aplastic anemia lack a suitable marrow donor, and immunosuppression is the treatment of choice. Overall survival is equivalent with transplantation and immunosuppression. However, successful transplant cures marrow failure, whereas patients who recover adequate blood counts after immunosuppression remain at risk of relapse and malignant evolution. Increasing age and the severity of neutropenia are the most important factors weighing in the decision between transplant and immunosuppression in adults who have a matched family donor: older patients do better with ATG and cyclosporine, whereas transplant is preferred if neutropenia is profound.

ELTROMBOPAG

Hematopoietic growth factors (HGFs) such as erythropoietin (EPO) and granulocyte colony-stimulating factor (G-CSF) are not effective in aplastic anemia, probably because endogenous blood levels in patients are extremely high. Circulating thrombopoietin is also elevated, but a thrombopoietin mimetic showed unexpected activity in refractory disease, producing robust, trilineage, and usually durable hematologic responses. Likely the mechanism of action of thrombopoietin mimetics is stimulation of the hematopoietic stem cell, but iron chelation and increased regulatory T cells are also possibly beneficial effects. Eltrombopag added to first-line immunosuppression with horse ATG markedly increased overall and complete response rates, to about 80% and 50%, respectively. Eltrombopag is approved by the U.S. Food and Drug Administration (FDA) as monotherapy for refractory aplastic anemia and in combination with horse ATG and cyclosporine as initial therapy.

Transplant from a suitable donor is preferred in the young patient, whereas immunosuppression is preferred in the older adult. Even heavily transfused and infected patients in whom immunosuppression has failed can be salvaged by stem cell transplant later.

ANDROGENS

The effectiveness of androgens has not been verified in controlled trials, but occasional patients will respond or even demonstrate blood count dependence on continued therapy. Sex hormones upregulate telomerase gene activity in vitro, which is possibly also their mechanism of action in improving marrow function. For patients with moderate disease, especially if a telomere gene defect is present, a 3- to 4-month trial may improve all blood counts **(Chap. 470)**.

SUPPORTIVE CARE

Meticulous medical attention is required so that the patient may survive to benefit from definitive therapy or, having failed treatment, to maintain a reasonable existence in the face of pancytopenia. First and most important, infection in the presence of severe neutropenia must be aggressively treated by prompt institution of parenteral, broad-spectrum antibiotics. Therapy is empirical and must not await results of culture, although specific foci of infection such as oropharyngeal or anorectal abscesses, pneumonia, sinusitis, and typhlitis (necrotizing colitis) should be sought on physical examination and with radiographic studies. When indwelling plastic catheters become contaminated, vancomycin should be added. Persistent or recrudescent fever implies fungal disease: *Candida* and *Aspergillus* are common, especially after several courses of antibacterial antibiotics. A major reason for the improved prognosis in aplastic anemia has been the development of better antifungal drugs and the timely institution of such therapy when infection is suspected. Granulocyte transfusions can be effective when bacterial or fungal infection is progressive or refractory to antibiotics. Hand washing, the single best method of preventing the spread of infection, remains a neglected practice. Nonabsorbed antibiotics for gut decontamination are poorly tolerated and unproven, nor does reverse isolation reduce mortality from infections.

Both platelet and erythrocyte numbers can be maintained by transfusion. Alloimmunization historically limited the usefulness of platelet transfusions and is now minimized by several strategies, including use of single donors to reduce exposure and physical or chemical methods to diminish leukocytes in the product; HLA-matched platelets are usually effective in patients refractory to random donor products. Inhibitors of fibrinolysis such as aminocaproic acid have not been shown to relieve mucosal oozing; the use of low-dose glucocorticoids to induce "vascular stability" is unproven and not recommended. With prophylactic platelet transfusions, the

goal is to maintain the platelet count >10,000/μL (oozing from the gut increases sharply at counts <5000/μL). Menstruation should be suppressed either by oral estrogens or nasal follicle-stimulating hormone/luteinizing hormone antagonists. Aspirin and other nonsteroidal anti-inflammatory agents must be avoided in the presence of thrombocytopenia.

RBCs should be transfused so as to allow patient a normal level of activity, usually at a hemoglobin value of 70 g/L (90 g/L if there is underlying cardiac or pulmonary disease); a regimen of 2 units every 2 weeks will replace normal losses in a patient without a functioning bone marrow. In chronic anemia, the iron chelators deferoxamine and deferasirox should be added at approximately the fiftieth transfusion to avoid secondary hemochromatosis.

PURE RED CELL APLASIA

Other more restricted forms of marrow failure occur, in which only a single cell type is affected and the marrow shows corresponding absence or decreased numbers of specific precursor cells: aregenerative anemia as in PRCA (see below), thrombocytopenia with amegakaryocytosis **(Chap. 115)**, and neutropenia without marrow myeloid cells in agranulocytosis **(Chap. 64)**. In general, and in contrast to aplastic anemia and MDS, the unaffected lineages appear quantitatively and qualitatively normal. Agranulocytosis, the most frequent of these syndromes, is usually a complication of medical drug use, either by a mechanism of direct chemical toxicity or by immune destruction. Agranulocytosis has an incidence similar to aplastic anemia (but geographically more frequent in Europe than in Asia); in contrast to aplastic anemia, agranulocytosis is more prevalent among older adults and in women. Agranulocytosis should resolve with discontinuation of exposure, but significant mortality is attached to neutropenia in the older and often previously unwell patient. Both pure white cell aplasia (agranulocytosis without incriminating drug exposure) and amegakaryocytic thrombocytopenia are exceedingly rare and, like PRCA, appear to be due to a destructive immune response. In all of the single-lineage failure syndromes, progression to pancytopenia or leukemia is unusual.

DEFINITION AND DIFFERENTIAL DIAGNOSIS

PRCA is characterized by anemia, reticulocytopenia, and absent or rare erythroid precursor cells in the bone marrow. The classification of PRCA is shown in **Table 102-4**. In adults, PRCA is acquired. An identical syndrome can occur constitutionally: Diamond-Blackfan anemia, or congenital PRCA, is diagnosed at birth or in early childhood and often responds to glucocorticoid treatment; mutations in ribosome protein genes are etiologic. Temporary red cell failure occurs in transient aplastic crisis of hemolytic anemias due to acute parvovirus infection **(Chap. 197)** and in transient erythroblastopenia of childhood, which occurs in normal children.

CLINICAL ASSOCIATIONS AND ETIOLOGY

PRCA has important associations with immune system diseases. A minority of cases occur with a thymoma. More frequently, red cell aplasia can be the major manifestation of large granular lymphocytosis or complicates chronic lymphocytic leukemia. Some patients may be hypogammaglobulinemic. A ribosomal protein gene is deleted in the 5q- syndrome, such that the MDS may manifest as an acquired red cell aplasia. Occasionally (as compared to agranulocytosis), PRCA can be due to an idiosyncratic drug reaction. Subcutaneous administration of EPO has provoked PRCA mediated by neutralizing antibodies to the hormone. PRCA due to antibodies to blood group antigens (isoagglutins) is a complication of allogeneic stem cell transplant. For most PRCAs, T-cell inhibition is probably the prevalent immune mechanism.

PERSISTENT PARVOVIRUS B19 INFECTION

Chronic parvovirus infection is a treatable cause of red cell aplasia. This common virus causes a benign exanthem of childhood (fifth disease) and a polyarthralgia/arthritis syndrome in adults. In patients with underlying hemolysis (or any condition that increases demand for RBC production), parvovirus infection can cause a transient aplastic crisis and an abrupt but temporary worsening of the anemia due to failed erythropoiesis. In normal individuals, acute infection is resolved by production of neutralizing antibodies to the virus, but in the setting of congenital, acquired, or iatrogenic immunodeficiency, persistent viral infection may occur. The bone marrow shows red cell aplasia and the presence of giant pronormoblasts **(Fig. 102-2)**, which is the cytopathic sign of B19 parvovirus infection. Viral tropism for human erythroid progenitor cells is due to its use of erythrocyte P antigen as a cellular receptor for entry. Direct cytotoxicity of virus causes anemia if demands on erythrocyte production are high; in normal individuals, the temporary cessation of red cell production is not clinically apparent, and skin and joint symptoms are mediated by immune complex deposition.

TABLE 102-4 Classification of Pure Red Cell Aplasia

Self-limited
Transient erythroblastopenia of childhood
Transient aplastic crisis of hemolysis (acute B19 parvovirus infection)
Fetal red blood cell aplasia
Nonimmune hydrops fetalis (in utero B19 parvovirus infection)
Constitutional pure red cell aplasia
Congenital pure red cell aplasia (Diamond-Blackfan anemia)
Acquired pure red cell aplasia
MDS (5q- syndrome)
Cancer
Thymoma
Lymphoid malignancies (and more rarely other hematologic diseases)
Paraneoplastic to solid tumors
Connective tissue disorders with immunologic abnormalities
Systemic lupus erythematosus, juvenile rheumatoid arthritis, rheumatoid arthritis
Multiple endocrine gland insufficiency
Viruses
Persistent B19 parvovirus, hepatitis, adult T-cell leukemia virus, Epstein-Barr virus
Pregnancy
Drugs
Especially phenytoin, azathioprine, chloramphenicol, procainamide, isoniazid
Antibodies to erythropoietin
Idiopathic (immune)

TREATMENT

Pure Red Cell Aplasia

History, physical examination, and routine laboratory studies may disclose an underlying disease or a drug exposure. Thymoma should be sought by radiographic procedures; tumor excision is indicated, but anemia does not necessarily improve with surgery. The diagnosis of parvovirus infection requires detection of viral DNA sequences in the blood (IgG and IgM antibodies are commonly absent). The presence of erythroid colonies has been considered predictive of response to immunosuppressive therapy in idiopathic PRCA.

Red cell aplasia is compatible with long-term survival with supportive care alone: a combination of erythrocyte transfusions and iron chelation. For persistent B19 parvovirus infection, almost all patients respond to intravenous immunoglobulin therapy. The majority of patients with acquired PRCA respond favorably to immunosuppression: glucocorticoids, cyclosporine, ATG, azathioprine, and cyclophosphamide are effective.

clinical outcomes will be increasingly important in defining classification, prognosis, and targeting therapy.

The diagnosis of MDS can be a challenge, even for the expert, because sometimes subtle clinical and pathologic features must be distinguished, and precise diagnostic categorization requires a hematopathologist knowledgeable in the latest classification scheme. Unfortunately, agreement among pathologists on morphologic features and classification is imperfect; changes in the appearance of megakaryocytes are more reliable than loss of granules in neutrophil precursors or dyserythropoiesis. Further, dysplastic changes can be observed in normal individuals, and they can occur with vitamin deficiencies and as drug effects. Genomic testing is increasingly routine and can be difficult to interpret, as in differences between somatic and germline mutations, pathogenic mutations versus those of unknown significance (clonal hematopoiesis increases in frequency with age and involves genetic changes that may be clinically silent or convey an increased risk of hematologic malignancy), and clone size and changes over time. It is important that the internist and primary care physician be sufficiently familiar with MDS to expedite referral to a hematologist because many new therapies are now available to improve hematopoietic function and the judicious use of supportive care can improve the patient's quality of life.

MYELODYSPLASTIC SYNDROMES

DEFINITION

The MDS are a heterogeneous group of hematologic disorders characterized by both (1) cytopenias due to bone marrow failure and (2) a high risk of development of AML. Anemia due to ineffective erythropoiesis, often with thrombocytopenia and neutropenia, occurs with dysmorphic (abnormal appearing) and usually cellular bone marrow, or with specific chromosome abnormalities or acquired mutations. In patients with "low-risk" MDS, marrow failure dominates the clinical course. In other patients, myeloblasts are present at diagnosis, chromosomes are abnormal, and the "high risk" is due to leukemic progression. MDS may be fatal due, most often, to complications of pancytopenia or to progression to leukemia, but a large proportion of patients will die of concurrent disease, the comorbidities typical in an elderly population. A useful nosology of these often-confusing entities was first developed by the French-American-British Cooperative Group in 1983. Five subtypes were defined then: refractory anemia (RA), refractory anemia with ringed sideroblasts (RARS), refractory anemia with excess blasts (RAEB), refractory anemia with excess blasts in transformation (RAEB-t), and chronic myelomonocytic leukemia (CMML). The World Health Organization (WHO) classification (2002) recognized that the distinction between RAEB-t and AML was arbitrary, grouped them together as acute leukemia, and clarified that CMML behaves as a myeloproliferative disease. The current WHO classification of 2016 is more refined but also more complicated **(Table 102-5)**: blast percentage remains critical in defining MDS categories; erythroid predominant leukemias are now largely regarded as MDS; defining cytogenetic abnormalities are reaffirmed; and a single somatic mutation, in *SF3B1*, is now a feature of sideroblastic anemias. Identification of somatically mutated genes and their correlation with

EPIDEMIOLOGY

MDS is a disease of the elderly; the mean age at onset is older than 70 years. There is a slight male predominance. MDS is a relatively common form of bone marrow failure, with reported incidence rates of 35 to >100 per million persons in the general population and 120 to >500 per million in older adults. Estimates of incidence in the United States range from 30,000 to 40,000 new cases annually and a prevalence of 60,000–120,000 in the population. Rates of MDS have increased over time due to better recognition of the syndrome by physicians and an aging population.

MDS is rare in children, in whom it often has a constitutional genetic basis that can be identified on genomic screens of myeloid cancer predisposition panels.

Secondary or therapy-related MDS, usually related to previous iatrogenic exposure to alkylating agents and other chemotherapy as well as radiation, is not age related.

ETIOLOGY AND PATHOPHYSIOLOGY

MDS is associated with environmental exposures such as radiation and benzene; other risk factors have been reported inconsistently. Secondary, therapy-related MDS occurs as a late toxicity of cancer treatment; radiation and the radiomimetic alkylating agents such as busulfan, nitrosourea, or procarbazine (with a latent period of 5–7 years); or the DNA topoisomerase inhibitors (2-year latency). Acquired aplastic anemia, Fanconi anemia, and other constitutional marrow failure diseases can evolve into MDS; occasionally, MDS in adults is recognized as due to germline *GATA2*, *RUNX1,* or telomere gene mutations. The typical MDS patient does not have a suggestive environmental exposure history or a preceding hematologic disease. MDS is a disease of aging, consistent with accumulation of mutations within a hematopoietic stem cell in an aging marrow environment.

TABLE 102-5 World Health Organization (WHO) Classification of Myelodysplastic Syndromes (MDS)/Neoplasms

NAME	RING SIDEROBLASTS	MYELOBLASTS	KARYOTYPE
MDS with single lineage dysplasia (MDS-SLD)	<15% (<5%)[a]	BM <5%, PB <1%, no Auer rods	Any, unless fulfills all criteria for MDS with isolated del(5q)
MDS with multilineage dysplasia (MDS-MLD)	<15% (<5%)[a]	BM <5%, PB <1%, no Auer rods	Any, unless fulfills all criteria for MDS with isolated del(5q)
MDS with ring sideroblasts (MDS-RS)			
MDS-RS with single lineage dysplasia (MDS-RS-SLD)	≥15% / ≥5%[a]	BM <5%, PB <1%, no Auer rods	Any, unless fulfills all criteria for MDS with isolated del(5q)
MDS-RS with multilineage dysplasia (MDS-RS-MLD)	≥15% / ≥5%[a]	BM <5%, PB <1%, no Auer rods	Any, unless fulfills all criteria for MDS with isolated del(5q)
MDS with isolated del(5q)	None or any	BM <5%, PB <1%, no Auer rods	del(5q) alone or with 1 additional abnormality except –7 or del(7q)
MDS with excess blasts (MDS-EB)			
MDS-EB-1	None or any	BM 5–9% or PB 2–4%, no Auer rods	Any
MDS-EB-2	None or any	BM 10–19% or PB 5–19% or Auer rods	Any
MDS, unclassifiable (MDS-U)			
• with 1% blood blasts	None or any	BM <5%, PB = 1%, no Auer rods	Any
• with single lineage dysplasia and pancytopenia	None or any	BM <5%, PB = 1%, no Auer rods	Any
• based on defining cytogenetic abnormality	<15%	BM <5%, PB = 1%, no Auer rods	MDS-defining abnormality
Refractory cytopenia of childhood	None	BM <5%, PB <2%	Any

[a]If *SF3B1* mutation is present.

Abbreviations: BM, bone marrow; PB, peripheral blood.

MDS is a clonal hematopoietic stem cell disorder characterized by disordered cell proliferation, impaired differentiation, and aberrant hematopoiesis, resulting in cytopenias and risk of progression to leukemia. Both chromosomal and genetic instability have been implicated; both are aging-related. Cytogenetic abnormalities are found in approximately one-half of patients, and some of the same specific lesions are also seen in leukemia; aneuploidy (chromosome loss or gain) is more frequent than translocations. Accelerated telomere attrition may destabilize the genome in marrow failure and predispose to acquisition of chromosomal lesions. Cytogenetic abnormalities are not random (loss of all or part of 5, 7, and 20, trisomy of 8) and may be related to etiology (11q23 following topoisomerase II inhibitors). The type and number of cytogenetic abnormalities strongly correlate with the probability of leukemic transformation and survival.

Genomics has illuminated the role of specific mutations and distinct molecular pathways in the pathophysiology of MDS. Somatic mutations in about 100 genes, which are recurrently present in myeloid neoplasms and are acquired in about 100 genes, are arise in the abnormal marrow cells (and are absent in the germline). Many of the same genes are mutated in AML and in MDS, whereas others are distinctive in subtypes of MDS. A prominent example is *SF3B1*, in which mutations strongly associate with sideroblastic anemia. Some mutations correlate with prognosis: spliceosome defects (like *SF3B1*) correlate with favorable outcome, and mutations in *EZH2, TP53, RUNX1*, and *ASXL1* with poor outcome. Correlation and exclusion in the pattern of mutations indicate a functional genomic architecture. Driver genes mutated early are consistent with normal blood counts and marrow morphology, but these expanded clones of cells containing them are susceptible to malignant transformation with the acquisition of additional mutations. Deep sequencing results in patients whose MDS evolved to AML have shown clonal succession, with founder clones acquiring additional mutations to produce clonal dominance. Mutations and cytogenetic abnormalities are not independent: *TP53* mutations associate with complex cytogenetic abnormalities and *TET2* mutations with normal cytogenetics. The prevalence of abnormal cells by morphology underestimates bone marrow involvement by MDS clones, as cells normal in appearance are derived from the abnormal clones. Presenting and evolving hematologic manifestations result from the accumulation of multiple genetic lesions: loss of tumor-suppressor genes, activating oncogene, epigenetic pathways that affect mRNA processing and methylation status, or other harmful alterations. Pathophysiology has been linked to mutations and chromosome abnormalities in some specific MDS syndromes. The 5q– deletion leads to heterozygous loss of a ribosomal protein gene which mimics constitutional red cell aplasia. An immune pathophysiology may be important in lower risk MDS, as cytopenias can respond to immunosuppressive therapy as administered for aplastic anemia. In general for MDS, the role of the immune system and its cells and cytokines; the role of the hematopoietic stem cell niche, the microenvironment, and cell–cell interactions; the fate of normal cells in the Darwinian competitive environment of the dysplastic marrow; and how mutant cells produce marrow failure in MDS are still not completely understood.

CLINICAL FEATURES

Anemia dominates the early course. Most symptomatic patients complain of the gradual onset of fatigue and weakness, dyspnea, and pallor, but at least one-half of patients are asymptomatic, and their MDS is discovered only incidentally on routine blood counts. Previous chemotherapy or radiation exposure is an important historic fact. Fever and weight loss are more often features of a myeloproliferative rather than myelodysplastic process. MDS in childhood is rare and, when diagnosed, implicates an underlying genetic disease. Children with Down syndrome are susceptible to MDS as well as leukemia. A family history may indicate a hereditary form of sideroblastic anemia, Fanconi anemia, or a telomeropathy. Inherited *GATA2* mutations, as in the MonoMAC syndrome (with increased susceptibility to viral, mycobacterial, and fungal infections, as well as deficient numbers of monocytes, natural killer cells, and B lymphocytes), predispose to MDS. Germline *RUNX1* mutations also confer a high risk of MDS and leukemia, often preceded by years of modest thrombocytopenia. A family history is important in all MDS patients, as constitutional mutations may not result in manifest disease until adulthood.

The physical examination in MDS is remarkable for signs of anemia; approximately 20% of patients have splenomegaly. Some unusual skin lesions, including Sweet's syndrome (febrile neutrophilic dermatosis), occur with MDS. Accompanying autoimmune syndromes are not infrequent. In the younger patient, stereotypical anomalies point to a constitutional syndrome (short stature, abnormal thumbs in Fanconi anemia; early graying in the telomeropathies; cutaneous warts in *GATA2* deficiency).

LABORATORY STUDIES

Blood Anemia is present in most cases, either alone or as part of bi- or pancytopenia; isolated neutropenia or thrombocytopenia is

more unusual. Macrocytosis is common, as in most marrow failure disease. Platelets also are large and lack granules. In functional studies, they may show marked abnormalities, and patients may have bleeding symptoms despite seemingly adequate numbers. Neutrophils are hypogranulated; have hyposegmented, ringed, or abnormally segmented nuclei; contain Döhle bodies; and may be functionally deficient. Circulating myeloblasts usually correlate with marrow blast numbers, and their quantity is important for classification and prognosis. The total white blood cell count (WBC) is usually normal or low, except in CMML. As in aplastic anemia, MDS can be associated with a clonal population of PNH cells. Genetic testing is commercially available for constitutional syndromes.

Bone Marrow The bone marrow is usually normal or hypercellular, but in about 20% of cases, it is sufficiently hypocellular to lead to confusion with aplastic anemia. No single characteristic feature of marrow morphology distinguishes MDS, but the following are commonly observed: dyserythropoietic changes (especially nuclear abnormalities) and ringed sideroblasts in the erythroid lineage; hypogranulation and hyposegmentation in granulocytic precursors, with an increase in myeloblasts; and megakaryocytes showing reduced numbers of or disorganized nuclei. Megaloblastic nuclei and defective hemoglobinization in the erythroid lineage are common. Prognosis strongly correlates with the proportion of marrow blasts, which should be enumerated manually on the marrow smear and by flow cytometry of an aspirate. Flow cytometry can also reveal characteristically aberrant hematopoietic differentiation. Cytogenetics and fluorescent in situ hybridization can identify chromosomal abnormalities.

DIFFERENTIAL DIAGNOSIS

Deficiencies of vitamin B_{12} or folate should be excluded by appropriate blood tests; vitamin B_6 deficiency can be assessed by a therapeutic trial of pyridoxine if the bone marrow shows ringed sideroblasts. Copper deficiency can lead to cytopenias and dysplastic marrows of varying cellularity. Marrow dysplasia can be observed in acute viral infections, drug reactions, or chemical toxicity but should be transient. More difficult are the distinctions between hypocellular MDS and aplasia or between RA with excess blasts and acute leukemia: the WHO considers 20% blasts in the marrow as the criterion that separates AML from MDS. In young patients, underlying, predisposing genetic diseases should be considered and appropriate genomic testing performed (see above).

PROGNOSIS

The median survival varies greatly from years for patients with 5q– or sideroblastic anemia to a few months in RA with excess blasts or severe pancytopenia associated with monosomy 7. The International Prognostic Scoring System (IPSS), revised in 2012 **(Table 102-6)**, assists in making predictions. Even "lower-risk" MDS has significant morbidity and mortality. More refined (and also more complicated) prognostic scoring systems can separate those with intermediate-1 risk who have relatively poor prognoses. Prognostic systems have been developed based on survival from diagnosis, but prognosis changes over time, and hazard ratios for survival and leukemic transformation converge over time among risk categories, consistent with dynamic changes in clonal architecture.

Most patients die as a result of complications of pancytopenia and not due to leukemic transformation; perhaps one-third succumb to diseases unrelated to their MDS. Precipitous worsening of pancytopenia, acquisition of new chromosomal abnormalities on serial cytogenetic determination, increase in the number of blasts, and marrow fibrosis are all poor prognostic indicators. The outlook in therapy-related MDS, regardless of type, is extremely poor, and most patients progress within a few months to refractory AML.

TABLE 102-6 Revised International Prognostic Scoring System (IPSS-R)

1. New marrow blast categories	≤2%, >2%–<5%, 5–10%, >10–30%
2. Refined cytogenetic abnormalities and risk groups	16 (vs 6) specific abnormalities, 5 (vs 3) subgroups[a]
3. Evaluation of depth of cytopenias[b]	Clinically and statistically relevant cut points used
4. Inclusion of differentiating features	Age, performance status, serum ferritin, LDH; β_2-microglobulin
5. Prognostic model with 5 (vs 4) risk categories	Improved predictive power

[a]Good, normal, –Y, del(5q), del (20q); poor, complex (≥3 abnormalities) or chromosome 7 abnormalities; intermediate, all other abnormalities. [b]Cytopenias at baseline, cut points: hemoglobin <80, 80–<100, or ≥100 g/L; platelet count <50, 50–100, or ≥100,000/μL, and absolute neutrophil count <800 versus ≥800/μL.

Abbreviation: LDH, lactate dehydrogenase.

TREATMENT

Myelodysplasia

Historically, therapy of MDS has been unsatisfactory, but several drugs may not only improve blood counts but also delay onset of leukemia and improve survival. The choice of therapy for an individual patient, administration of treatment, and management of toxicities are complicated and require hematologic expertise.

Only hematopoietic stem cell transplantation offers cure of MDS. The survival rate in selected patient cohorts is ~50% at 3 years but improving. Results using unrelated matched donors are similar to those with siblings, and patients in their fifties and older have been successfully transplanted. Nevertheless, treatment-related mortality and morbidity increase with recipient age. The transplant conundrum is that the high-risk patient (by IPSS score and presence of monosomal karyotype), for whom the procedure is most obviously indicated, has a high probability of a poor outcome from transplant-related mortality or disease relapse, whereas the low-risk patient, who is more likely to tolerate transplant, also may do well for years with less aggressive therapies. In practice, only a small proportion of MDS patients undergo transplantation.

MDS has been regarded as particularly refractory to cytotoxic chemotherapy regimens, and as in AML in the older adult, drug toxicity is frequent and often fatal, and remissions, if achieved, are brief. Low doses of cytotoxic drugs have been administered for their "differentiation" potential, and from this experience, drug therapies have emerged based on pyrimidine analogues. These drugs are classified as epigenetic modulators, believed to act through a demethylating mechanism to alter gene regulation and allow differentiation to mature blood cells from the abnormal MDS stem cell. The hypomethylating agents azacitidine and decitabine are frequently used in bone marrow failure clinics. Azacitidine improves blood counts and survival in MDS, compared to best supportive care. Azacitidine is usually administered subcutaneously, daily for 7 days, at 4-week intervals, for at least four cycles before assessing for response. Overall, generally improved blood counts with a decrease in transfusion requirements occurred in ~50% of patients in published trials. Response is dependent on continued drug administration, and most patients eventually become refractory to drug intervention and experience recurrent cytopenias or progression to AML. Decitabine is closely related to azacitidine; 30–50% of patients show responses in blood counts, with a duration of response of almost a year. Decitabine is usually administered by continuous intravenous infusion in regimens of varying doses and durations of 3–10 days in repeating cycles. The major toxicity of azacitidine and decitabine is myelosuppression, leading to worsening blood counts. Hypomethylating agents are frequently used in the high-risk patient who is not a candidate for stem cell transplant. In the lower risk patient, they are also effective, but alternative therapies should be considered.

Lenalidomide, a thalidomide derivative with a more favorable toxicity profile, is particularly effective in reversing anemia in MDS patients with 5q– syndrome; not only do a high proportion of these

patients become transfusion independent with normal or near-normal hemoglobin levels, but their cytogenetics also become normal. The drug has many biologic activities, and it is unclear which is critical for clinical efficacy. Lenalidomide is administered orally. Most patients will improve within 3 months of initiating therapy. Toxicities include myelosuppression (worsening thrombocytopenia and neutropenia, necessitating blood count monitoring) and an increased risk of deep vein thrombosis and pulmonary embolism.

Immunosuppression also may produce sustained independence from transfusion and improve survival. ATG, cyclosporine, and the anti-CD52 monoclonal antibody alemtuzumab are especially effective in younger MDS patients (<60 years old) with more favorable IPSS. In a consortium retrospective review, about 50% of patients with mainly refractory anemia responded to ATG, usually combined with cyclosporine, particularly patients with hypocellular marrow.

HGFs can improve blood counts but, as in most other marrow failure states, have been most beneficial to patients with the least severe pancytopenia. EPO alone or in combination with G-CSF can improve hemoglobin levels, particularly in those with low serum EPO levels who have no or a modest need for transfusions. Survival may be enhanced by EPO and amelioration of anemia. G-CSF treatment alone failed to improve survival in a controlled trial. Thrombopoietin mimetics appear to improve platelet counts in some MDS patients, with no clear evidence that they increase the rate of leukemic transformation.

New drugs for MDS are entering the clinic or are in late development. Luspatercept, which affects transforming growth factor β–mediated suppression of erythropoiesis, has been approved by the FDA for anemia in MDS. Novel targeted therapies in trials include inhibitors of hypoxia-inducible factor and spliceosome genes, drugs that act to restore TP53 activity, and venetoclax, an inhibitor of the bcl2 protein that increases programmed cell death (and is approved for use or employed off-label in other hematologic malignancies).

The same principles of supportive care described for aplastic anemia apply to MDS. Many patients will be anemic for years. RBC transfusion support should be accompanied by iron chelation to prevent secondary hemochromatosis.

MYELOPHTHISIC ANEMIAS

Fibrosis of the bone marrow (see **Fig. 100-2**), usually accompanied by a characteristic blood smear picture called *leukoerythroblastosis*, can occur as a primary hematologic disease, called *myelofibrosis* or *myeloid metaplasia* **(Chap. 103)**, and as a secondary process, called *myelophthisis*. Myelophthisis, or secondary myelofibrosis, is reactive. Fibrosis can be a response to invading tumor cells, usually an epithelial cancer of breast, lung, or prostate origin or neuroblastoma. Marrow fibrosis may occur with infection of mycobacteria (both *Mycobacterium tuberculosis* and *Mycobacterium avium*), fungi, or HIV and in sarcoidosis. Intracellular lipid deposition in Gaucher disease and obliteration of the marrow space related to absence of osteoclast remodeling in congenital osteopetrosis also can produce fibrosis. Secondary myelofibrosis is a late consequence of radiation therapy or treatment with radiomimetic drugs. Usually the infectious or malignant underlying processes are obvious. Marrow fibrosis can also be a feature of a variety of hematologic syndromes, especially chronic myeloid leukemia, multiple myeloma, lymphomas, myeloma, and hairy cell leukemia.

The pathophysiology has three distinct features: proliferation of fibroblasts in the marrow space (myelofibrosis); the extension of hematopoiesis into the long bones and into extramedullary sites, usually the spleen, liver, and lymph nodes (myeloid metaplasia); and ineffective erythropoiesis. The etiology of the fibrosis is unknown but most likely involves dysregulated production of growth factors: platelet-derived growth factor and transforming growth factor β have been implicated. Abnormal regulation of other hematopoietins would lead to localization of blood-producing cells in nonhematopoietic tissues and uncoupling of the usually balanced processes of stem cell proliferation and differentiation. Myelofibrosis is remarkable for pancytopenia despite very large numbers of circulating hematopoietic progenitor cells.

Anemia is dominant in secondary myelofibrosis, usually normocytic and normochromic. The diagnosis is suggested by the characteristic leukoerythroblastic smear (see **Fig. 100-1**). Erythrocyte morphology is highly abnormal, with circulating nucleated RBCs, teardrops, and shape distortions. WBC numbers are often elevated, sometimes mimicking a leukemoid reaction, with circulating myelocytes, promyelocytes, and myeloblasts. Platelets may be abundant and are often of giant size. Inability to aspirate the bone marrow, the characteristic "dry tap," can allow a presumptive diagnosis in the appropriate setting before the biopsy is decalcified.

The course of secondary myelofibrosis is determined by its etiology, usually a metastatic tumor or an advanced hematologic malignancy. Treatable causes must be excluded, especially tuberculosis and fungus. Transfusion support can relieve symptoms.

103 Polycythemia Vera and Other Myeloproliferative Neoplasms

Jerry L. Spivak

The World Health Organization (WHO) classification of the chronic myeloproliferative neoplasms (MPNs) includes eight disorders, some of which are rare or poorly characterized **(Table 103-1)** but all of which share an origin in a hematopoietic cell; overproduction of one or more of the formed elements of the blood without significant dysplasia; and a predilection to extramedullary hematopoiesis, myelofibrosis, and transformation at varying rates to acute leukemia. Within this broad classification, however, significant phenotypic heterogeneity exists. Some diseases such as chronic myelogenous leukemia (CML), chronic neutrophilic leukemia (CNL), and chronic eosinophilic leukemia (CEL) express primarily a myeloid phenotype, whereas in other diseases, such as polycythemia vera (PV), primary myelofibrosis (PMF), and essential thrombocytosis (ET), erythroid or megakaryocytic

TABLE 103-1 World Health Organization Classification of Chronic Myeloproliferative Neoplasms

Essential thrombocytosis
Mastocytosis
Myeloproliferative neoplasms, unclassifiable

hyperplasia predominates. The latter three disorders, in contrast to the former three, also appear capable of transforming into each other.

Such phenotypic heterogeneity has a genetic basis; CML is the consequence of the balanced translocation between chromosomes 9 and 22 (t[9;22][q34;11]); CNL has been associated with a t(15;19) translocation; and CEL occurs with a deletion or balanced translocations involving the *PDGFRα* gene. By contrast, PV, PMF, and ET are characterized by driver mutations that directly or indirectly constitutively activate JAK2, a tyrosine kinase essential for the function of the erythropoietin and thrombopoietin receptors and also utilized by the granulocyte colony-stimulating factor receptor. This important distinction is reflected in the natural histories of CML, CNL, and CEL, which are usually measured in years, with a high rate of leukemic transformation. The natural histories of PV, PMF, and ET, by contrast, are usually measured in decades, and transformation to acute leukemia is uncommon in the absence of chemotherapy. This chapter focuses only on PV, PMF, and ET because their clinical features and driver mutation overlap are substantial, although their disease duration varies.

The other chronic MPNs will be discussed in **Chaps. 105** and **110**.

POLYCYTHEMIA VERA

PV is a clonal hematopoietic stem cell disorder in which phenotypically normal red cells, granulocytes, and platelets accumulate in the absence of a recognizable physiologic stimulus. The most common of the MPNs, PV occurs in 2.5 per 100,000 persons, sparing no adult age group and increasing with age to rates >10/100,000. Familial transmission is infrequent, and women under age 50 predominate among sporadic cases.

ETIOLOGY

Nonrandom chromosome abnormalities such as deletion 20q and deletion 13q or trisomy 9 occur in up to 30% of untreated PV patients, but unlike CML, no consistent cytogenetic abnormality has been associated with the disorder. However, a mutation in the autoinhibitory pseudokinase domain of the tyrosine kinase JAK2 that replaces valine with phenylalanine (V617F), causing constitutive kinase activation, has a central role in PV pathogenesis.

JAK2 is a member of an evolutionarily well-conserved, nonreceptor tyrosine kinase family and serves as the cognate tyrosine kinase for the erythropoietin and thrombopoietin receptors. It also functions as an obligate chaperone for these receptors in the Golgi apparatus and is responsible for their cell-surface expression. The conformational change induced in the erythropoietin and thrombopoietin receptors following binding to their respective cognate ligands, erythropoietin or thrombopoietin, leads to JAK2 autophosphorylation, receptor phosphorylation, and phosphorylation of proteins involved in cell proliferation, differentiation, and resistance to apoptosis. Transgenic animals lacking *JAK2* die as embryos from severe anemia. Constitutive activation of JAK2, on the other hand, explains the erythropoietin hypersensitivity, erythropoietin-independent erythroid colony formation, rapid terminal differentiation, increased Bcl-X_L expression, and apoptosis resistance in the absence of erythropoietin that characterize the in vitro behavior of PV erythroid progenitor cells.

More than 95% of PV patients express this mutation, as do ~50% of PMF and ET patients. Importantly, the *JAK2* gene is located on the short arm of chromosome 9, and loss of heterozygosity on chromosome 9p involving the segment containing the *JAK2* locus over time due to mitotic recombination (uniparental disomy) is the most common cytogenetic abnormality in PV. Loss of heterozygosity in this region leads to homozygosity for *JAK2* V617F and occurs in ~60% of PV patients and to a lesser extent in PMF but is rare in ET. Most PV patients who do not express *JAK2* V617F express a mutation in exon 12 of the gene and are not clinically different from those who do, with the exception of a higher frequency of isolated erythrocytosis, nor do *JAK2* V617F heterozygotes differ clinically from homozygotes. Importantly, the predisposition to acquire *JAK2* mutations appears to be associated with a specific *JAK2* gene haplotype, GGCC. *JAK2* V617F is the basis for many of the phenotypic and biochemical characteristics of PV such as increased blood cell production and increased inflammatory cytokine production; however, it cannot solely account for the entire PV phenotype and is probably not the initiating lesion in any of the MPNs. First, PV patients with the same phenotype and documented clonal disease can have mutations in *LNK*, a JAK2 inhibitor, or rarely, calreticulin (*CALR*), an ER chaperone. Second, ET and PMF patients have the same mutation but different clinical phenotypes. Third, familial PV can occur without the mutation, even when other members of the same family express it. Fourth, inhibition of *JAK2* V617F–expressing hematopoietic progenitor cells by the nonspecific JAK1/2 kinase inhibitor, ruxolitinib, does not affect the behavior of the involved hematopoietic stem cells. Finally, in some *JAK2* V617F–positive PV or ET patients, acute leukemia can occur in a *JAK2* V617F–negative progenitor cell, suggesting the presence of an ancestral precursor cell.

CLINICAL FEATURES

Although PV is a panmyelopathy, isolated thrombocytosis, leukocytosis, or splenomegaly may be its initial presenting manifestation, but most often, the disorder is first recognized by the incidental discovery of a high hemoglobin, hematocrit, or red cell count. With the exception of aquagenic pruritus, or erythromelalgia, no symptoms distinguish PV from other causes of erythrocytosis.

Uncontrolled erythrocytosis causes hyperviscosity, leading to neurologic symptoms such as vertigo, tinnitus, headache, visual disturbances, and transient ischemic attacks (TIAs). Systolic hypertension is also a feature of the red cell mass elevation. In some patients, venous or arterial thrombosis may be the presenting manifestation of PV. Any vessel can be affected, but cerebral, cardiac, and mesenteric vessels are most commonly involved. Hepatic venous thrombosis (Budd-Chiari syndrome) is particularly common in young women and may be catastrophic if sudden and complete obstruction of the hepatic vein occurs. Indeed, PV should be suspected in any patient who develops hepatic vein thrombosis, since this is the only type of thrombosis associated with *JAK2* V617F expression. Digital ischemia, easy bruising, epistaxis, acid-peptic disease, or gastrointestinal hemorrhage may occur due to vascular stasis or thrombocytosis. In the latter instance, absorption and proteolysis of high-molecular-weight von Willebrand multimers by the large platelet mass cause acquired von Willebrand's disease. Erythema, burning, and pain in the extremities, a symptom complex known as erythromelalgia, is another complication of thrombocytosis in PV due to increased platelet stickiness. Given the large turnover of hematopoietic cells, hyperuricemia with secondary gout, uric acid stones, and symptoms due to hypermetabolism can also complicate the disorder.

DIAGNOSIS

When PV presents with erythrocytosis in combination with leukocytosis, thrombocytosis, or splenomegaly or any combination of these, the diagnosis is apparent. However, when patients present with an elevated hemoglobin, hematocrit, or red cell count alone, the diagnostic evaluation is more complex because of the many diagnostic possibilities **(Table 103-2)**. Furthermore, unless the hemoglobin level is ≥20 g/dL (hematocrit ≥60%), it is not possible to distinguish true erythrocytosis from disorders causing plasma volume contraction. This is because uniquely in PV, in contrast to other causes of true erythrocytosis, there is expansion of the plasma volume, which can mask the elevated red cell mass, particularly in women; thus, red cell mass and plasma

volume determinations are necessary to establish the presence of an absolute erythrocytosis and distinguish this from relative erythrocytosis due to a reduction in plasma volume alone (also known as *stress* or *spurious erythrocytosis* or *Gaisböck's syndrome*). **Figure 63-18** illustrates a diagnostic algorithm for the evaluation of suspected erythrocytosis. Assay for *JAK2* mutations in the presence of a normal arterial oxygen saturation provides an alternative diagnostic approach to erythrocytosis when red cell mass and plasma volume determinations are not available; a normal serum erythropoietin level does not exclude the presence of PV, but an elevated erythropoietin level is more consistent with a secondary cause for the erythrocytosis.

Other laboratory studies that may aid in diagnosis include the red cell count, mean corpuscular volume, and red cell distribution width (RDW), particularly when the hematocrit or hemoglobin levels are less than 60% or 20 g/dL, respectively. Only three situations cause microcytic erythrocytosis: β-thalassemia trait, hypoxic erythrocytosis, and PV. With β-thalassemia trait, the RDW is usually normal, whereas with hypoxic erythrocytosis and PV, the RDW may be elevated due to associated iron deficiency. Today, however, the assay for *JAK2* V617F has superseded other tests for establishing the diagnosis of PV. Of course, in patients with associated acid-peptic disease, occult gastrointestinal bleeding may lead to a presentation with hypochromic, microcytic anemia, masking the presence of PV.

A bone marrow aspirate and biopsy provide no specific diagnostic information because these may be normal or indistinguishable from ET or PMF. Similarly, no specific cytogenetic abnormality is associated with the disease, and the absence of a cytogenetic marker does not exclude the diagnosis.

COMPLICATIONS

Many of the clinical complications of PV relate directly to the increase in blood viscosity associated with red cell mass elevation and indirectly to the increased turnover of red cells, leukocytes, and platelets with the attendant increase in uric acid and inflammatory cytokine production. The latter appears to be responsible for constitutional symptoms. Peptic ulcer disease can also be due to *Helicobacter pylori* infection, the incidence of which is increased in PV, while the pruritus associated with this disorder may be a consequence of mast cell activation by *JAK2* V617F. A sudden increase in spleen size can be associated with painful splenic infarction. Myelofibrosis appears to be part of the natural history of the disease but is a reactive, reversible process that does not itself impede hematopoiesis and by itself has no prognostic significance. In ~15% of patients, however, myelofibrosis is associated with hematopoietic stem cell failure, manifested by substantial extramedullary hematopoiesis in the liver and spleen and transfusion-dependent anemia. The organomegaly can cause significant mechanical discomfort, portal hypertension, and progressive cachexia. Although the incidence of acute myeloid leukemia is increased in PV, the incidence of acute leukemia in patients not exposed to chemotherapy or radiation therapy is low. Interestingly, chemotherapy, including hydroxyurea, has been associated with acute leukemia in *JAK2* V617F–negative stem cells in some PV patients. *Erythromelalgia* is a curious syndrome of unknown etiology associated with thrombocytosis, primarily involving the lower extremities and usually manifested by erythema, warmth, and pain of the affected appendage and occasionally digital infarction. It occurs with a variable frequency and is usually responsive to salicylates. Some of the central nervous system symptoms observed in patients with PV, such as ocular migraine, appear to represent a variant of erythromelalgia.

Left uncontrolled, erythrocytosis can lead to thrombosis involving vital organs such as the liver, heart, brain, or lungs. Patients with massive splenomegaly are particularly prone to thrombotic events because the associated increase in plasma volume masks the true extent of the red cell mass elevation measured by the hematocrit or hemoglobin level. A "normal" hematocrit or hemoglobin level in a PV patient with massive splenomegaly should be considered indicative of an elevated red cell mass until proven otherwise.

TREATMENT

Polycythemia Vera

PV is generally an indolent disorder, the clinical course of which is measured in decades, and its management should reflect its tempo. Thrombosis due to erythrocytosis is the most significant complication and often the presenting manifestation; maintenance of the hemoglobin level at ≤140 g/L (14 g/dL; hematocrit <45%) in men and ≤120 g/L (12 g/dL; hematocrit <42%) in women is mandatory to avoid thrombotic complications. Phlebotomy serves initially to reduce hyperviscosity by reducing the red cell mass to normal while further expanding the plasma volume. Periodic phlebotomies thereafter serve to maintain the red cell mass within the normal range and induce a state of iron deficiency that prevents accelerated reexpansion of the red cell mass. In most PV patients, once an iron-deficient state is achieved, phlebotomy is usually only required at 3-month intervals. Neither phlebotomy nor iron deficiency increases the platelet count relative to the effect of the disease itself, and neither thrombocytosis nor leukocytosis is correlated with thrombosis in PV, in contrast to the strong correlation between erythrocytosis and thrombosis. The use of salicylates to prevent thrombosis in PV patients is not only potentially harmful if the red cell mass is not controlled by phlebotomy but also an unproven remedy, particularly in patients over age 70.

Anticoagulation is indicated when a thrombosis has occurred, and the newer oral anticoagulants may be preferable to a vitamin K antagonist since they do not require monitoring. Asymptomatic hyperuricemia (<10 mg/dL) requires no therapy, but allopurinol should be administered to avoid further elevation of the uric acid when chemotherapy is used to reduce splenomegaly or leukocytosis or to treat pruritus. Generalized pruritus intractable to antihistamines or antidepressants such as doxepin can be a major problem in PV; the JAK1/2 inhibitor ruxolitinib, pegylated interferon α (IFN-α), psoralens with ultraviolet light in the A range (PUVA) therapy, and hydroxyurea are other methods of palliation. Asymptomatic thrombocytosis requires no therapy unless the platelet count is sufficiently high to cause bleeding due to acquired von Willebrand's disease, but bleeding in this situation is not usually spontaneous and is responsive to tranexamic acid or ε-aminocaproic acid. Symptomatic

splenomegaly can be treated with either ruxolitinib or pegylated IFN-α. Pegylated IFN-α has the advantage over recombinant IFN-α of being better tolerated and requiring only weekly administration and produced complete hematologic and molecular remissions in ~20% of PV patients; its role in this disorder is currently under investigation. Anagrelide, a phosphodiesterase inhibitor, can reduce the platelet count and, if tolerated, is preferable to hydroxyurea because it lacks marrow toxicity and is also protective against venous thrombosis while hydroxyurea is not.

A reduction in platelet number may be necessary for the treatment of erythromelalgia or ocular migraine if salicylates are not effective or if the platelet count is sufficiently high to increase the risk of hemorrhage but only to the degree that symptoms are alleviated. Alkylating agents and radioactive sodium phosphate (^{32}P) are leukemogenic in PV, and their use should be avoided. If a cytotoxic agent must be used, hydroxyurea is preferred, but this drug does not prevent either thrombosis or myelofibrosis in PV, is itself leukemogenic, and should be used for as short a time as possible. Previously, PV patients with massive splenomegaly unresponsive to reduction by chemotherapy or interferon required splenectomy. However, with the introduction of the nonspecific JAK2 inhibitor ruxolitinib, it has been possible in the majority of patients with PV complicated by myelofibrosis and myeloid metaplasia to reduce spleen size while at the same time alleviating constitutional symptoms and pruritus due to cytokine release and reducing the phlebotomy requirement. However, in contrast to PMF, these patients have a more chronic course. In contrast to other malignancies, PV patients have a low rate of mutation accumulation, and the acquisition of deleterious mutations such as *TP*53 mutations as detected by next-generation sequencing is usually associated with leukemic transformation. Since hydroxyurea antagonizes *TP53* and also causes del17p, leading to *TP53* haploinsufficiency, its use should be constrained in PV.

Ruxolitinib has also been demonstrated in a phase 3 clinical trial to be effective in PV patients without myelofibrosis who are intolerant or refractory to hydroxyurea or best available supportive therapy. In some patients with end-stage disease, pulmonary hypertension may develop due to fibrosis or extramedullary hematopoiesis. A role for bone marrow transplantation, either allogeneic or haploidentical, in PV has not been defined.

Most patients with PV can live long lives without functional impairment when their red cell mass is effectively managed with phlebotomy alone. Chemotherapy is never indicated to control the red cell mass in PV, but when venous access is an issue, ruxolitinib or pegylated interferon is the preferred therapy.

PRIMARY MYELOFIBROSIS

Chronic PMF (other designations include *idiopathic myelofibrosis*, *agnogenic myeloid metaplasia*, or *myelofibrosis with myeloid metaplasia*) is a clonal hematopoietic stem cell disorder associated with mutations in *JAK2, MPL*, or *CALR* and characterized by marrow fibrosis, extramedullary hematopoiesis, and splenomegaly. PMF is the least common MPN, and establishing its diagnosis in the absence of a specific clonal marker is difficult because myelofibrosis and splenomegaly are also features of both PV and CML. Furthermore, myelofibrosis and splenomegaly also occur in a variety of benign and malignant disorders **(Table 103-3)**, many of which are amenable to specific therapies not effective in PMF. In contrast to the other MPNs and so-called acute or malignant myelofibrosis, which can occur at any age, PMF primarily afflicts men in their sixth decade or later.

ETIOLOGY

Nonrandom chromosome abnormalities such as 9p, 20q−, 13q−, trisomy 8 or 9, or partial trisomy 1q are common in PMF, but no cytogenetic abnormality specific to the disease has been identified. *JAK2* V617F is present in ~55% of PMF patients, and mutations in the thrombopoietin receptor, *MPL*, occur in ~4%. Most of the rest have mutations in the calreticulin gene (*CALR*) that alter the carboxy-terminal portion of the protein, permitting it to bind and activate MPL.

TABLE 103-3 Disorders Causing Myelofibrosis

MALIGNANT	NONMALIGNANT
Acute leukemia (lymphocytic, myelogenous, megakaryocytic)	HIV infection
Chronic myeloid leukemia	Hyperparathyroidism
Hairy cell leukemia	Renal osteodystrophy
Hodgkin's disease	Systemic lupus erythematosus
Primary myelofibrosis	Tuberculosis
Lymphoma	Vitamin D deficiency
Multiple myeloma	Thorium dioxide exposure
Myelodysplasia	Gray platelet syndrome
Metastatic carcinoma	
Polycythemia vera	
Systemic mastocytosis	

The degree of myelofibrosis and the extent of extramedullary hematopoiesis are not related. Fibrosis in this disorder is associated with overproduction of transforming growth factor β and tissue inhibitors of metalloproteinases, while osteosclerosis is associated with overproduction of osteoprotegerin, an osteoclast inhibitor. Marrow angiogenesis occurs due to increased production of vascular endothelial growth factor. Importantly, fibroblasts in PMF are polyclonal and not part of the neoplastic clone but can be induced by it to produce inflammatory cytokines.

CLINICAL FEATURES

No signs or symptoms are specific for PMF. Many patients are asymptomatic at presentation, and the disease is often detected by the discovery of splenic enlargement and/or abnormal blood counts during a routine examination. In contrast to its companion MPN, night sweats, fatigue, and weight loss are common presenting complaints. A blood smear will show the characteristic features of extramedullary hematopoiesis: teardrop-shaped red cells, nucleated red cells, myelocytes, and promyelocytes; myeloblasts may also be present **(Fig. 103-1)**. Anemia, usually mild initially, is common, whereas the leukocyte and platelet counts are either normal or increased, but either can be depressed. Mild hepatomegaly may accompany the splenomegaly but is unusual in its absence; isolated lymphadenopathy should suggest another diagnosis. Both serum lactate dehydrogenase and alkaline phosphatase levels can be elevated. Marrow is usually inaspirable due to the myelofibrosis **(Fig. 103-2)**, and bone x-rays may reveal osteosclerosis. Exuberant extramedullary hematopoiesis can cause ascites; portal, pulmonary, or

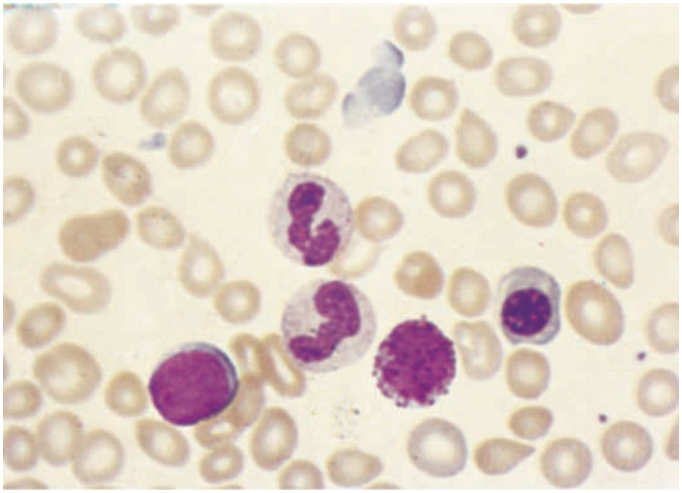

FIGURE 103-1 Teardrop-shaped red blood cells indicative of membrane damage from passage through the spleen, a nucleated red blood cell, and immature myeloid cells indicative of extramedullary hematopoiesis are noted. This peripheral blood smear is related to any cause of extramedullary hematopoiesis.

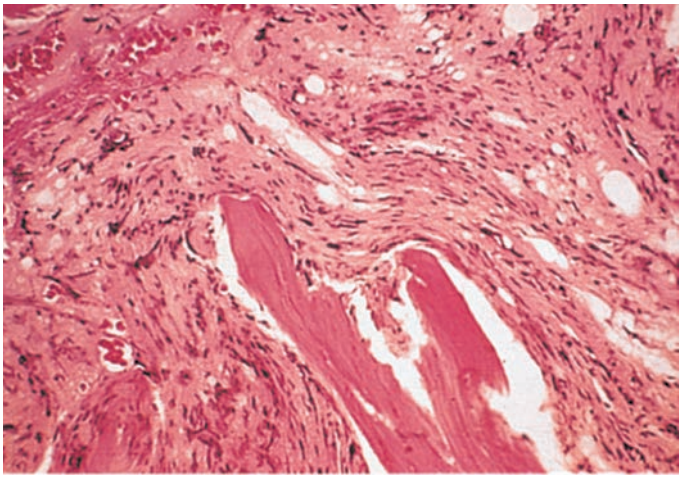

FIGURE 103-2 This marrow section shows the marrow cavity replaced by fibrous tissue composed of reticulin fibers and collagen. When this fibrosis is due to a primary hematologic process, it is called *myelofibrosis*. When the fibrosis is secondary to a tumor or a granulomatous process, it is called *myelophthisis*.

intracranial hypertension; intestinal or ureteral obstruction; pericardial tamponade; spinal cord compression; or skin nodules. Splenic enlargement can be sufficiently rapid to cause splenic infarction with fever and pleuritic chest pain. Hyperuricemia and secondary gout may ensue.

DIAGNOSIS

While the clinical picture described above is characteristic of PMF, all of these clinical features can be observed in PV or CML. Massive splenomegaly commonly masks erythrocytosis in PV, and reports of intraabdominal thrombosis in PMF most likely represent instances of unrecognized PV. In some PMF patients, erythrocytosis has developed during the course of the disease. Furthermore, because many other disorders have features that overlap with PMF but respond to distinctly different therapies, the diagnosis of PMF is one of exclusion, which requires that the disorders listed in Table 103-3 be ruled out.

The presence of teardrop-shaped red cells, nucleated red cells, myelocytes, and promyelocytes establishes the presence of extramedullary hematopoiesis, while the presence of leukocytosis, thrombocytosis with large and bizarre platelets, and circulating myelocytes suggests the presence of an MPN as opposed to a secondary form of myelofibrosis (Table 103-3). Marrow is usually inaspirable due to increased marrow reticulin, but marrow biopsy will reveal a hypercellular marrow with trilineage hyperplasia and, in particular, increased numbers of megakaryocytes in clusters and with large, dysplastic nuclei. However, there are no characteristic bone marrow morphologic abnormalities that distinguish PMF from the other MPNs. Splenomegaly due to extramedullary hematopoiesis may be sufficiently massive to cause portal hypertension and variceal formation. In some patients, exuberant extramedullary hematopoiesis can dominate the clinical picture. An intriguing feature of PMF is the occurrence of autoimmune abnormalities such as immune complexes, antinuclear antibodies, rheumatoid factor, or a positive Coombs' test. Whether these represent a host reaction to the disorder or are involved in its pathogenesis is unknown. Cytogenetic analysis of the blood is useful both to exclude CML and for prognostic purposes because the development of complex karyotype abnormalities portends a poor prognosis in PMF. For unknown reasons, the number of circulating CD34+ cells is markedly increased in PMF (>15,000/μL) compared to the other MPNs, unless they too develop extramedullary hematopoiesis.

Importantly, ~55% of PMF patients, like patients with its companion MPNs, express the *JAK2* V617F mutation, often as homozygotes. Such patients are usually older and have higher hematocrits than patients with *MPL* (4%) or *CALR* (36%) mutations; PMF patients expressing an *MPL* mutation tend to be more anemic and have lower leukocyte counts than *JAK2* V617F–positive patients. Somatic mutations (due to deletions [type 1] or insertions [type 2]) in exon 9 of *CALR* have been found in a majority of patients with PMF who lack mutations in either *JAK2* or *MPL*. In some studies, type 1 mutations, the most common *CALR* mutation in PMF, had a survival advantage compared to *JAK2* or *MPL* mutations but not with respect to leukemic transformation. PMF patients who lack a known MPN driver mutation appear to have the worst prognosis.

TABLE 103-4 Three Current Scoring Systems for Estimating Prognosis in PMF Patients

RISK FACTOR	IPSS (2009)[a]	DIPSS (2010)[b]	DIPSS PLUS (2011)[c]
Anemia (<10 g/dL)	X	X	X
Leukocytosis (>25,000/μL)	X	X	X
Peripheral blood blasts (≥1%)	X	X	X
Constitutional symptoms	X	X	X
Age (>65 years)	X	X	X
Unfavorable karyotype			X
Platelet count (<100,000/μL)			X
Transfusion dependence			X

[a]Blood 113:2895, 2009. [b]Blood 115:1703, 2010. [c]J Clin Oncol 29:392, 2011.

Note: The Dynamic International Prognostic Scoring System (DIPSS) was developed to determine if the International Prognostic Scoring System (IPSS) risk factors identified as important for survival at the time of primary myelofibrosis (PMF) diagnosis could also be used for risk stratification following their acquisition during the course of the disease. One point is assigned to each risk factor for IPSS scoring. For DIPSS, the same is true, but anemia is assigned 2 points. The DIPSS Plus scoring system represents recognition that the addition of unfavorable karyotype, thrombocytopenia, and transfusion dependence improved the DIPSS risk stratification system for which additional points are assigned (Table 103-5). More recent studies suggest that mutational analysis of the *ASXL1, EZH2, SRSF2,* and *IDH1/2* genes further improves risk stratification for survival and leukemic transformation (Leukemia 27:1861, 2013), as can cytogenetic abnormalities (Leukemia 32:1631, 2018). These prognostic scoring systems are not accurate for risk assessment in polycythemia vera or essential thrombocytosis patients who have developed myelofibrosis (Haematologica 99:e55, 2014).

COMPLICATIONS

Survival in PMF varies according to specific risk factors at diagnosis (Tables 103-4 and 103-5) but is shorter than in PV and ET patients. The natural history of PMF is one of increasing marrow failure with transfusion-dependent anemia and increasing organomegaly due to extramedullary hematopoiesis. As with CML, PMF can evolve from a chronic to an accelerated phase with constitutional symptoms and increasing marrow failure. About 10% of patients spontaneously transform to an aggressive form of acute leukemia for which therapy is usually ineffective. Additional important prognostic factors for disease acceleration during the course of PMF include the presence of complex cytogenetic abnormalities, thrombocytopenia, and transfusion-dependent anemia. Mutations in the *ASXL1*, *EZH2*, *SRSF2*, and *IDH1/2* genes have been identified as risk factors for early death or transformation to acute leukemia, as have complex cytogenetic abnormalities, and have proved to be more useful for PMF risk assessment than clinical scoring systems.

TABLE 103-5 IPSS and DIPSS Risk Stratification Systems

RISK CATEGORIES[a]	NUMBER OF RISK FACTORS		
	IPSS	DIPSS	DIPSS PLUS
Low	0	0	0
Intermediate-1	1	1–2	1
Intermediate-2	2	3–4	2–3
High	≥3	>4	4–6

[a]The corresponding survival curves for each risk category can be found in the references cited in the footnotes of Table 103-4.

Abbreviations: DIPSS, Dynamic International Prognostic Scoring System; IPSS, International Prognostic Scoring System.

TREATMENT

Primary Myelofibrosis

No specific therapy exists for PMF. The causes for anemia are multifarious and include ineffective erythropoiesis uncompensated by splenic extramedullary hematopoiesis, hemodilution due to splenomegaly, splenic sequestration, blood loss secondary to thrombocytopenia or portal hypertension, folic acid deficiency, systemic inflammation, and autoimmune hemolysis. Neither recombinant erythropoietin nor androgens such as danazol have proven to be consistently effective as therapy for anemia. Erythropoietin may worsen splenomegaly and will be ineffective if the serum erythropoietin level is >125 mU/L. Given the inflammatory milieu that characterizes PMF, glucocorticoids can ameliorate anemia as well as constitutional symptoms such as fever, chills, night sweats, anorexia, and weight loss, and combining these with low-dose thalidomide has proved effective as well. Thrombocytopenia can be due to impaired marrow function, splenic sequestration, or autoimmune destruction and may also respond to low-dose thalidomide and prednisone.

Splenomegaly is by far the most distressing and intractable problem for PMF patients, causing abdominal pain, portal hypertension, easy satiety, and cachexia, whereas surgical removal of a massive spleen is associated with significant postoperative complications including mesenteric venous thrombosis, hemorrhage, rebound leukocytosis and thrombocytosis, and hepatic extramedullary hematopoiesis with no amelioration of either anemia or thrombocytopenia when present. For unexplained reasons, splenectomy also increases the risk of blastic transformation.

Splenic irradiation is, at best, temporarily palliative and associated with a significant risk of neutropenia, infection, and subsequent operative hemorrhage if splenectomy is attempted. Allopurinol can control significant hyperuricemia, and bone pain can be alleviated by local irradiation. Pegylated IFN-α can ameliorate fibrosis in early PMF, but in advanced disease, it may exacerbate the bone marrow failure. The JAK2 inhibitor ruxolitinib has proved effective in reducing splenomegaly and alleviating constitutional symptoms in a majority of advanced PMF patients while possibly prolonging survival, although it usually does not significantly influence the *JAK2* V617F neutrophil allele burden. Although anemia and thrombocytopenia are its major side effects, these are dose-dependent, and with time, anemia stabilizes and thrombocytopenia may improve. Fedratinib, a new tyrosine kinase inhibitor with anti-FLT3 activity, has proved useful in patients with disease refractory to ruxolitinib.

In some patients, hypomethylating agents such as azacytidine or decitabine in combination with high-dose ruxolitinib have been used to control the disease or prepare patients for bone marrow transplantation. Transformation to acute leukemia in PMF, like PV or ET, is usually refractory to treatment.

Allogeneic bone marrow transplantation is the only curative treatment for PMF and should be considered in younger patients and older patients with high-risk disease; nonmyeloablative conditioning regimens permit hematopoietic cell transplantation to be extended to older individuals.

ESSENTIAL THROMBOCYTOSIS

ET (other designations include *essential thrombocythemia*, *idiopathic thrombocytosis*, *primary thrombocytosis*, and *hemorrhagic thrombocythemia*) is a clonal hematopoietic stem cell disorder associated with mutations in *JAK2* (V617F), *MPL*, or *CALR* and manifested clinically by overproduction of platelets without a definable cause. ET has an incidence of 1–2/100,000 and a distinct female predominance. Canonical MPN driver mutations distinguish 90% of ET patients from the more common nonclonal, reactive forms of thrombocytosis **(Table 103-6)**; mutation-negative ET patients may have either uncommon *MPL* mutations, *JAK2* V617F expression limited to the platelets, or a hereditary form of thrombocytosis. Once considered a disease of the elderly and responsible for significant morbidity due to hemorrhage or thrombosis, it is now clear that ET can occur at any age in adults and often without symptoms or disturbances of hemostasis. There is an unexplained female predominance in contrast to PMF or the reactive forms of thrombocytosis where no sex difference exists. Because no specific clonal marker is available, clinical and laboratory criteria have been proposed to distinguish ET from other MPNs, which may also present with initially with isolated thrombocytosis but have differing prognoses and therapies (Table 103-6). These criteria are useful in identifying disorders such as CML, PV, PMF, or myelodysplasia, which can masquerade as ET. Furthermore, as with "idiopathic" erythrocytosis, nonclonal benign forms of thrombocytosis exist (e.g., hereditary overproduction of thrombopoietin and those with noncanonical *JAK2* driver mutations) that are not widely recognized because we currently lack diagnostic assays. Approximately 50% of ET patients express *JAK2* V617F, 30% *CALR* (both type 1 and type 2), and 8% *MPL* mutations. ET patients lacking a canonical MPN driver mutation usually have a benign prognosis.

TABLE 103-6 Causes of Thrombocytosis

Tissue inflammation: collagen vascular disease, inflammatory bowel disease	Hemorrhage
Malignancy	Iron-deficiency anemia
Infection	Surgery
Myeloproliferative disorders: polycythemia vera, primary myelofibrosis, essential thrombocytosis, chronic myelogenous leukemia	Rebound: Correction of vitamin B_{12} or folate deficiency, post-ethanol abuse
Myelodysplastic disorders: 5q– syndrome, idiopathic refractory sideroblastic anemia	Hemolysis
Postsplenectomy or hyposplenism	Familial: Thrombopoietin overproduction, *JAK2* or *MPL* mutations

ETIOLOGY

Megakaryocytopoiesis and platelet production depend on thrombopoietin and its receptor MPL. As in the case of early erythroid and myeloid progenitor cells, early megakaryocytic progenitors require the presence of interleukin 3 (IL-3) and stem cell factor for optimal proliferation in addition to thrombopoietin. Their subsequent terminal development is also enhanced by the chemokine stromal cell-derived factor 1 (SDF-1). Interestingly, terminal megakaryocyte maturation and platelet production do not require thrombopoietin.

Megakaryocytes are unique among hematopoietic progenitor cells because reduplication of their genome is endomitotic rather than mitotic and promoted by thrombopoietin. Unlike erythropoietin, thrombopoietin is produced primarily in the liver but has important functions in the bone marrow where it functions to maintain hematopoietic stem cells quiescent in their endosteal niches; once released from their niches, thrombopoietin promotes the proliferation of these cells in the sinusoidal niche. Like plasma erythropoietin and its target erythroblasts, an inverse correlation exists between the platelet count and plasma thrombopoietin. However, unlike erythropoietin, thrombopoietin is only constitutively produced and the plasma thrombopoietin level is controlled by the size of the platelet and megakaryocyte progenitor cell pools. Also, in contrast to erythropoietin, but like its myeloid counterparts, granulocyte and granulocyte-macrophage colony-stimulating factors, thrombopoietin not only enhances the proliferation of its target cells but also enhances the reactivity of their end-stage product, the platelet. Paradoxically, in the three MPNs, expression of the thrombopoietin receptor, MPL, is impaired and plasma thrombopoietin is increased despite the increased number of megakaryocytes and platelets.

The clonal nature of ET was established by analysis of glucose-6-phosphate dehydrogenase isoenzyme expression in patients hemizygous for this gene. Although thrombocytosis is its principal manifestation,

like the other MPNs, a hematopoietic stem cell is involved in ET. Furthermore, a number of families have been described in which ET was inherited, in one instance as an autosomal dominant trait. In addition to ET, PMF and PV have also been observed in such kindreds.

CLINICAL FEATURES

Clinically, ET is most often identified incidentally when a platelet count is obtained during the course of a routine medical evaluation. Occasionally, review of previous blood counts will reveal that an elevated platelet count was present but overlooked for many years. No symptoms or signs are specific for ET, but these patients can have hemorrhagic and thrombotic tendencies expressed as easy bruising for the former and microvascular occlusive events for the latter such as erythromelalgia, ocular migraine, or a TIA. Physical examination is generally unremarkable. Splenomegaly is indicative of another MPN, in particular PV, PMF, or CML.

Anemia is unusual, but a mild neutrophilic leukocytosis is not. The blood smear is most remarkable for the number of platelets present, some of which may be very large. The large mass of circulating platelets may prevent the accurate measurement of serum potassium due to release of platelet potassium upon blood clotting. This type of hyperkalemia is a test tube artifact and not associated with electrocardiographic abnormalities. Similarly, arterial oxygen measurements can be inaccurate unless thrombocythemic blood is collected on ice. The prothrombin and partial thromboplastin times are normal, whereas abnormalities of platelet function such as a prolonged bleeding time and impaired platelet aggregation can be present. However, despite much study, no platelet function abnormality is characteristic of ET, and no platelet function test predicts the risk of clinically significant bleeding or thrombosis.

The elevated platelet count may hinder marrow aspiration, but marrow biopsy usually reveals megakaryocyte hypertrophy and hyperplasia, as well as an overall increase in marrow cellularity. If marrow reticulin is increased, another diagnosis should be considered. The absence of stainable iron demands an explanation because iron deficiency alone can cause thrombocytosis, and absent marrow iron in the presence of marrow hypercellularity is a feature of PV.

Nonrandom cytogenetic abnormalities occur in ET but are uncommon, and no specific or consistent abnormality is notable, even those involving chromosomes 3 and 1, where the genes for thrombopoietin and its receptor, MPL, respectively, are located.

DIAGNOSIS

Thrombocytosis is encountered in a broad variety of clinical disorders (Table 103-6), in many of which inflammatory cytokine production is increased. The absolute level of the platelet count is not a useful diagnostic aid for distinguishing between benign and clonal causes of thrombocytosis. About 50% of ET patients express the *JAK2* V617F mutation. When *JAK2* V617F is absent, cytogenetic evaluation is mandatory to determine if the thrombocytosis is due to CML or a myelodysplastic disorder such as the 5q– syndrome or sideroblastic anemia. Because the *BCR-ABL* translocation can be present in the absence of the Ph chromosome, and because the *BCR-ABL* reverse transcriptase polymerase chain reaction is associated with false-positive results, fluorescence in situ hybridization (FISH) analysis for *BCR-ABL* is the preferred assay in patients with thrombocytosis in whom a cytogenetic study for the Ph chromosome is negative. *CALR* mutations (type 1 or type 2) are present in 30% and *MPL* mutations are present in 8% of ET patients who do not have a *JAK2* mutation. Anemia and ringed sideroblasts are not features of ET, but they are features of idiopathic refractory sideroblastic anemia, and in some of these patients, the thrombocytosis occurs in association with expression of *JAK2* V617F, *CALR*, or an *MPL* mutation. Significant splenomegaly should suggest the presence of another MPN, and in this setting, a red cell mass determination should be performed because splenomegaly can mask the presence of erythrocytosis. Importantly, what appears to be ET can evolve into PV (usually in women with *JAK2* V617F) or PMF (usually in men with type 1 *CALR* mutations) after a period of many years due to clonal evolution or succession. There is sufficient overlap of the *JAK2* V617F neutrophil allele burden between ET and PV that this cannot be used as a distinguishing diagnostic feature with the exception that, in ET, the quantitative *JAK2* V617F neutrophil allele is never greater than 50%; only a red cell mass and plasma volume determination can distinguish PV from ET, and importantly in this regard, 64% of *JAK2* V617F–positive ET patients in one study actually were found to have PV when red cell mass and plasma volume determinations were performed. Claims that ET and PV form a biological continuum are unfounded as these disorders have different gene expression profiles and different natural histories.

COMPLICATIONS

Perhaps no other condition in clinical medicine has caused otherwise astute physicians to intervene inappropriately more often than thrombocytosis, particularly if the platelet count is $>1 \times 10^6/\mu L$. It is commonly believed that a high platelet count causes thrombosis; however, no controlled clinical study has ever established this association, and in patients younger than age 60 years, the incidence of thrombosis was not greater in patients with thrombocytosis than in age-matched controls, and tobacco use appears to be the most important risk factor for thrombosis in ET patients.

To the contrary, very high platelet counts are associated primarily with hemorrhage due to acquired von Willebrand's disease. This is not meant to imply that an elevated platelet count cannot cause symptoms in an ET patient, but rather that the focus should be on the patient, not the platelet count. For example, some of the most dramatic neurologic problems in ET are migraine-related and respond only to lowering of the platelet count, whereas other symptoms such as erythromelalgia respond simply to platelet cyclooxygenase-1 inhibitors such as aspirin or ibuprofen, without a reduction in platelet number. Still others may represent an interaction between an atherosclerotic vascular system and a high platelet count, and others may have no relationship to the platelet count whatsoever. Recognition that PV can present with thrombocytosis alone as well as the discovery of previously unrecognized causes of hypercoagulability **(Chaps. 116 and 117)** make the older literature on the complications of thrombocytosis unreliable.

TREATMENT

Essential Thrombocytosis

Survival of ET patients is not different than the general population regardless of their driver mutation. An elevated platelet count in an asymptomatic patient without cardiovascular risk factors or tobacco use requires no therapy. Indeed, before any therapy is initiated in a patient with thrombocytosis, the cause of symptoms must be clearly identified as due to the elevated platelet count. When the platelet count rises above $1 \times 10^6/\mu L$, a substantial quantity of high-molecular-weight von Willebrand multimers are removed from the circulation and destroyed by the enlarged platelet mass, resulting in an acquired form of von Willebrand's disease. This can be identified by a reduction in ristocetin cofactor activity. In this situation, aspirin could promote hemorrhage. Bleeding in this situation is rarely spontaneous and usually responds to tranexamic acid or ε-aminocaproic acid, which can be given prophylactically before and after elective surgery.

Plateletpheresis is at best a temporary and inefficient remedy that is rarely required. Importantly, ET patients treated with ^{32}P or alkylating agents are at risk of developing acute leukemia without any proof of benefit; combining either therapy with hydroxyurea increases this risk. If platelet reduction is deemed necessary on the basis of symptoms refractory to salicylates alone, pegylated IFN-α, the quinazoline derivative anagrelide, or hydroxyurea can be used to reduce the platelet count, but none of these is uniformly effective or without significant side effects. Hydroxyurea and aspirin were more effective than anagrelide and aspirin for prevention of TIA because hydroxyurea is a nitric oxide donor, but they were not more effective for the prevention of other types of arterial thrombosis and actually less effective for venous thrombosis. The risk of

gastrointestinal bleeding is also higher when aspirin is combined with anagrelide. Normalizing the platelet count does not prevent either arterial or venous thrombosis. Pegylated interferon can produce a complete molecular remission in some ET patients, but a role for it or ruxolitinib in ET management has not yet been established.

As more clinical experience is acquired, ET appears more benign than previously thought. Evolution to acute leukemia is more likely to be a consequence of therapy than of the disease itself. In managing patients with thrombocytosis, the physician's first obligation is to do no harm.

104 Acute Myeloid Leukemia

William Blum

INCIDENCE

Acute myeloid leukemia (AML) is a neoplasm characterized by infiltration of the blood, bone marrow, and other tissues by proliferative, clonal, poorly differentiated cells of the hematopoietic system. These leukemias comprise a spectrum of malignancies that untreated are uniformly fatal. In 2020, the estimated number of new AML cases in the United States was 19,940. AML is the diagnosis in 1.3% of all cancer cases and 31% of all new acute leukemias but causes 62% of leukemic deaths. AML is the most common acute leukemia in older patients, with a median age at diagnosis of 67 years. Long-term survival is infrequent; U.S. registry data report that only 27% of patients survive 5 years.

ETIOLOGY

Most cases of AML are idiopathic. Genetic predisposition, radiation, chemical/other occupational exposures, and drugs have been implicated in the development of AML, but AML cases with established etiology are relatively rare. No direct evidence suggests a viral etiology. Genome sequencing studies suggest that most cases of AML arise from a limited number of mutations that accumulate with advancing age. Indeed, genome sequencing is providing paradigm-shifting advances in our understanding of leukemogenesis. The Cancer Genome Atlas (TCGA) and other databases demonstrate that blood cells from up to 5–6% of normal individuals aged >70 years contain potentially "premalignant" mutations that are associated with clonal expansion.

Use of the term *premalignant* to describe these lesions is not precisely accurate; rather, these mutations represent clonal hematopoiesis of *indeterminate* potential (CHIP; sometimes called age-related clonal hematopoiesis). The genes most commonly altered include the epigenetic regulators *DNMT3A, TET2,* and *ASXL1.*

Study of CHIP is important because CHIP has relevance not just to blood cancer evolution but also other medical conditions. Clonal expansion driven by the acquisition of new mutations is associated with a 10-fold increase in risk for developing a hematologic malignancy (compared to matched patients without CHIP), but it is clear that additional "hits" must occur to drive toward leukemia. We do not yet fully understand why or how these secondary lesions occur. Patients with CHIP also have increased risk of cardiovascular mortality that is not fully explained. The link between these two seemingly unrelated issues (cardiovascular and hematologic malignancy) may lie in understanding the interactions between circulating clonally expanded blood cells and vascular endothelium. A "proinflammatory" state caused by clonal, infiltrating monocytes leads to accelerated atherosclerotic plaque development and altered cardiac remodeling. Similar phenomena may occur in the marrow and blood—altered relationships between hematopoietic stem cells with the marrow microenvironment along with altered immune surveillance. Both increase the likelihood that a clone may survive, acquire additional mutations, and then further expand eventually to leukemia. Whether early identification of CHIP in patients will provide therapeutic opportunities for patients remains to be seen. Certainly, modifying cardiovascular risk in patients with CHIP seems prudent, but development of mutation-directed therapies to eliminate problematic clones to prevent leukemia is likely to be more elusive.

Genetic Predisposition Myeloid neoplasms typically occur sporadically in adults; inherited predisposition is rare. Yet, it is clear that myeloid neoplasms with germline predisposition represent an important and growing subset of disease. Germline mutations associated with increased risk of developing a myeloid neoplasm include *CEBPA*, *DDX41*, *RUNX1*, *ANKRD26*, *ETV6*, and *GATA2* **(Table 104-1)**. Likewise, myeloid neoplasms with germline predisposition are a feature of several well-described clinical syndromes, including bone marrow failure disorders (e.g., Fanconi anemia, Shwachman-Diamond syndrome, Diamond-Blackfan anemia) and telomere biology disorders (e.g., dyskeratosis congenita). As new mutations and associations are added to a rapidly growing list, it is increasingly clear that genetic predisposition plays a larger role than has been previously understood.

Several genetic syndromes with somatic cell chromosome aneuploidy, such as Down syndrome with trisomy 21, are associated with an increased incidence of AML. Down syndrome–associated AML in young children (<4 years) is typically of the acute megakaryocytic subtype and is associated with mutation in the *GATA1* gene. Such

TABLE 104-1 WHO 2016 Classification of Myeloid Neoplasms with Germline Predisposition

CLASSIFICATION[a]
Myeloid neoplasms with germline predisposition without a preexisting disorder or organ dysfunction
Acute myeloid leukemia with germline *CEBPA* mutation
Myeloid neoplasms with germline *DDX41* mutation[b]
Myeloid neoplasms with germline predisposition and preexisting platelet disorders
Myeloid neoplasms with germline *RUNX1* mutation[b]
Myeloid neoplasms with germline *ANKRD26* mutation[b]
Myeloid neoplasms with germline *ETV6* mutation[b]
Myeloid neoplasms with germline predisposition and other organ dysfunction
Myeloid neoplasms with germline *GATA2* mutation
Myeloid neoplasms associated with bone marrow failure syndromes
Myeloid neoplasms associated with telomere biology disorders
Myeloid neoplasms associated with Noonan syndrome
Myeloid neoplasms associated with Down syndrome[b]

[a]Recognition of familial myeloid neoplasms requires that physicians take a thorough patient and family history to assess for typical signs and symptoms of known syndromes, including data on malignancies and previous bleeding episodes. Molecular genetic diagnostics is guided by a detailed patient and family history. Diagnostics should be performed in close collaboration with a genetic counselor; patients with a suspected heritable myeloid neoplasm, who test negative for known predisposition genes, should ideally be entered on a research study to facilitate new syndrome discovery. [b]Lymphoid neoplasms also reported.

Source: Reproduced with permission from L Peterson et al: Myeloid neoplasms with germline predisposition, in *World Health Organization Classification of Tumours of Haematopoietic and Lymphoid Tissues,* 4th revised ed. Geneva, Switzerland: World Health Organization, 2017.

patients have excellent clinical outcomes but require dose modification of chemotherapy due to high treatment-related toxicities. Inherited diseases with defective DNA repair (e.g., Fanconi anemia, Bloom syndrome, and ataxia-telangiectasia) are also associated with AML. Each syndrome is associated with unique clinical features and atypical toxicities with chemotherapy, requiring expert care. Congenital neutropenia (Kostmann syndrome), due to mutations in the genes encoding the granulocyte colony-stimulating factor receptor and neutrophil elastase, is another disorder that may evolve into AML.

Chemical, Radiation, and Other Exposures Anticancer drugs are the leading cause of therapy-associated AML. Alkylating agent–associated leukemias occur on average 4–6 years after exposure, and affected individuals often have multilineage dysplasia and monosomy/aberrations in chromosomes 5 and 7. Topoisomerase II inhibitor–associated leukemias occur 1–3 years after exposure, and affected individuals often have AML with monocytic features and aberrations involving chromosome 11q23. Exposure to ionizing radiation, benzene, chloramphenicol, phenylbutazone, and other drugs can uncommonly result in bone marrow failure that may evolve into AML.

CLASSIFICATION

The current categorization of AML uses the World Health Organization (WHO) classification **(Table 104-2)**, which defines biologically distinct groups based on cytogenetic and molecular abnormalities in addition to clinical features and light microscope morphology. Myeloid neoplasms with germline predisposition, as introduced above, are included as a new and important feature of this classification (Table 104-1).

TABLE 104-2 WHO 2016 Classification of Acute Myeloid Leukemia and Related Neoplasms

Acute myeloid leukemia (AML) with recurrent genetic abnormalities
AML with t(8;21)(q22;q22); *RUNX1-RUNX1T1*
AML with inv(16)(p13.1q22) or t(16;16)(p13.1;q22); *CBFB-MYH11*
Acute promyelocytic leukemia with *PML-RARA*
AML with t(9;11)(p21.3;q23.3); *MLLT3-KMT2A*
AML with t(6;9)(p23;q34.1); *DEK-NUP214*
AML with inv(3)(q21.3q26.2) or t(3;3)(q21.3;q26.2); *GATA2, MECOM*
AML (megakaryoblastic) with t(1;22)(p13.3;q13.3); *RBM15-MKL1*
Provisional entity: AML with BCR-ABL1
AML with mutated *NPM1*
AML with biallelic mutations of *CEBPA*
Provisional entity: AML with mutated RUNX1
AML with myelodysplasia-related changes
Therapy-related myeloid neoplasms
AML, not otherwise specified (NOS)
AML with minimal differentiation
AML without maturation
AML with maturation
Acute myelomonocytic leukemia
Acute monoblastic/monocytic leukemia
Pure erythroid leukemia
Acute megakaryoblastic leukemia
Acute basophilic leukemia
Acute panmyelosis with myelofibrosis
Myeloid sarcoma
Myeloid proliferations related to Down syndrome
Transient abnormal myelopoiesis (TAM)
Myeloid leukemia associated with Down syndrome

Note: Marrow blast count of ≥20% is required, except for AML with the recurrent genetic abnormalities t(15;17), t(8;21), inv(16), or t(16;16).

Source: Adapted from DA Arber et al: Acute myeloid leukaemia (AML) with recurrent genetic abnormalities, in *World Health Organization Classification of Tumours of Haematopoietic and Lymphoid Tissues*, 4th revised ed. Geneva, Switzerland: World Health Organization; 2017.

The WHO classification enables the identification of subsets of disease that may be treated differently (now or in the future) and enhances recognition of the molecular basis of disease from the time of diagnosis. Marrow (or blood) blast count of ≥20% is required to establish the diagnosis of AML, except for AML with the recurrent genetic abnormalities t(15;17), t(8;21), inv(16), or t(16;16).

Clinical Features Even with advances in molecular biology, recognizing clinical features remains important in understanding AML. For example, therapy-related AML is a distinct entity that develops following prior chemotherapy (e.g., alkylating agents, topoisomerase II inhibitors) or ionizing radiation. AML with myelodysplasia-related changes is recognized in part on morphology but also on a medical history of an antecedent myelodysplastic syndrome (MDS) or myelodysplastic/myeloproliferative neoplasm. These clinical features contribute to AML prognosis and are therefore in the WHO classification.

Genetic Findings Subtypes of AML are recognized due to the presence or absence of specific, recurrent cytogenetic, and/or genetic abnormalities. For example, the diagnosis of *acute promyelocytic leukemia* (APL) is based on the presence of either the t(15;17)(q22;q12) cytogenetic rearrangement or the *PML-RARA* fusion product of the translocation. Similarly, core binding factor (CBF) AML is designated based on the presence of t(8;21)(q22;q22), inv(16)(p13.1q22), or t(16;16)(p13.1;q22) or the respective fusion products *RUNX1-RUNX1T1* and *CBFB-MYH11*. Each of these three groups identifies patients with favorable clinical outcomes when appropriately treated.

Several cytogenetic or genetic AML subtypes often associate with a specific morphologic appearance, such as a complex karyotype (and/or mutation of *TP53*) and AML with myelodysplasia-related changes. Patients with such changes typically fare poorly with standard treatments. However, only one abnormality is invariably associated with specific morphologic features: t(15;17)(q22;q12) or the molecular fusion *PML-RARA* with APL. Other cytogenetic and genetic findings may be commonly, but not always, associated with a morphologic description, highlighting the necessity of genetic and cytogenetic testing for precise diagnosis. Several chromosomal abnormalities often associate primarily with one morphologic/immunophenotypic group. Examples include inv(16)(p13.1q22) with AML with abnormal bone marrow eosinophils; t(8;21)(q22;q22) with slender Auer rods, expression of CD19, and increased normal eosinophils; and t(9;11)(p22;q23) and other translocations involving 11q23 with monocytic features. Mutation of nucleophosmin (nucleolar phosphoprotein B23, numatrin, *NPM1*), especially when co-occurring with mutation of fms-related tyrosine kinase 3 (*FLT3*), often presents with "cup-shaped" nuclear morphology. Recurring chromosomal abnormalities in AML may also be loosely associated with specific clinical characteristics. More commonly associated with younger age are t(8;21) and t(15;17), and with older age, del(5q), del(7q), and mutated *TP53*. Myeloid sarcomas are associated with t(8;21); disseminated intravascular coagulation (DIC) is associated with t(15;17). 11q23 aberrations and monocytic leukemia are associated with extramedullary sites of involvement at presentation, especially gingival hypertrophy. High leukocyte count is commonly observed with *NPM1* or *FLT3* mutation.

The WHO classification also incorporates molecular abnormalities by recognizing fusion genes or specific genetic mutations with a role in leukemogenesis. As a classic example, t(15;17) results in the fusion gene *PML-RARA* that encodes a chimeric protein, promyelocytic leukemia (Pml)–retinoic acid receptor α (Rarα), which is formed by the fusion of the retinoic acid receptor α (*RARA*) gene from chromosome 17 and the promyelocytic leukemia (*PML*) gene from chromosome 15. Unique clinical therapy with retinoic acid and arsenic trioxide has revolutionized the care of APL patients (see "Treatment of Acute Promyelocytic Leukemia" section). Similar examples of molecular subtypes included in the category of AML with recurrent genetic abnormalities are those characterized by the leukemogenic fusion genes *RUNX1-RUNX1T1* and *CBFB-MYH11* and the so-called CBF AML subtypes noted cytogenetically as t(8;21), inv(16), or t(16;16). Additional fusions

are *MLLT3-KMT2A* and *DEK-NUP214*, resulting from t(9;11) and t(6;9)(p23;q34), respectively, among others.

The WHO classification of AML continues to expand as knowledge of specific genetic or cytogenetic aberrations grows. Several AML subtypes are defined by the presence of genetic mutations rather than chromosomal aberrations. For example, *AML with mutated NPM1* and *AML with biallelic mutated CEBPA*, respectively, are associated with more favorable clinical outcome, though the presence of coexisting mutation in *FLT3* affects *NPM1* prognostic impact. Activating mutations of *FLT3* are present in ~30% of adult AML patients, primarily due to internal tandem duplications (ITDs) in the juxtamembrane domain that have negative prognostic impact. In contrast, point mutations of the activating loop of the kinase (called tyrosine kinase domain [TKD] mutations) have uncertain prognostic impact. Aberrant activation of the *FLT3*-encoded protein provides increased proliferation and antiapoptotic signals to the myeloid progenitor cell. *FLT3*-ITD, the more common of the *FLT3* mutations, occurs preferentially in patients with cytogenetically normal AML (CN-AML). The importance of identifying *FLT3*-ITD at diagnosis relates to the fact that it is not only useful as a prognosticator but also may predict response to specific treatment such as a tyrosine kinase inhibitor (TKI). Several TKIs targeting FLT3 are either approved for AML (e.g., midostaurin, only in first-line therapy in combination with chemotherapy; gilteritinib, in relapse as monotherapy) or currently in clinical investigation (e.g., quizartinib, crenolanib, sorafenib, and others). The *FLT3* allelic ratio (of the number of mutated alleles to wild-type alleles) provides information beyond the mere presence or absence of the mutation. Several mutational scenarios, such as one mutated gene and one wild-type gene or one mutated gene with no (deleted) wild-type gene, and the ratio of malignant to nonmalignant cells in the sample affect the ratio. The allelic ratio affects the prognostic impact of the *FLT3*-ITD mutation; patients with *FLT3*-ITD "low" allelic ratio (<0.5) fare better. Accordingly, mutated *NPM1* without *FLT3*-ITD or with *FLT3*-ITD^{low} is viewed as favorable risk by the European LeukemiaNet (ELN) risk stratification schema **(Table 104-3)**. Conversely, *FLT3*-ITD^{high} has an adverse prognostic impact; patients with both mutated *NPM1* and *FLT3*-ITD with an allelic ratio >0.5 are intermediate risk by ELN stratification. Involving a different tyrosine kinase, AML with *BCR-ABL1* fusion is a new WHO provisional entity to recognize rare cases that may benefit from *BCR-ABL* TKI therapy (Table 104-2).

Immunophenotypic Findings The immunophenotype of human leukemia cells can be studied by multiparameter flow cytometry after the cells are labeled with monoclonal antibodies to cell-surface antigens. This can be important in quickly distinguishing AML from acute lymphoblastic leukemia and for identifying some subtypes of AML. For example, AML with minimal differentiation, characterized by immature morphology and no lineage-specific cytochemical reactions, may be diagnosed by flow-cytometric demonstration of the myeloid-specific antigens cluster designation (CD) 13 and/or 117. Similarly, acute megakaryoblastic leukemia can often be diagnosed only by expression of the platelet-specific antigens CD41 and/or CD61. Although flow cytometry is widely used, and in some cases essential for the diagnosis of AML, it has only a supportive role in establishing the different subtypes of AML through the WHO classification. Increasingly, multiparameter flow cytometry is used for the measurement of measurable residual disease (MRD) after remission is achieved.

PROGNOSTIC FACTORS

Several factors predict outcome of AML patients treated with chemotherapy; they should be used for risk stratification and treatment guidance.

Chromosome and molecular investigations performed at diagnosis currently provide the most important prognostic information. WHO has categorized patients as having favorable, intermediate, or adverse risk based on the presence of structural and/or numerical chromosomal or genetic aberrations. Patients with t(15;17) have a very good prognosis (~85% cured), and those with t(8;21) and inv(16) have a good prognosis (~55% cured), whereas those with no cytogenetic abnormality have an intermediate outcome risk (~40% cured). Patients with a *TP53* mutation, complex karyotype, t(6;9), inv(3), or –7 have a very poor prognosis. Another cytogenetic subgroup, the monosomal karyotype, has been suggested to adversely influence the outcome of AML patients other than those with t(15;17), t(8;21), or inv(16) or t(16;16). The monosomal karyotype subgroup is defined by the presence of at least two autosomal monosomies (loss of chromosomes other than Y or X) or a single autosomal monosomy with additional structural abnormalities.

For patients lacking prognostic cytogenetic abnormalities, i.e., those with CN-AML, testing for several mutated genes can help to risk-stratify. In addition to *NPM1* mutation and *FLT3*-ITD as described above, biallelic *CEBPA* mutations have prognostic value. Such mutations predict favorable outcome. Given the proven prognostic importance of *NPM1*, *CEBPA*, and *FLT3*, molecular assessment of these genes at diagnosis has been incorporated into AML management guidelines by the National Comprehensive Cancer Network (NCCN) and the ELN. The same markers help to define genetic groups in the ELN standardized reporting system, which is based on both cytogenetic and molecular abnormalities and is used for comparing clinical features/treatment response among subsets of patients reported across different clinical studies (Table 104-3). These genetic groups should be used for risk stratification and treatment guidance.

TABLE 104-3 2017 European LeukemiaNet Risk Stratification by Genetics for Acute Myeloid Leukemia (AML)[a]

RISK CATEGORY[b]	GENETIC ABNORMALITY
Favorable	t(8;21)(q22;q22); *RUNX1-RUNX1T1*
	inv(16)(p13.1q22) or t(16;16)(p13.1;q22); *CBFB-MYH11*
	Mutated *NPM1* without *FLT3*-ITD or with *FLT3*-ITD$^{low(c)}$
	Biallelic mutated *CEBPA*
Intermediate	Mutated *NPM1* and *FLT3*-ITD$^{high(c)}$
	Wild-type *NPM1* without *FLT3*-ITD or with *FLT3*-ITD$^{low(c)}$ (w/o adverse-risk genetic lesions)
	t(9;11)(p21.3;q23.3); *MLLT3-KMT2A*[d]
	Cytogenetic abnormalities not classified as favorable or adverse
Adverse	t(6;9)(p23;q34.1); *DEK-NUP214*
	t(v;11q23.3); *KMT2A* rearranged
	t(9;22)(q34.1;q11.2); *BCR-ABL1*
	inv(3)(q21.3q26.2) or t(3;3)(q21.3;q26.2); *GATA2, MECOM(EVI1)*
	–5 or del(5q); –7; –17/abn(17p)
	Complex karyotype,[e] monosomal karyotype[f]
	Wild type *NPM1* and *FLT3*-ITD$^{high(c)}$
	Mutated *RUNX1*[g]
	Mutated *ASXL1*[g]
	Mutated *TP53*[h]

[a]This table excludes acute promyelocytic leukemia. Frequencies, response rates, and outcome measures should be reported by risk category and, if sufficient numbers are available, by specific genetic lesions indicated. [b]Prognostic impact of a marker is treatment-dependent and may change with new therapies. [c]Low, low allelic ratio (<0.5); high, high allelic ratio (≥0.5); semiquantitative assessment of *FLT3*-ITD allelic ratio (using DNA fragment analysis) is determined as ratio of the area under the curve (AUC) "*FLT3*-ITD" divided by AUC "*FLT3*-wild type"; recent studies indicate that acute myeloid leukemia with *NPM1* mutation and *FLT3*-ITD low allelic ratio may also have a more favorable prognosis and patients should not routinely be assigned to allogeneic hematopoietic cell transplantation. [d]The presence of t(9;11)(p21.3;q23.3) takes precedence over rare, concurrent adverse-risk gene mutations. [e]Three or more unrelated chromosome abnormalities in the absence of one of the World Health Organization–designated recurring translocations or inversions, i.e., t(8;21), inv(16) or t(16;16), t(9;11), t(v;11)(v;q23.3), t(6;9), inv(3), or t(3;3); AML with *BCR-ABL1*. [f]Defined by the presence of one single monosomy (excluding loss of X or Y) in association with at least one additional monosomy or structural chromosome abnormality (excluding core binding factor AML). [g]These markers should not be used as an adverse prognostic marker if they co-occur with favorable-risk AML subtypes. [h]*TP53* mutations are significantly associated with AML with complex and monosomal karyotype.

TABLE 104-4 Molecular Prognostic Markers in AML[a]

GENE SYMBOL	GENE LOCATION	PROGNOSTIC IMPACT
Genes Included in the WHO Classification and ELN Reporting System		
NPM1 mutations	5q35.1	Favorable
CEBPA mutations	19q13.1	Favorable
FLT3-ITD	13q12	Depends on allelic ratio and *NPM1* mutational status
Genes Encoding Receptor Tyrosine Kinases		
KIT mutation	4q12	Adverse
FLT3-TKD	13q12	Unclear
Genes Encoding Transcription Factors		
RUNX1 mutations	21q22.12	Adverse
WT1 mutations	11p13	Adverse
Genes Encoding Epigenetic Modifiers		
ASXL1 mutations	20q11.21	Adverse
DNMT3A mutations	2p23.3	Adverse
IDH mutations (*IDH1* and *IDH2*)	2q34 & 15q26.1	Adverse
KMT2A-PTD	11q23	Adverse
TET2 mutations	4q24	Adverse
Deregulated Genes		
BAALC overexpression	8q22.3	Adverse
ERG overexpression	21q22.3	Adverse
MN1 overexpression	22q12.1	Adverse
EVI1 overexpression	3q26.2	Adverse
Deregulated MicroRNAs		
miR-155 overexpression	21q21.3	Adverse
miR-3151 overexpression	8q22.3	Adverse
miR-181a overexpression	1q32.1 and 9q33.3	Favorable

[a]This table excludes acute promyelocytic leukemia.

Abbreviations: AML, acute myeloid leukemia; ELN, European LeukemiaNet; ITD, internal tandem duplication; PTD, partial tandem duplication; TKD, tyrosine kinase domain; WHO, World Health Organization.

In addition to *NPM1*, *CEBPA* , *FLT3*, and *TP53* mutations, molecular aberrations in other genes may be routinely used for prognostication (Table 104-4). Among these mutated genes are those encoding receptor tyrosine kinases (*KIT*), transcription factors (*RUNX1* and *WT1*), and epigenetic modifiers (*ASXL1*, *DNMT3A*, isocitrate dehydrogenase 1 [*IDH1*], *IDH2*, *KMT2A* [also known as *MLL*], and *TET2*). Although *KIT* mutations are almost exclusively present in CBF AML and impact adversely the outcome, the remaining markers have been reported primarily in CN-AML. Mutations of *ASXL1* and *RUNX1* are associated with adverse outcome, independent of other prognostic factors. However, for some of these mutations, data remain unclear on the prognostic impact due to conflicting reports (e.g., *TET2*, *IDH1*, *IDH2*). Increasingly, novel drugs that inhibit/modulate aberrant pathways activated by some of these genes (especially *FLT3*, *IDH1*, and *IDH2*) have been remarkably effective in subsets of disease, leading to U.S. Food and Drug Administration approvals (see section on treatment of AML).

In addition to gene mutations, deregulation of the expression levels of coding genes and of short noncoding RNAs (microRNAs) also provides prognostic information (Table 104-4). Overexpression of genes such as *BAALC*, *ERG*, *MN1*, and MDS1 and EVI1 complex locus (*MECOM*; also known as *EVI1*) predict poor outcome, especially in CN-AML. Similarly, deregulated expression levels of microRNAs, naturally occurring noncoding RNAs that regulate the expression of proteins via degradation or translational inhibition of their target coding RNAs, have also been associated with prognosis in AML. Overexpression of *miR-155* and *miR-3151* predicts unfavorable outcome in CN-AML, whereas overexpression of *miR-181a* predicts favorable outcome both in CN-AML and cytogenetically abnormal AML.

Because prognostic molecular markers in AML are not mutually exclusive and often occur concurrently (>80% patients have at least two or more prognostic gene mutations), the likelihood that distinct marker combinations may be more informative than single markers is increasingly clear.

Epigenetic changes (e.g., DNA methylation and/or posttranslational histone modification) and microRNAs are often involved in deregulation of genes involved in hematopoiesis, contribute to leukemogenesis, and may associate with the previously discussed prognostic gene mutations. These changes have been shown to provide biologic insights into leukemogenic mechanisms and provide independent prognostic information. Therapeutic progress based on advances in understanding the role of epigenetic changes in AML is currently unfolding. For example, in patients with mutations of *IDH1* or *IDH2*, novel active enzymes produced from these respective mutations hijack the citric acid cycle, leading to production of a novel "oncometabolite," 2-hydroxyglutarate, which disrupts a myriad of epigenetic processes. Pharmacologic inhibition of these aberrant enzymes can reverse these leukemogenic activities.

In addition to cytogenetic and molecular aberrations, several other factors are associated with outcome in AML. Age at diagnosis is one of the most important risk factors. Advancing age is associated with a poor prognosis for two reasons: (1) its influence on the ability to survive induction therapy due to coexisting medical comorbidities, and (2) with each successive decade of age, a greater proportion of patients have intrinsically more resistant disease. A prolonged symptomatic interval with cytopenias preceding AML diagnosis or a history of antecedent hematologic disorders including MDS or myeloproliferative neoplasms is often found in older patients. Cytopenia is a clinical feature associated with a lower complete remission (CR) rate and shorter survival time. The CR rate is lower in patients who have had anemia, leukopenia, and/or thrombocytopenia for >3 months before the diagnosis of AML, when compared to those without such a history. Responsiveness to chemotherapy declines as the duration of the antecedent disorder increases. Likewise, AML developing after treatment with cytotoxic agents for other malignancies is usually difficult to treat successfully. In addition, older patients less frequently harbor favorable cytogenetic abnormalities (i.e., t[8;21], inv[16], and t[16;16]) and more frequently harbor adverse cytogenetic (e.g., complex and monosomal karyotypes) and/or molecular (e.g., *ASXL1*, *TP53*) abnormalities.

Other factors independently associated with worse outcome are a poor performance status that influences ability to survive induction therapy and a high presenting leukocyte count that in some series is an adverse prognostic factor for attaining a CR. Among patients with hyperleukocytosis (>100,000/μL), early central nervous system bleeding and pulmonary leukostasis contribute to poor outcomes.

Following administration of therapy, achievement of CR is associated with better outcome and longer survival. CR is defined after examination of both blood and bone marrow and essentially represents eradication of detectable leukemia *and* restoration of normal hematopoiesis. The blood neutrophil count must be ≥1000/μL and the platelet count ≥100,000/μL. Hemoglobin concentration is not considered in determining CR. Circulating blasts should be absent. Although rare blasts may be detected in the blood during marrow regeneration, they should disappear on successive studies. At CR, the bone marrow should contain <5% blasts, and Auer rods should be absent. Extramedullary leukemia should not be present.

CLINICAL PRESENTATION

Symptoms Patients with AML usually present with nonspecific symptoms that begin gradually, or abruptly, and are the consequence of anemia, leukocytosis, leukopenia/leukocyte dysfunction, or thrombocytopenia. Nearly half have symptoms for ≤3 months before the leukemia is diagnosed.

Fatigue is a frequent first symptom among AML patients. Anorexia and weight loss are common. Fever with or without an identifiable infection is the initial symptom in ~10% of patients. Signs of abnormal hemostasis (bleeding, easy bruising) are common. Bone pain,

lymphadenopathy, nonspecific cough, headache, or diaphoresis may also occur.

Rarely, patients may present with symptoms from a myeloid sarcoma (a tumor mass consisting of myeloid blasts occurring at anatomic sites other than bone marrow). Sites involved are most commonly the skin, lymph node, gastrointestinal tract, soft tissue, and testis. This rare presentation, often characterized by chromosome aberrations (e.g., monosomy 7, trisomy 8, 11q23 rearrangement, inv[16], trisomy 4, t[8;21]), may precede or coincide with blood and/or marrow involvement by AML. Patients who present with isolated myeloid sarcoma typically develop blood and/or marrow involvement quickly thereafter and cannot be cured with local therapy (radiation or surgery) alone.

Physical Findings Fever, infection, and hemorrhage are often found at the time of diagnosis; splenomegaly, hepatomegaly, lymphadenopathy, and "bone pain" may also be present less commonly. Hemorrhagic complications are most commonly and, classically, found in APL. APL patients often present with DIC-associated minor hemorrhage but may have significant gastrointestinal bleeding, intrapulmonary hemorrhage, or intracranial hemorrhage. Likewise, thrombosis is another less frequent but well recognized clinical feature of DIC in APL. Bleeding associated with coagulopathy may also occur in monocytic AML and with extreme degrees of leukocytosis or thrombocytopenia in other morphologic subtypes. Retinal hemorrhages are detected in 15% of patients. Infiltration of the gingiva, skin, soft tissues, or meninges with leukemic blasts at diagnosis is characteristic of the monocytic subtypes and those with 11q23 chromosomal abnormalities.

Hematologic Findings Anemia is usually present at diagnosis, although it is not typically severe. The anemia is usually normocytic normochromic. Decreased erythropoiesis in the setting of AML often results in a reduced reticulocyte count, and red blood cell (RBC) survival is decreased by accelerated destruction. Active blood loss may rarely contribute to the anemia.

The median presenting leukocyte count is ~15,000/μL. Lower presenting leukocyte counts are more typical of older patients and those with antecedent hematologic disorders. Between 25 and 40% of patients have counts <5000/μL, and 20% have counts >100,000/μL. Fewer than 5% have no detectable leukemic cells in the blood. In AML, the cytoplasm often contains primary (nonspecific) granules, and the nucleus shows fine, lacy chromatin with one or more nucleoli characteristic of immature cells. Abnormal rod-shaped granules called Auer rods are not uniformly present, but when they are, AML is virtually certain **(Fig. 104-1)**.

Platelet counts <100,000/μL are found at diagnosis in ~75% of patients, and ~25% have counts <25,000/μL. Both morphologic and functional platelet abnormalities can be observed, including large and bizarre shapes with abnormal granulation and inability of platelets to aggregate or adhere normally to one another.

Pretreatment Evaluation Once the diagnosis of AML is suspected, thorough evaluation and initiation of appropriate therapy should follow. In addition to clarifying the subtype of leukemia, initial studies should evaluate the overall functional integrity of the major organ systems, including the cardiovascular, pulmonary, hepatic, and

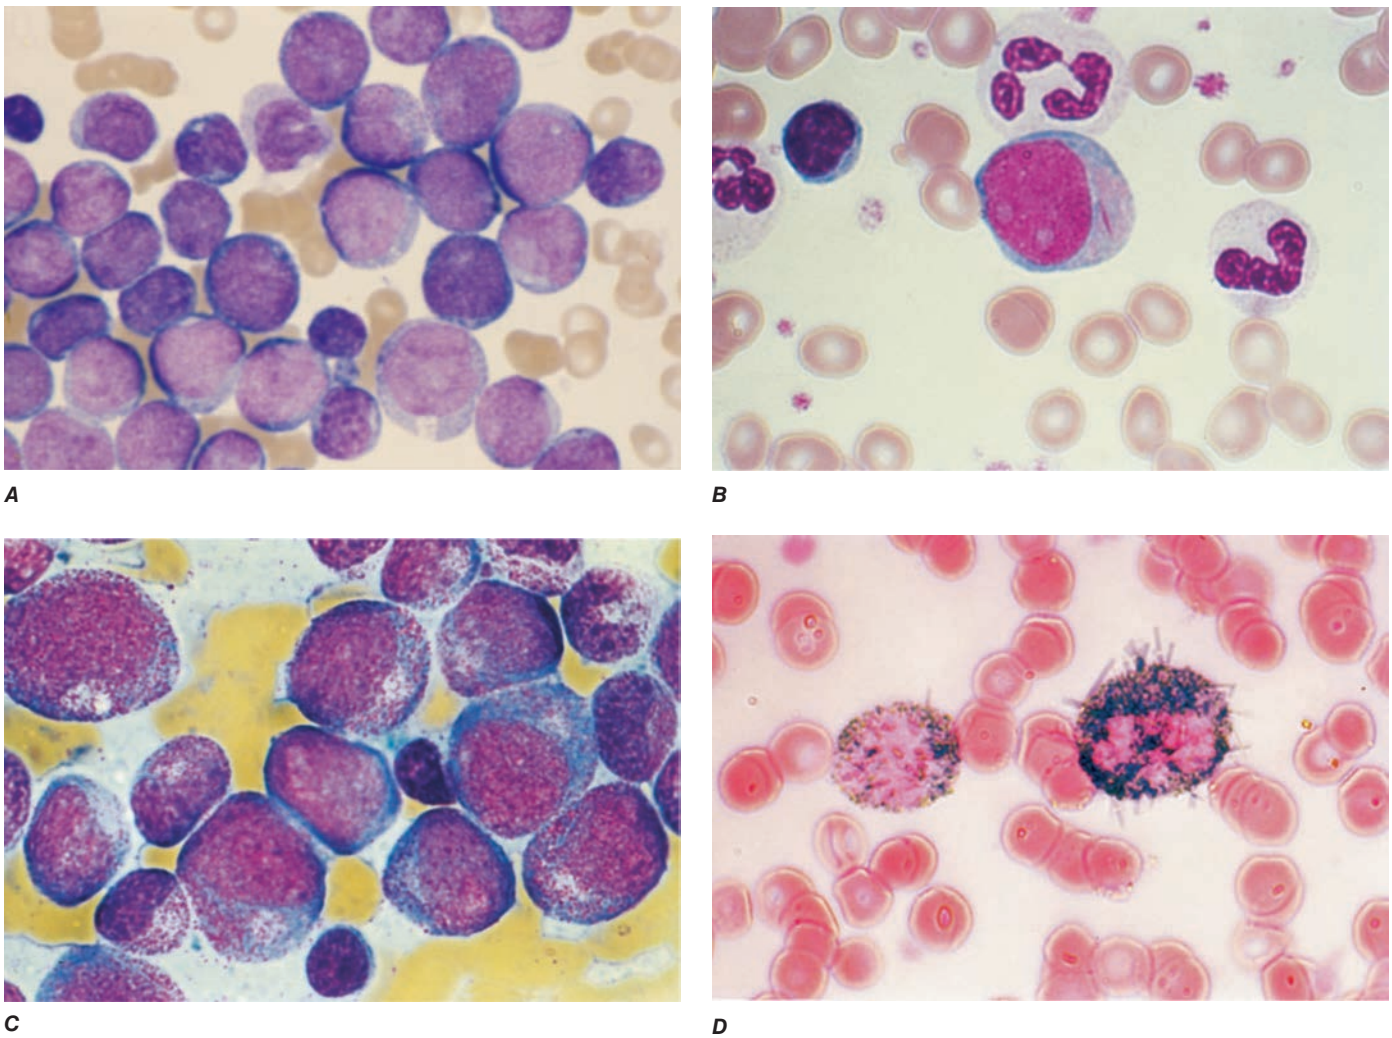

FIGURE 104-1 Morphology of acute myeloid leukemia (AML) cells. ***A.*** Uniform population of primitive myeloblasts with immature chromatin, nucleoli in some cells, and primary cytoplasmic granules. ***B.*** Leukemic myeloblast containing an Auer rod. ***C.*** Promyelocytic leukemia cells with prominent cytoplasmic primary granules. ***D.*** Peroxidase stain shows dark blue color characteristic of peroxidase in granules in AML.

TABLE 104-5 Initial Diagnostic Evaluation and Management of Adult Patients with AML

History
Increasing fatigue or decreased exercise tolerance (anemia)
Excess bleeding or bleeding from unusual sites (DIC, thrombocytopenia)
Fevers or recurrent infections (neutropenia)
Headache, vision changes, nonfocal neurologic abnormalities (CNS leukemia or bleed)
Early satiety (splenomegaly)
Family history of AML (Fanconi, Bloom, or Kostmann syndromes or ataxia-telangiectasia)
History of cancer (exposure to alkylating agents, radiation, topoisomerase II inhibitors)
Occupational exposures (radiation, benzene, petroleum products, paint, smoking, pesticides)
Physical Examination
Performance status (prognostic factor)
Ecchymosis and oozing from IV sites (DIC, possible acute promyelocytic leukemia)
Fever and tachycardia (signs of infection)
Papilledema, retinal infiltrates, cranial nerve abnormalities (CNS leukemia)
Poor dentition, dental abscesses
Gum hypertrophy (leukemic infiltration, most common in monocytic leukemia)
Skin infiltration or nodules (leukemia infiltration, most common in monocytic leukemia)
Lymphadenopathy, splenomegaly, hepatomegaly
Back pain, lower extremity weakness (spinal granulocytic sarcoma, most likely in t[8;21] patients)
Laboratory and Radiologic Studies
CBC with manual differential cell count
Chemistry tests (electrolytes, creatinine, BUN, calcium, phosphorus, uric acid, hepatic enzymes, bilirubin, LDH, amylase, lipase)
Clotting studies (prothrombin time, partial thromboplastin time, fibrinogen, D-dimer)
Viral serologies (CMV, HSV-1, varicella-zoster)
RBC type and screen
HLA typing for potential allogeneic HCT
Bone marrow aspirate and biopsy (morphology, cytogenetics, flow cytometry, molecular studies for *NPM1* and *CEBPA* mutations and *FLT3*-ITD)
Cryopreservation of viable leukemia cells
Myocardial function (echocardiogram or MUGA scan)
PA and lateral chest radiograph
Placement of central venous access device
Interventions for Specific Patients
Dental evaluation (for those with poor dentition)
Lumbar puncture (for those with symptoms of CNS involvement)
Screening spine MRI (for patients with back pain, lower extremity weakness, paresthesias)
Social work referral for patient and family psychosocial support
Counseling for All Patients
Provide patients with information regarding their disease and genetic risks, sperm banking or menstrual suppression, financial counseling, and support group contact

Abbreviations: AML, acute myeloid leukemia; BUN, blood urea nitrogen; CBC, complete blood count; CMV, cytomegalovirus; CNS, central nervous system; DIC, disseminated intravascular coagulation; HLA, human leukocyte antigen; HCT, hematopoietic stem cell transplantation; HSV, herpes simplex virus; IV, intravenous; LDH, lactate dehydrogenase; MRI, magnetic resonance imaging; MUGA, multigated acquisition; PA, posteroanterior; RBC, red blood (cell) count.

renal systems (Table 104-5). Factors that have prognostic significance, either for achieving CR or for CR duration, should also be assessed before initiating treatment including cytogenetics and molecular markers. Leukemic cells should be obtained from all patients and cryopreserved for future investigational testing as well as potential future use as new diagnostics and therapeutics become available. All patients should be evaluated for infection. During the ongoing global pandemic, testing for the presence of the novel coronavirus, SARS-COV2, is recommended before initiation of chemotherapy.

Most patients are anemic and thrombocytopenic at presentation. Replacement of the appropriate blood components, if necessary, should begin promptly. Because qualitative platelet dysfunction or the presence of an infection may increase the likelihood of bleeding, evidence of hemorrhage justifies the immediate use of platelet transfusion, even if the platelet count is only moderately decreased.

About 50% of patients have a mild to moderate elevation of serum uric acid at presentation. Only 10% have marked elevations, but renal precipitation of uric acid and the nephropathy that may result is a serious but uncommon complication. The initiation of chemotherapy may aggravate hyperuricemia, and patients are usually started immediately on allopurinol and hydration at diagnosis. Rasburicase (recombinant uric oxidase) is also useful for treating uric acid nephropathy and often can normalize the serum uric acid level within hours with a single dose of treatment, although its expense suggests that limiting its use to patients with severe hyperuricemia and/or kidney injury may be prudent. The presence of high concentrations of lysozyme, a marker for monocytic differentiation, may be etiologic in renal tubular dysfunction for a minority of patients.

TREATMENT

Acute Myeloid Leukemia

Treatment of the newly diagnosed patient with AML is usually divided into two phases, induction and postremission management (consolidation) (Fig. 104-2). The initial goal is to induce CR. Once CR is obtained, further therapy must be given to prolong survival and achieve cure. The initial induction treatment and subsequent postremission therapy are chosen based on the patient's age, overall fitness, and cytogenetic/molecular risk. Intensive therapy with cytarabine and anthracycline in younger patients (<60 years) increases the cure rate of AML. In older patients, the benefit of intensive therapy is controversial in all but favorable-risk patients; novel approaches for selecting patients predicted to be responsive to treatment and new therapies are being pursued. Additional options for therapy have emerged for older AML patients such as the addition of the BCL2 antagonist venetoclax to one of several low-intensity chemotherapies. Likewise, novel oral drugs targeting IDH1 or IDH2, alone or in combination with low-intensity chemotherapy, may be considered as initial therapy for older patients who have mutations in those respective pathways.

INDUCTION CHEMOTHERAPY

The most commonly used induction regimens (for patients other than those with APL) consist of combination chemotherapy with cytarabine and an anthracycline (e.g., daunorubicin, idarubicin). Cytarabine is a cell cycle S-phase–specific antimetabolite that becomes phosphorylated intracellularly to an active triphosphate form that interferes with DNA synthesis. Anthracyclines are DNA intercalators. Their primary mode of action is thought to be inhibition of topoisomerase II, leading to DNA breaks.

In adults, cytarabine used at standard dose (100–200 mg/m^2) is administered as a continuous intravenous infusion for 7 days. With cytarabine, anthracycline therapy generally consists of daunorubicin (60–90 mg/m^2) or idarubicin (12 mg/m^2) intravenously on days 1, 2, and 3 (the 7 and 3 regimen). Other agents can be added (e.g., gemtuzumab ozogamicin) when 60 mg/m^2 of daunorubicin is used. With the 7 and 3 regimen, it is now clearly established that 45 mg/m^2 dosing of daunorubicin results in inferior outcomes; patients should receive higher doses as described. Patients failing remission after one induction are offered reinduction with the same (or slightly modified) therapy. The CD33-targeting immunoconjugate gemtuzumab ozogamicin may be added to induction therapy for subsets of patients, especially those with CBF AML.

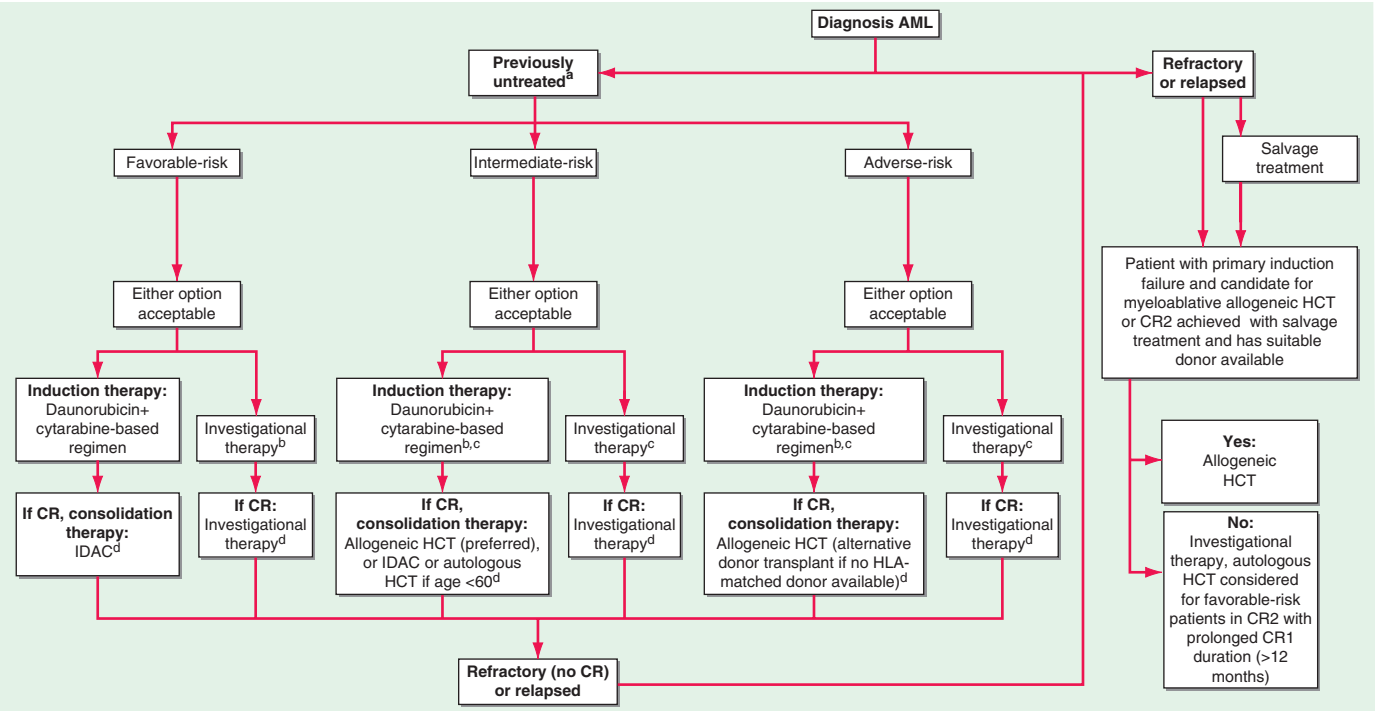

FIGURE 104-2 Algorithm for the therapy of newly diagnosed acute myeloid leukemia (AML). [a]Risk stratification according to the European LeukemiaNet (see Table 104-3). [b]Younger patients (<60–65 years) should routinely be offered investigational therapy on a backbone of standard chemotherapy for induction and consolidation. [c]Older patients, especially those >65 years or with adverse risk disease, or those who are unfit for intensive anthracycline + cytarabine regimens, may be considered for investigational therapy alone or in combination with lower intensity chemotherapy (azacitidine, decitabine, cytarabine), or lower intensity chemotherapy in combination with venetoclax. [d]Investigational therapy as maintenance should be considered if available (after consolidation for younger patients and older patients with favorable-risk disease, and for all other older patients after induction).

Allogeneic hematopoietic cell transplantation (HCT) is a consideration for all eligible patients in first complete remission (CR) with non–favorable-risk disease and highly recommended for older patients (60–75 years) and those with adverse risk.

For all forms of AML in fit patients, except acute promyelocytic leukemia (APL), standard induction therapy includes a regimen based on a 7-day continuous infusion of cytarabine (100–200 mg/m^2/d) and a 3-day course of daunorubicin (60–90 mg/m^2/d) with or without additional drugs. Idarubicin (12 mg/m^2/d) can be used in place of daunorubicin (not shown). The value of postremission/consolidation therapy for older patients (>60 years) who do not have favorable-risk disease is uncertain. Patients who achieve CR undergo postremission consolidation therapy, including sequential courses of intermediate-dose cytarabine, allogeneic HCT, autologous HCT, or novel therapies, based on their predicted risk of relapse (i.e., risk-stratified therapy). Patients receiving induction of lower intensity chemotherapy with venetoclax (or investigational therapy) typically receive repetitive cycles of same on an attenuated schedule, if necessary due to myelotoxicity, after achieving remission. Patients with APL (see text for treatment) usually receive tretinoin and arsenic trioxide–based regimens with or without anthracycline-based chemotherapy and possibly maintenance with tretinoin. HLA, human leukocyte antigen; IDAC, intermediate-dose cytarabine.

In older patients (age ≥60–65 years), the outcome with conventional intensive therapy is generally poor due to a higher frequency of resistant disease and increased rate of treatment-related mortality. This is especially true in patients with prior hematologic disorders (MDS or myeloproliferative neoplasms), therapy-related AML, or cytogenetic and genetic abnormalities that adversely influence clinical outcome. Patients still fare far better with treatment than with supportive care only. Conventional therapy for fit older patients is similar to that for younger patients: the 7 and 3 regimen with standard-dose cytarabine and idarubicin (12 mg/m^2), or daunorubicin (60 mg/m^2). For patients aged >65 years, high-dose daunorubicin (90 mg/m^2) has increased toxicity and is not recommended. A novel liposomal preparation of cytarabine and daunorubicin in a fixed molar ratio may instead be administered to fit patients with AML with myelodysplasia-related changes or arising from MDS. Older patients and those unable to receive intensive therapy due to medical comorbidity may receive repetitive cycles of lower intensity therapy with a hypomethylating agent (HMA; decitabine or azacitidine) or low-dose cytarabine, in combination with daily venetoclax. As noted, targeted IDH1- or IDH2-directed therapy is another consideration. All patients should be considered for clinical trials. Investigational therapy remains the best option for many older patients but especially those with adverse-risk features. **(Table 104-6)**.

With the 7 and 3 regimen, 60–80% of younger and 33–60% of older patients (among those who are candidates for intensive therapy) with primary AML achieve CR. Response rates around 60% have been similarly reported with the combination of HMA plus venetoclax in older or infirm patient groups. Of patients who do not achieve CR, most have drug-resistant leukemia. Induction death is more frequent with advancing age and medical comorbidity. Patients with refractory disease after induction should be considered for salvage treatments, preferably on clinical trials. Planning for the possibility of allogeneic hematopoietic stem cell transplantation (HCT) for all eligible patients under age 75 years is part of optimal initial AML care. Typically, allogeneic HCT is performed for patients in CR but at risk for relapse, but fit younger patients with primary refractory disease (not in remission after initial induction) have ~15–20% cure rates with allogeneic HCT (after myeloablative conditioning). For this reason, early planning for possible future allogeneic HCT (including human leukocyte antigen [HLA] typing, donor search, etc.) should be part of the initial approach for most AML patients.

POSTREMISSION THERAPY

Induction of a durable first CR (CR1) is critical to long-term survival in AML. However, without further therapy, virtually all CR patients will eventually relapse. Thus, postremission therapy is designed to eradicate residual (typically undetectable) leukemic cells to prevent relapse and prolong survival. As with induction, the type of postremission therapy in AML is selected for each individual patient based on age, fitness, and cytogenetic/molecular risk.

TABLE 104-6 Novel Therapies in Clinical Development in Acute Myeloid Leukemia (AML)

Protein kinase inhibitors	• FLT3 inhibitors (midostaurin, quizartinib, gilteritinib, crenolanib, sorafenib) • KIT inhibitors • PI3K/AKT/mTOR inhibitors • Aurora and polo-like kinase inhibitors, CDK4/6 inhibitors, CHK1, WEE1, and MPS1 inhibitors • SRC and HCK inhibitors • Syk inhibitors
Epigenetic modulators	• New DNA methyltransferase inhibitors (SGI-110) • Histone deacetylase (HDAC) inhibitors • IDH1 and IDH2 inhibitors • DOT1L inhibitors • BET-bromodomain inhibitors
Chemotherapeutic agents	• CPX-351 (liposomal cytarabine and daunorubicin, especially in secondary AML) • Vosaroxin • Nucleoside analogues
Mitochondrial inhibitors	• Bcl-2, Bcl-xL, and Mcl-1 inhibitors • Caseinolytic protease inhibitors
Therapies targeting oncogenic proteins	• Fusion transcript targeting • EVI1 targeting • NPM1 targeting • Hedgehog inhibitors (glasdegib)
Antibodies and immunotherapies	• Monoclonal antibodies against CD33, CD44, CD47, CD123, CLEC12A • Immunoconjugates (e.g., gemtuzumab ozogamicin, SGN33A) • Bispecific T-cell engagers (BiTEs) and dual affinity retargeting molecules (DARTs) • Chimeric antigen receptor (CAR) T cells or genetically engineered T-cell receptor (TCR) T cells • Immune checkpoint inhibitors (PD-1/PD-L1, CTLA-4) • Vaccines (e.g., WT1)
Therapies targeting AML environment	• CXCR4 and CXCL12 antagonists • Antiangiogenic therapies

Source: Republished with permission of American Society of Hematology, from Diagnosis and management of acute myeloid leukemia in adults: 2017 recommendations from an international expert panel, Döhner H et al. 129:424, 2017; permission conveyed through Copyright Clearance Center, Inc.

The choice between consolidation with chemotherapy or with transplantation is complex and based on age, risk, and practical considerations. In younger patients receiving chemotherapy, postremission therapy with intermediate- or high-dose cytarabine for two to four cycles is standard practice. Higher doses of cytarabine during postremission therapy appear more effective than standard doses (such as are used in induction) for those who do not have adverse-risk genetics. Recent studies suggest that the long-standing practice of high-dose cytarabine (3 g/m^2, every 12 h on days 1, 3, and 5) may not improve survival over intermediate-dose cytarabine (IDAC; 1–1.5 g/m^2) for such patients. Thus, the ELN has recommended IDAC at 1–1.5 g/m^2, every 12 h, on days 1–3, as the optimal postremission chemotherapy approach for favorable- and intermediate-risk younger patients, for two to four cycles. While high-dose cytarabine may not be necessary, it is important to note that younger, favorable-risk patients have worse outcomes when doses <1 g/m^2 are used. In contrast to favorable-risk patients, intermediate- or adverse-risk patients should proceed with allogeneic HCT in CR1 when feasible (see transplant discussion below). Because older patients have increased toxicities with higher doses of cytarabine, ELN recommends relatively attenuated cytarabine doses (0.5–1 g/m^2, every 12 h, on days 1–3) in favorable-risk older patients. There is no clear value for intensive postremission therapy in non–favorable-risk older patients; allogeneic HCT in CR1 (up to age 75 years) or investigational postremission therapy is recommended. Indeed, postremission therapy is an appropriate setting for introduction of new agents in both older and younger patients (Table 104-6).

For patients treated initially with lower intensity regimens that include venetoclax, the current practice is to continue repetitive cycles of the same combination of agents after remission until disease progression. Therapy often must be abbreviated over time due to cumulative myelotoxicity.

Allogeneic HCT is the best relapse-prevention strategy currently available for AML. Allogeneic HCT is probably best understood as an opportunity for immunotherapy; residual leukemia cells potentially elicit an immunologic response from donor immune cells, the so-called graft-versus-leukemia (GVL) effect. The benefit of GVL in relapse risk reduction, unfortunately, is offset somewhat by increased morbidity and mortality from complications of allogeneic HCT including graft-versus-host disease (GVHD). Given that relapsed AML is typically resistant to chemotherapy, allogeneic HCT in CR1 (e.g., before relapse ever occurs) is a favored strategy. We have often explained to patients that transplant can effectively "eliminate the needle in a haystack, but not a stack of needles." Transplant is recommended for patients age <75 years who do not have favorable-risk disease and who have an HLA-matched donor (related or unrelated). We also recommend allogeneic HCT in CR1 for patients with intermediate-risk disease (Table 104-3). However, considerable debate exists regarding whether allogeneic HCT in CR1 is a requirement for younger patients with intermediate-risk AML, as one large series from the Medical Research Council reported that such patients have similar outcomes if transplanted only after relapse (and achievement of CR2), sparing some the long-term morbidity of transplantation. That said, allogeneic HCT is generally recommended as soon as possible after CR1 is achieved unless the patient is in a favorable-risk group. Increasingly, patients without HLA-matched donors are considered for alternative donor transplants (e.g., HLA-mismatched unrelated, haploidentical related, and umbilical cord blood) even in CR1. More effective and safe methods of in vivo T-cell depletion (i.e., posttransplant cyclophosphamide following mismatched transplantation) have broadened the availability of potential allogeneic HCT donors. Now, virtually any patient with a healthy parent or child (i.e., haploidentical) has an available donor suitable for allogeneic HCT if desired. Long-term outcomes with conventional chemotherapy for older patients are dismal; transplantation for such patients is expanding. Even for older patients, nonrandomized data demonstrate curative potential for older patients in CR1 treated with reduced-intensity conditioning regimens and allogeneic HCT.

Trials comparing allogeneic HCT with intensive chemotherapy or autologous HCT have shown improved duration of remission with allogeneic HCT. However, the relapse risk reduction observed with allogeneic HCT is partially offset by the increase in fatal treatment-related toxicity (GVHD, organ toxicity). Despite this, there is no debate that patients with adverse-risk AML have improved long-term survival with early allogeneic HCT. Alternatively, high-dose chemotherapy with autologous HCT rescue is another postremission approach in non–adverse-risk subsets. Autologous HCT patients receive their own stem cells (collected during remission and cryopreserved), following administration of myeloablative chemotherapy. The toxicity is relatively low with autologous HCT (5% mortality rate), but the relapse rate is higher than with allogeneic HCT due to the absence of the GVL effect. Favorable- and intermediate-risk patients may benefit from autologous HCT more so than adverse-risk patients. Practically speaking, however, autologous HCT in AML patients is less frequently employed currently due to enhanced relapse risk reduction seen with allogeneic HCT and the growing availability of HLA-mismatched donors (in novel transplantation approaches).

Prognostic factors help to select the appropriate postremission therapy in patients in CR1. Our approach includes allogeneic HCT

in CR1 for patients without favorable cytogenetics or genotype. Patients with adverse-risk disease should proceed to allogeneic HCT at CR1 if possible. The decision for allogeneic HCT for younger intermediate-risk patients is complex and individualized as described above; we recommend it when an HLA-matched donor is available. Subsets of patients may benefit from targeted therapy given during remission; emerging data demonstrate survival benefit from incorporation of the FLT3 inhibitor midostaurin, for example, into induction and postremission therapies for patients with *FLT3*-mutated AML. Allogeneic transplantation in CR1 is still recommended for these patients.

For patients in morphologic CR, measurement of MRD remains a very important and challenging research area. Cytogenetics are a mainstay of disease assessment, and persistence of abnormal karyotype (in spite of morphologic CR) is clearly associated with poor clinical outcomes. Immunophenotyping to detect minute populations of blasts or sensitive molecular assays (e.g., reverse transcriptase polymerase chain reaction [RT-PCR]) to detect AML-associated molecular abnormalities (e.g., *NPM1*, *RUNX1/RUNX1T1* and *CBFB/MYH11* transcripts, *PML/RARA*) can be performed to assess whether MRD is present at sequential time points during or after treatment. Whether emerging next-generation sequencing or serial quantitative assessment using flow or RT-PCR, performed during remission, can effectively direct successful subsequent therapy and improve clinical outcome remains to be determined. Currently, no consensus exists for the optimal MRD measurement technique or its application, although it is increasingly employed in clinical practice. Data suggest that MRD measurement can in some settings be a reliable discriminator between patients who will continue in CR or relapse, but whether subsequent therapy (i.e., allogeneic HCT or additional therapy) can effectively eradicate disease in such patients is not yet clear. However, in the subset of patients with APL, serial RT-PCR (for the *PML/RARA* transcript) is a very useful and reliable tool to detect early relapse and to direct initiation of reinduction therapy prior to onset of overt relapse. Critical in the general understanding of MRD in all disease subsets is the recognition that even patients with undetectable levels of MRD remain at risk for leukemic relapse.

SUPPORTIVE CARE

Measures geared to supporting patients through several weeks of neutropenia and thrombocytopenia are critical to successful AML therapy. Patients with AML should be treated in centers expert in providing supportive care. Multi-lumen central venous catheters should be inserted as soon as newly diagnosed AML patients have been stabilized. They should be used thereafter for administration of intravenous medications/chemotherapy and transfusions, as well as for blood drawing instead of venipuncture during prolonged periods of myelosuppression.

Adequate and prompt blood bank support is critical to therapy of AML. Platelet transfusions should be given as needed to maintain a platelet count ≥10,000/μL. The platelet count should be kept at higher levels in febrile patients and during episodes of active bleeding or DIC. Patients with poor posttransfusion platelet count increments may benefit from administration of ABO-matched platelets or platelets from HLA-matched donors. RBC transfusions should be considered to keep the hemoglobin level >70–80 g/L (7–8 g/dL) in the absence of active bleeding, DIC, or congestive heart failure, which require higher hemoglobin levels. Blood products leukodepleted by filtration should be used to avert or delay alloimmunization as well as febrile reactions. Blood products may also be irradiated to prevent transfusion-associated GVHD. Cytomegalovirus (CMV)-negative blood products should be used for CMV-seronegative patients who are potential candidates for allogeneic HCT; fortunately, white blood cell filtration is quite effective at reducing CMV exposure as well.

Neutropenia (neutrophils <500/μL or <1000/μL and predicted to decline to <500/μL over the next 48 h) can be part of the initial presentation and/or a side effect of the chemotherapy treatment in AML patients. Thus, infectious complications remain the major cause of morbidity and death during induction and postremission chemotherapy for AML. Antibacterial (i.e., quinolones) and antifungal (i.e., posaconazole) prophylaxis, especially in conjunction with regimens that cause mucositis, is beneficial. For patients who are herpes simplex virus or varicella-zoster seropositive, antiviral prophylaxis should be initiated (e.g., acyclovir, valacyclovir).

Fever develops in most patients with AML, but infections are documented in only half of febrile patients. Early initiation of empirical broad-spectrum antibacterial and antifungal antibiotics has significantly reduced the number of patients dying of infectious complications **(Chap. 74)**. An antibiotic regimen adequate to treat gram-negative organisms should be instituted at the onset of fever in a neutropenic patient after clinical evaluation, including a detailed physical examination with inspection of the indwelling catheter exit site and a perirectal examination (for perirectal abscess), as well as procurement of cultures and radiographs aimed at documenting the source of fever. Specific antibiotic regimens should be based on institutional antibiotic sensitivity data obtained from where the patient is being treated. Acceptable regimens for empiric antibiotic therapy include monotherapy with imipenem-cilastatin, meropenem, piperacillin/tazobactam, or an extended-spectrum antipseudomonal cephalosporin (cefepime or ceftazidime). The combination of an aminoglycoside with an antipseudomonal penicillin (e.g., piperacillin) or an aminoglycoside in combination with an extended-spectrum antipseudomonal cephalosporin should be considered in complicated or resistant cases. Aminoglycosides should be avoided, if possible, in patients with renal insufficiency. Empirical vancomycin should be added in neutropenic patients with catheter-related infections, blood cultures positive for gram-positive bacteria before final identification and susceptibility testing, hypotension or shock, or known colonization with penicillin/cephalosporin-resistant pneumococci or methicillin-resistant *Staphylococcus aureus*. In special situations where decreased susceptibility to vancomycin, vancomycin-resistant organisms, or vancomycin toxicity is documented, other options including linezolid and daptomycin need to be considered.

Caspofungin (or a similar echinocandin), voriconazole, isavuconazonium, or liposomal amphotericin B should be considered for antifungal treatment if fever persists for 4–7 days following initiation of empiric antibiotic therapy. Although liposomal formulations of amphotericin B have improved the toxicity profile of this agent, use has been limited to situations with high risk of or documented mold infections, especially in those in whom an azole fails. Caspofungin has been approved for empiric antifungal treatment. Voriconazole has also been shown to be equivalent in efficacy and less toxic than amphotericin B; isavuconazonium may also be effective with fewer drug-drug interactions. Antibacterial and antifungal antibiotics should be continued until patients are no longer neutropenic, regardless of whether a specific source has been found for the fever. Unfortunately, this practice likely contributes to development of resistance and increased incidence of nosocomial infections such as *Clostridium difficile* colitis, so great care should be taken preferably in hospital-wide antibiotic surveillance and isolation strategies to reduce these complications. Recombinant hematopoietic growth factors have a limited role in AML; myeloid growth factors may be useful in the postremission setting but are not recommended in induction or for "palliative" care for patients not in remission.

TREATMENT FOR REFRACTORY OR RELAPSED AML

In patients who relapse after achieving CR, the length of first CR is predictive of response to salvage chemotherapy treatment; patients with longer first CR (>12 months) generally relapse with drug-sensitive disease and have a higher chance of attaining a CR, even with the same chemotherapeutic agents used for first remission induction. Patients with short prior CR duration are at high risk for treatment failure. Similar to patients with refractory disease, patients with relapsed disease are rarely cured by salvage chemotherapy treatments alone. Therefore, patients who eventually

achieve a second CR and are eligible for allogeneic HCT should be transplanted. For patients who relapse after allogeneic HCT, no consensus for best therapy exists; outcomes in this setting are very poor.

Because achievement of a second CR with routine salvage therapies is relatively uncommon, especially in patients who relapse rapidly after achievement of first CR (<12 months), these patients and those lacking HLA-compatible donors or who are not candidates for allogeneic HCT should be considered for innovative approaches on clinical trials. Many new agents are in current testing (Table 104-6). The discovery of novel gene mutations and mechanisms of leukemogenesis that might represent actionable therapeutic targets has prompted the development of many new targeting agents. In addition to kinase inhibitors for *FLT3*-mutated AML, other compounds targeting the aberrant activity of mutant proteins (e.g., IDH1/2 inhibitors) and numerous other biologic mechanisms are being tested in clinical trials. Inhibitors of FLT3 (gilteritinib), IDH1 (ivosidenib), or IDH2 (enasidenib) are monotherapies for relapsed AML patients who have targetable mutations. Furthermore, approaches with antibodies targeting markers commonly expressed on leukemia blasts (e.g., CD33) or leukemia-initiating cells (e.g., CD123) are also under investigation. Once these compounds have demonstrated safety and activity as single agents, investigation of combinations with other molecular targeting compounds and/or chemotherapy should be pursued.

TREATMENT OF ACUTE PROMYELOCYTIC LEUKEMIA

APL is a highly curable AML subtype, and ~85% of these patients achieve long-term survival with current approaches. APL has long been shown to be responsive to cytarabine and daunorubicin, but in the past, patients who were treated with these drugs alone frequently died from DIC induced by the release of granule components by the chemotherapy-treated leukemia cells. However, the prognosis of APL patients has changed dramatically with the introduction of tretinoin (all-*trans*-retinoic acid [ATRA]), an oral drug that induces the differentiation of leukemic cells bearing the t(15;17), where disruption of the *RARA* gene encoding a retinoid acid receptor occurs. ATRA decreases the frequency of DIC but often produces another complication called the APL (differentiation) syndrome. Occurring within the first 3 weeks of treatment, it is characterized by fever, fluid retention, dyspnea, chest pain, pulmonary infiltrates, pleural and pericardial effusions, and hypoxemia. The syndrome is related to adhesion of differentiated neoplastic cells to the pulmonary vasculature endothelium. Glucocorticoids, chemotherapy for cytoreduction, and/or supportive measures can be effective for management of the APL syndrome. Temporary discontinuation of ATRA is necessary in cases of severe APL syndrome (i.e., patients developing renal failure or requiring admission to the intensive care unit due to respiratory distress). The mortality rate of this syndrome is ~10%. APL syndrome may also occur, less commonly, with arsenic trioxide (ATO) in APL.

In adults with low-risk APL (low leukocyte count at presentation), ATRA (45 mg/m^2/d) plus ATO (0.15 mg/kg/d) was recently compared to ATRA plus concurrent idarubicin chemotherapy. ATRA/ATO was superior and is the new standard of care for such patients. CR rates in low-risk disease approach 100%, with excellent long-term survival. Notably, patients with high-risk APL (defined as leukocyte count >10,000/μL) must be uniquely treated, as they require immediate cytoreduction with chemotherapy due to life-threatening APL syndrome and rapidly rising leukocyte count after initiation of ATRA. High-risk patients are at increased risk for induction death due to this syndrome as well as increased frequency of hemorrhagic complications (related to DIC).

Assessment of residual disease by RT-PCR amplification of the t(15;17) chimeric gene product *PML-RARA* following the final cycle of treatment is important. Disappearance of the signal is associated with long-term disease-free survival; its persistence or reemergence invariably predicts relapse. Sequential monitoring of RT-PCR for *PML-RARA* is now considered standard for postremission monitoring of APL, at least in high-risk patients.

Patients in molecular, cytogenetic, or clinical relapse should be salvaged with ATO with or without ATRA; in patients who were treated with ATRA plus chemotherapy in the front-line setting, ATO-based therapy at relapse produces meaningful responses in up to 85% of patients. Although experience with relapsed APL in patients who received ATO during initial induction is limited (given that few relapses occur in low-risk patients and widespread use of ATO during first-line therapy is relatively new), ATO remains the preferred reinduction therapy for patients who relapse, although the duration of prior remission should be a factor in this choice. Achievement of CR2 should be followed by consolidation with autologous HCT (for patients who achieve RT-PCR-negative status). In the minority who do not achieve negative RT-PCR or who relapse again, allogeneic HCT may still be potentially curative.

105 Chronic Myeloid Leukemia

Hagop Kantarjian, Elias Jabbour, Jorge Cortes

Chronic myeloid leukemia (CML) is a clonal hematopoietic myeloproliferative stem cell neoplasm. The disease is driven by the *BCR/ABL1* chimeric gene that codes for a constitutively active tyrosine kinase, resulting from a reciprocal balanced translocation between the long arms of chromosomes 9 and 22, t(9;22)(q34.1;q11.2), known as the

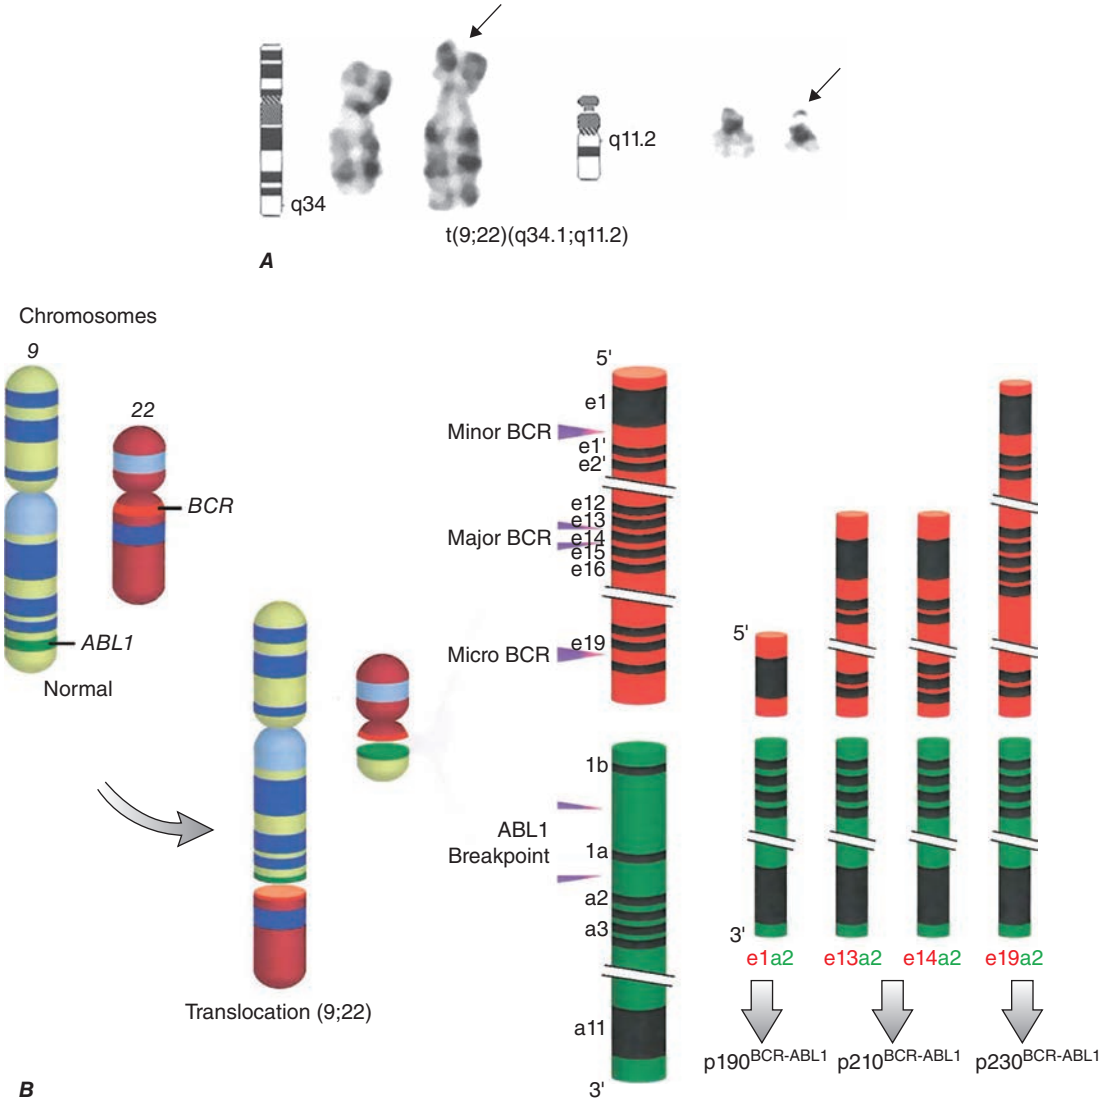

FIGURE 105-1 ***A.*** The Philadelphia (Ph) chromosome cytogenetic abnormality. ***B.*** Breakpoints in the long arms of chromosome 9 (*ABL1* locus) and chromosome 22 (*BCR* regions) result in at least three different BCR-ABL1 oncoprotein messages, $p210^{BCR\text{-}ABL1}$ (most common message in chronic myeloid leukemia [CML]), $p190^{BCR\text{-}ABL1}$ (present in two-thirds of patients with Ph-positive acute lymphoblastic leukemia; rare in CML), and $p230^{BCR\text{-}ABL1}$ (rare in CML and associated with an indolent course). Other rearrangements (e.g., e14a3, e14a3) are less common. *(© 2013 The University of Texas MD Anderson Cancer Center.)*

Philadelphia chromosome (Ph) (Fig. 105-1). Untreated, the course of CML is typically biphasic or triphasic, with an early indolent or chronic phase, followed often by an accelerated phase and a terminal blastic phase. Before the era of BCR-ABL1 tyrosine kinase inhibitors (TKIs), the median survival in CML was 3–7 years, and the 10-year survival rate was 30% or less. Introduced into standard CML therapy in 2000, TKIs have revolutionized the treatment, natural history, and prognosis of CML. Today, the estimated 10-year survival rate with imatinib mesylate, the first BCR-ABL1 TKI approved, is greater than 85% and approaches that of the general population. Allogeneic stem cell transplantation (SCT), a curative approach but one that involves more risks, is now offered as second- or third-line therapy after failure of TKIs.

INCIDENCE AND EPIDEMIOLOGY

CML accounts for ~15% of all cases of leukemia. There is a slight male predominance (male-to-female ratio 1.6:1). The median age at diagnosis is 55–65 years. It is uncommon in children; only 3% of patients with CML are younger than 20 years, although in recent years, a higher proportion of young patients are diagnosed. The incidence of CML increases gradually with age, with a steeper increase after the age of 40–50 years. The annual incidence of CML is 1.6 cases per 100,000 individuals. In the United States, this translates into about 8500–9000 new cases per year. The incidence of CML has not changed over several decades. By extrapolation, the worldwide annual incidence of CML is about 200,000 cases. With a median survival of 3–6 years before 2000, the disease prevalence in the United States was ~30,000 cases. With TKI therapy, the annual mortality has been reduced from 10–20% to about 2%. Therefore, the prevalence of CML is expected to continue to increase. Based on an estimated annual mortality of 2% and an incidence of 8500 cases per year, the plateau prevalence of CML is estimated to be reached at ~425,000 in the United Stated (8500 × 100/2) by about 2040, with full TKI optimal treatment penetration. The worldwide prevalence will depend on the treatment penetration of TKIs and their effect on reduction of worldwide annual mortality. Ideally, with full TKI treatment penetration, the worldwide prevalence should plateau at 35 times the incidence, or ~9–10 million patients. These estimates are all based on extrapolations from the incidence and prevalence of CML in the United States, as well as an estimated annual mortality of 2% with modern TKI therapy; they could vary considerably if the estimates were to change.

ETIOLOGY

There are no familial associations in CML. The risk of developing CML is not increased in monozygotic twins or in relatives of patients with CML. No etiologic agents are incriminated, and no associations exist with exposures to benzene or other toxins, fertilizers, insecticides, or

viruses. CML is not a frequent secondary leukemia following therapy of other cancers with alkylating agents and/or radiation. Exposure to ionizing radiation (e.g., nuclear accidents, radiation treatment for ankylosing spondylitis or cervical cancer) has increased the risk of CML, which peaks at 5–10 years after exposure and is dose-related. The median time to development of CML among atomic bomb survivors was 6.3 years. Following the Chernobyl accident, no increase in the incidence of CML was reported, suggesting that larger dose exposures of radiation are required to cause CML. Because of adequate protection, the risk of CML has not increased among individuals working in the nuclear industry or among radiologists.

PATHOPHYSIOLOGY

The t(9;22)(q34.1;q11.2) is present in >90% of classical CML cases. It results from a balanced reciprocal translocation between the long arms of chromosomes 9 and 22. It is present in hematopoietic cells (myeloid, erythroid, megakaryocytes, and monocytes; less often mature B lymphocytes; rarely mature T lymphocytes, but not stromal cells), but not in other cells in the human body. As a result of the genetic translocation, DNA sequences from the cellular oncogene *ABL1* are juxtaposed to the major breakpoint cluster region (*BCR*) gene on chromosome 22, generating a hybrid oncogene, *BCR/ABL1*. Depending on the breakpoint site in the major *BCR* region on chromosome 22 (e13 or e14), two main messenger RNA transcripts occur, e13a2 (previously b2a2) and e14a2 (previously b3a2). Both of them encode for a novel oncoprotein of molecular weight 210 kDa, referred to as $p210^{BCR\text{-}ABL1}$ (Fig. 105-1*B*). This oncoprotein exhibits constitutive kinase activity that leads to excessive proliferation and reduced apoptosis of CML cells, endowing them with a growth advantage over their normal counterparts. Over time, normal hematopoiesis is suppressed, but normal stem cells can persist and reemerge following effective therapy, for example with TKIs. In most instances of Ph-positive acute lymphoblastic leukemia (ALL) and in rare cases of CML, the breakpoint in *BCR* is more centromeric, in a region called the minor *BCR* region (*mBCR*). As a result, a shorter sequence of *BCR* is fused to *ABL1*, with a consequent e1a2 transcript and a smaller BCR-ABL1 oncoprotein, $p190^{BCR\text{-}ABL1}$. When occurring in Ph-positive CML, this translocation is associated with a worse outcome. A rarer breakpoint in *BCR* occurs telomeric to the major *BCR* region in the *micro-BCR* (μ-BCR) region. It juxtaposes a larger fragment of the *BCR* gene to *ABL1* and produces an e19a2 transcript and a larger $p230^{BCR\text{-}ABL1}$ oncoprotein (associated with a more indolent CML course). Other rearrangements (based on different breakpoints in the *ABL* region), such as e13a3 or e14a3 (also resulting in a $p210^{BCR\text{-}ABL1}$ oncoprotein), occur much less frequently. These are not readily identifiable nor quantifiable with the routine polymerase chain reaction (PCR) probes, thus producing falsely negative PCR levels on follow-up studies if not tested at diagnosis.

The constitutive activation of *BCR/ABL1* results in autophosphorylation and activation of multiple downstream pathways that affect gene transcription, apoptosis, stromal adherence, skeletal organization, and degradation of inhibitory proteins. These transduction pathways involve RAS, mitogen-activated protein (MAP) kinases, signal transducers and activators of transcription (STAT), phosphatidylinositol-3-kinase (PI3k), MYC, and others. These interactions are mostly mediated through tyrosine phosphorylation and require binding of BCR-ABL1 to adapter proteins such as GRB-2, CRK, CRK-like (CRK-L) protein, and Src homology containing proteins (SHC). Most BCR-ABL1 TKIs bind to the BCR-ABL1 ATP-binding domain, inhibiting its kinase activity, preventing the activation of transformation pathways, and inhibiting downstream signaling. As a result, proliferation of CML cells is inhibited and apoptosis induced, allowing the reemergence of normal hematopoiesis. An additional layer of complexity is related to differences in signal transduction between CML-differentiated cells and early progenitors. Beta-catenin, Wnt1, Foxo3a, transforming growth factor β, interleukin-6, PP2A, SIRT1, and others have been implicated in CML stem cell survival. ABL1 also has a myristoyl site that functions as a negative regulator of its kinase activity. This site and its negative regulatory activity are lost upon fusion with BCR. Novel ABL1 inhibitors (e.g., asciminib) bind this myristoyl site and restore the lost inhibitory activity. Mutations in other cancer-associated genes may also occur at diagnosis, most frequently in *ASXL1*, *IKZF1*, and *RUNX1*; their presence is associated with worse response to therapy and a higher risk of transformation to blastic phase.

Experimental models have established the causal relationship between the *BCR/ABL1* rearrangement and the development of CML. In animal models, expression of *BCR/ABL1* in normal hematopoietic cells produced CML-like disorders or lymphoid leukemia, demonstrating the leukemogenic potential of *BCR/ABL1* as a single oncogenic abnormality. Other models, however, suggest the need for a "second hit."

The cause of the *BCR/ABL1* rearrangement is unknown. Molecular techniques that detect *BCR/ABL1* at a level of 1 in 10^8 cells identify this molecular abnormality in the blood of up to 25% of normal adults and 5% of infants, but 0% of cord blood samples. This suggests that *BCR/ABL1* is not sufficient to cause overt CML in the overwhelming majority of individuals in whom it occurs. Because CML develops in only 1.6 of 100,000 individuals annually, additional molecular events or poor immune recognition of the rearranged cells may contribute to overt CML.

CML is defined by the presence of the *BCR/ABL1* fusion gene in a patient with a myeloproliferative neoplasm. In some patients with a typical morphologic picture of CML, the Ph chromosome is not detectable by standard G-banding karyotype, but fluorescence in situ hybridization (FISH) and/or molecular studies (PCR) detect *BCR/ABL1*. These patients have a course similar to patients with Ph-positive CML and respond to TKI therapy. Many of the remaining patients have atypical morphologic or clinical features and have other diseases, such as atypical CML, chronic myelomonocytic leukemia, and myelodysplastic/myeloproliferative neoplasms (MDS/MPN). These individuals do not respond to TKI therapy and usually have a poor prognosis with a median survival of about 2–3 years. Detection of mutations in the granulocyte colony-stimulating factor receptor (*CSF3R*) in chronic neutrophilic leukemia (80% of cases) and in some cases of atypical CML (5–10% of cases), mutations in *SETBP1* in atypical CML (25% of cases), and mutations in *SF3B1* in MDS/MPN with ringed sideroblasts and marked thrombocytosis (MDS/MPN-RS-T; 50–70% of cases, associated with longer median survival of 7 years vs 3.3 years with wild-type *SF3B1*) supports the notion that these are distinct molecular and biologic entities. Patients with chronic neutrophilic leukemia or atypical CML whose disease is associated with *CSF3R* mutation may respond well to ruxolitinib (a JAK2 inhibitor) therapy (complete response in 50–60% of such patients).

The events associated with the transition of CML from a chronic to accelerated-blastic phase are poorly understood. Characteristic chromosomal abnormalities such as a double Ph, trisomy 8, isochromosome 17 or deletion of 17p (loss of *TP53*), 20q–, translocations involving 3q26, and others may be seen with disease acceleration. Molecular events associated with transformation include mutations in *TP53*, retinoblastoma 1 (*RB1*), myeloid transcriptions factors like *RUNX1*, and cell cycle regulators like *p16*. A plethora of other mutations or functional abnormalities have been implicated in blastic transformation, but no unifying theme has emerged other than the fact that *BCR/ABL1* itself induces genetic instability that favors the acquisition of additional molecular defects and eventually results in blastic transformation. One critical effect of TKIs is to stabilize the CML genome, leading to a reduced transformation rate. In particular, the previously observed sudden blastic transformations (i.e., abrupt transformation to blastic phase in a patient who had been in cytogenetic response) have become uncommon, occurring rarely in younger patients in the first 1–2 years of TKI therapy (usually sudden lymphoid blastic transformations). Sudden transformations beyond the third year of TKI therapy are rare in patients who continue on TKI therapy. Moreover, the course of CML is now frequently more indolent in patients treated with TKI, even without cytogenetic response, compared to previous experience with hydroxyurea/busulfan, suggesting a definite clinical benefit of continued inhibition of the kinase activity.

Among patients developing resistance to TKIs, several resistance mechanisms have been observed. The most clinically relevant one is the development of *ABL1* kinase domain mutations that may prevent the

binding of TKIs to the catalytic site (ATP-binding site) of the kinase or maintain the kinase activity despite the presence of a TKI. More than 100 *ABL1* kinase domain mutations have now been described, many of which confer relative or absolute resistance to imatinib. Consequently, second-generation (i.e., dasatinib, nilotinib, bosutinib) and third-generation (ponatinib) TKIs were developed, the latter with significant efficacy against T315I, a "gatekeeper" mutation that prevents binding of and causes resistance to all other currently available TKIs. Asciminib, olverembatinib (HQP1351) and other novel TKIs under development are also active against the T315I mutation.

CLINICAL PRESENTATION

The presenting signs and symptoms in CML depend on the availability of and access to health care, including physical examinations and screening tests. In the United States, because of the wider access to health care screening and physical examinations, 50–60% of patients are diagnosed on routine blood tests and have minimal symptoms at presentation, such as fatigue. In geographic locations where access to health care is more limited, patients often present with high CML burden including splenomegaly, anemia, and related symptoms (abdominal pain, weight loss, fatigue), associated with a higher frequency of high-risk CML. Presenting findings in patients diagnosed in the United States are shown in Table 105-1.

Symptoms Most patients with CML (90%) present in the indolent or chronic phase. Depending on the timing of diagnosis, patients are often asymptomatic (if the diagnosis is discovered during health care screening tests). Common symptoms, when present, are manifestations of anemia and splenomegaly. These may include fatigue, malaise, weight loss (if high leukemia burden), or early satiety and left upper quadrant pain or masses (from splenomegaly). Less common presenting findings include thrombotic or hyperviscosity-related events from severe leukocytosis or thrombocytosis. These include priapism, cardiovascular complications, myocardial infarction, venous thrombosis, visual disturbances, dyspnea and pulmonary insufficiency, drowsiness, loss of coordination, confusion, or cerebrovascular accidents.

TABLE 105-1 Presenting Signs and Symptoms of Newly Diagnosed Philadelphia Chromosome–Positive Chronic Myeloid Leukemia in Chronic Phase

PARAMETER	PERCENTAGE
Age ≥60 years (median)	40–50 (55–65)
Female gender	35–45
Splenomegaly	30
Hepatomegaly	5–10
Lymphadenopathy	5
Other extramedullary disease	2
Hemoglobin <10 g/dL	10–15
Platelets	
>450 × 10^9 cells/L	30–35
<100 × 10^9 cells/L	3–5
White blood cells ≥50 × 10^9 cells/L	35–40
Marrow	
≥5% blasts	5
≥5% basophils	10–15
Peripheral blood	
≥3% blasts	8–10
≥7% basophils	10
Cytogenetic clonal evolution other than the Philadelphia chromosome	4–5
Sokal risk	
Low	60–65
Intermediate	25–30
High	10

Manifestations of bleeding diatheses include retinal hemorrhages, gastrointestinal bleeding, and others. Patients who present with, or progress to, the accelerated or blastic phases frequently have additional symptoms including unexplained fever, significant weight loss, severe fatigue, bone and joint pain, bleeding and thrombotic events, and infections.

Physical Findings Splenomegaly is the most common physical finding, occurring in 20–70% of patients depending on health care screening frequency. Other less common findings include hepatomegaly (5–10%), lymphadenopathy (5–10%), and extramedullary disease (skin or subcutaneous lesions). The latter indicates CML transformation if a biopsy confirms predominance of blasts. Other physical findings are manifestations of complications of high tumor burden described earlier (e.g., cardiovascular, cerebrovascular, bleeding). High basophil counts may be associated with histamine overproduction causing pruritus, diarrhea, flushing, and even gastrointestinal ulcers.

Hematologic and Marrow Findings In untreated CML, leukocytosis ranging from 10–500 × 10^9/L is common. The peripheral blood differential shows left-shifted hematopoiesis with predominance of neutrophils and the presence of bands, myelocytes, metamyelocytes, promyelocytes, and blasts (usually ≤5%). Basophils and/or eosinophils are frequently increased. Thrombocytosis is common, but thrombocytopenia is rare and, when present, suggests a worse prognosis, disease acceleration, or an unrelated etiology. Anemia is present in one-third of patients. Cyclic oscillations of counts are noted in 10–20% of patients without treatment. Biochemical abnormalities include a low leukocyte alkaline phosphatase score and high levels of vitamin B_{12}, uric acid, lactic dehydrogenase, and lysozyme. The presence of unexplained and sustained leukocytosis, with or without splenomegaly, should lead to a marrow examination and cytogenetic analysis.

The bone marrow is hypercellular with marked myeloid hyperplasia and a high myeloid-to-erythroid ratio of 15–20:1. Marrow blasts are typically 5% or less; when higher, they carry a worse prognosis or represent transformation to accelerated phase (if they are ≥15%). Increased reticulin fibrosis (detected with silver stain) is common, with 30–40% of patients demonstrating grade 3–4 reticulin fibrosis. This was considered adverse in the pre-TKI era. With TKI therapy, reticulin fibrosis resolves in most patients and is not an indicator of poor prognosis. Collagen fibrosis (Wright-Giemsa stain) is rare at diagnosis. Disease progression with a "spent phase" of myelofibrosis (myelophthisis, or burnt-out marrow) was a relatively common end-stage CML condition with busulfan therapy (20–30%); it is extremely rare now with TKI therapy.

Cytogenetic and Molecular Findings The diagnosis of CML is straightforward and depends on documenting the t(9;22) (q34.1;q11.2), which is identified by G-banding in 90% of cases. This is known as the Philadelphia chromosome (initially identified in Philadelphia as a minute chromosome, later identified to be chromosome 22) (Fig. 105-1). Some patients (~10%) may have complex translocations (complex variant Ph) involving three or more chromosomes including chromosomes 9 and 22 and one or more additional chromosomes. Others may have a "masked Ph," involving translocations between chromosome 9 and a chromosome other than 22 (but molecularly showing the *BCR/ABL1* rearrangement; known as simple variant Ph). The prognosis of these patients and their response to TKI therapy are similar to those in patients with Ph. About 5–10% of patients may have additional chromosomal abnormalities (ACAs) in the Ph-positive cells at diagnosis. These usually involve trisomy 8, a double Ph, isochromosome 17 or 17p deletion, 20q–, or others. This is referred to as cytogenetic clonal evolution and was historically a sign of adverse prognosis, particularly when trisomy 8, double Ph, or chromosome 17 abnormalities were noted. A less common abnormality involving chromosome 3q26.2 occurs with disease progression and carries a poor prognosis.

Techniques such as FISH and PCR are now used to aid in the diagnosis of CML. They are more sensitive to estimate the CML burden in patients on TKI therapy. They can be done on peripheral blood and thus are more convenient to patients. Patients with CML at diagnosis

should have a FISH analysis to quantify the percentage of Ph-positive cells, if FISH is used to replace marrow cytogenetic analysis in monitoring response to therapy. FISH will not detect additional chromosomal abnormalities (clonal evolution); thus, a cytogenetic analysis is recommended at the time of diagnosis. In addition, 10–15% of patients may develop chromosomal abnormalities in Ph-negative metaphases after responding to TKIs. These abnormalities may carry a worse prognosis but are not detected by FISH unless already identified and FISH is used to follow them. Molecular studies at diagnosis are important to document the type and presence of *BCR-ABL1* transcripts to avoid spurious "undetectable" *BCR-ABL1* transcripts on follow-up studies, with the false impression of a complete molecular response. The presence of the Philadelphia chromosome with "negative" PCR with standard methodology should prompt investigation of atypical transcripts.

Both FISH and PCR studies can be falsely positive at low levels or falsely negative because of technical issues. Therefore, a diagnosis of CML must always rely on a marrow analysis with routine cytogenetics. The diagnostic bone marrow confirms the presence of the Ph chromosome, detects clonal evolution, and quantifies the percentage of marrow blasts and basophils. In 10% of patients, the percentage of marrow blasts and basophils can be significantly higher than in the peripheral blood, conferring poorer prognosis or even representing disease transformation.

Monitoring patients on TKI therapy by cytogenetics, FISH, and PCR has become an important standard practice to assess response to therapy, emphasize compliance, evaluate possible treatment resistance, identify the need to change TKI therapy, and determine the need to assess for kinase domain mutations. Because of the decreasing reliance of bone marrow aspirations to monitor response, equivalence has been established to correlate cytogenetic results with PCR values. These are not absolute correlations but provide adequate guidance. A partial cytogenetic response is defined as the presence of 35% or less Ph-positive metaphases by routine cytogenetic analysis. This is roughly equivalent to *BCR-ABL1* transcripts by the International Scale (IS) of 10% or less. A complete cytogenetic response refers to the absence of Ph-positive metaphases (0% Ph positivity). This is approximately equivalent to *BCR-ABL1* transcripts (IS) of 1% or less. A major molecular response (MMR or MR3) refers to *BCR-ABL1* transcripts (IS) ≤0.1%, or roughly a 3-log or greater reduction of *BCR-ABL1* transcripts from a standardized baseline. MR4 refers to *BCR-ABL1* transcripts (IS) ≤0.01%, and MR4.5 (deep molecular response) refers to *BCR-ABL1* transcripts (IS) ≤0.0032%, roughly equivalent to a 4.5-log reduction or greater of transcripts.

Findings in CML Transformation Progression of CML is usually associated with leukocytosis resistant to therapy, increasing anemia, fever and constitutional symptoms, and increased blasts and basophils in the peripheral blood or marrow. Criteria of accelerated-phase CML, historically associated with median survival of <1.5 years, include the presence of 15% or more peripheral blasts, 30% or more peripheral blasts plus promyelocytes, 20% or more peripheral basophils, cytogenetic clonal evolution (presence of chromosomal abnormalities in addition to Ph), and thrombocytopenia $<100 \times 10^9$/L (unrelated to therapy). About 5–10% of patients present with de novo accelerated phase or blastic phase. The prognosis of de novo accelerated phase with TKI therapy has improved significantly, with an estimated 8-year survival rate of 75%. The median survival of accelerated phase evolving from chronic phase has also improved from a historical median survival of 18 months to an estimated 4-year survival rate of 70% on TKI therapy. Therefore, the criteria for accelerated-phase CML should be revisited because most clinical criteria defining accelerated phase have lost much of their prognostic significance. Blastic-phase CML is defined by the presence of 30% or more peripheral or marrow blasts or the presence of sheets of blasts in extramedullary disease (usually skin, soft tissues, or lytic bone lesions). Blastic-phase CML is commonly myeloid (60%) but can present uncommonly as erythroid, promyelocytic, monocytic, or megakaryocytic. Lymphoid blastic phase occurs in about 25% of patients. Lymphoblasts are terminal deoxynucleotide transferase positive and peroxidase negative (although occasionally with low positivity up to 3–5%) and express lymphoid markers (CD10, CD19, CD20, CD22). However, they also often express myeloid markers (50–80%), resulting in diagnostic challenges. Proper immunophenotypic diagnosis is important because lymphoid blastic-phase CML is quite responsive to anti-ALL-type chemotherapy (e.g., hyper-CVAD [cyclophosphamide, vincristine, doxorubicin, and dexamethasone]) in combination with TKIs (complete response rate 70%; median survival 3 years; high rates of bridging to allogeneic SCT and possible cure).

PROGNOSIS AND CML COURSE

Before the imatinib era, the annual mortality in CML was 10% in the first 2 years and 15–20% thereafter. The median survival in CML was 3–7 years (with hydroxyurea-busulfan and interferon α). Without a curative option of allogeneic SCT, the course of CML was toward transformation to, and death from, accelerated or blastic phases for most patients as the rate of complete cytogenetic response with interferon was low. Even apparent disease stability was unpredictable, with some patients demonstrating sudden transformation to a blastic phase. With imatinib therapy, the annual mortality in CML has decreased to 1–2% in the first 20 years of observation. More than half of the deaths are from conditions other than CML, such as old age, comorbidities, accidents, suicides, other cancers, and other medical conditions (e.g., infections, surgical procedures). The estimated 10-year survival rate is 86%, or 92% if only CML-related deaths are considered **(Fig. 105-2)**. The course of CML has also become quite predictable. In the first 2 years of TKI therapy, rare sudden transformations are still reported (1–2%), usually lymphoid blastic transformations that respond to combinations of chemotherapy and TKIs followed by allogeneic SCT. These may be explained by the intrinsic mechanisms of sudden transformation already existing in the CML clones before the start of therapy that were not amenable to TKI inhibition, in particular imatinib. Second-generation TKIs (nilotinib, dasatinib, bosutinib) used as frontline therapy have reduced the incidence of transformation in the first 2–3 years from 6–8% with imatinib to 2–5% with second-generation TKIs. Disease transformation to accelerated or blastic phase is rare with continued TKI therapy, estimated at <1% annually in years 4–10 of follow-up on the original imatinib trials. Patients usually develop resistance in the form of cytogenetic resistance or relapse, followed by hematologic relapse and subsequent transformation, rather than the previously feared sudden transformations without the warning signals of cytogenetic-hematologic relapse.

Before the imatinib era, several pretreatment prognostic factors predicted for worse outcome in CML and have been incorporated into prognostic models and staging systems. These have included older age, significant splenomegaly, anemia, thrombocytopenia or thrombocytosis, high percentages of blasts and basophils (and/or eosinophils), marrow fibrosis, interstitial deletions in the long arm of chromosome 9, clonal evolution, and others. Different risk models and staging systems, derived from multivariate analyses, were proposed to define different risk groups. As with the introduction of cisplatin into testicular cancer therapy, the introduction of TKIs into CML therapy has decreased or, in some instances, eliminated the prognostic impact of most of these prognostic factors and the significance of the CML models (e.g., Sokal, Hasford, European Treatment and Outcome Study [EUTOS]). Treatment-related prognostic factors have emerged as the most important prognostic factors in the era of imatinib therapy. Achievement of complete cytogenetic response has become the major therapeutic endpoint and is the only endpoint associated with improvement in survival. Achievement of MMR or MR3 is associated with decreased risk of events (relapse) and CML transformation but has not been associated with survival prolongation among patients with complete cytogenetic response. This may be due to the survival benefit conferred by the achievement of complete cytogenetic response, which approximates normal life expectancy, and to the efficacy of salvage TKI therapies, which are and should be implemented at the first evidence of cytogenetic relapse. Achievement of undetectable *BCR-ABL1* transcripts (complete molecular response [CMR]) or deep molecular response (DMR; defined as MR4 or MR4.5), particularly when sustained (>2–5 years), may offer the possibility of treatment-free remission and may

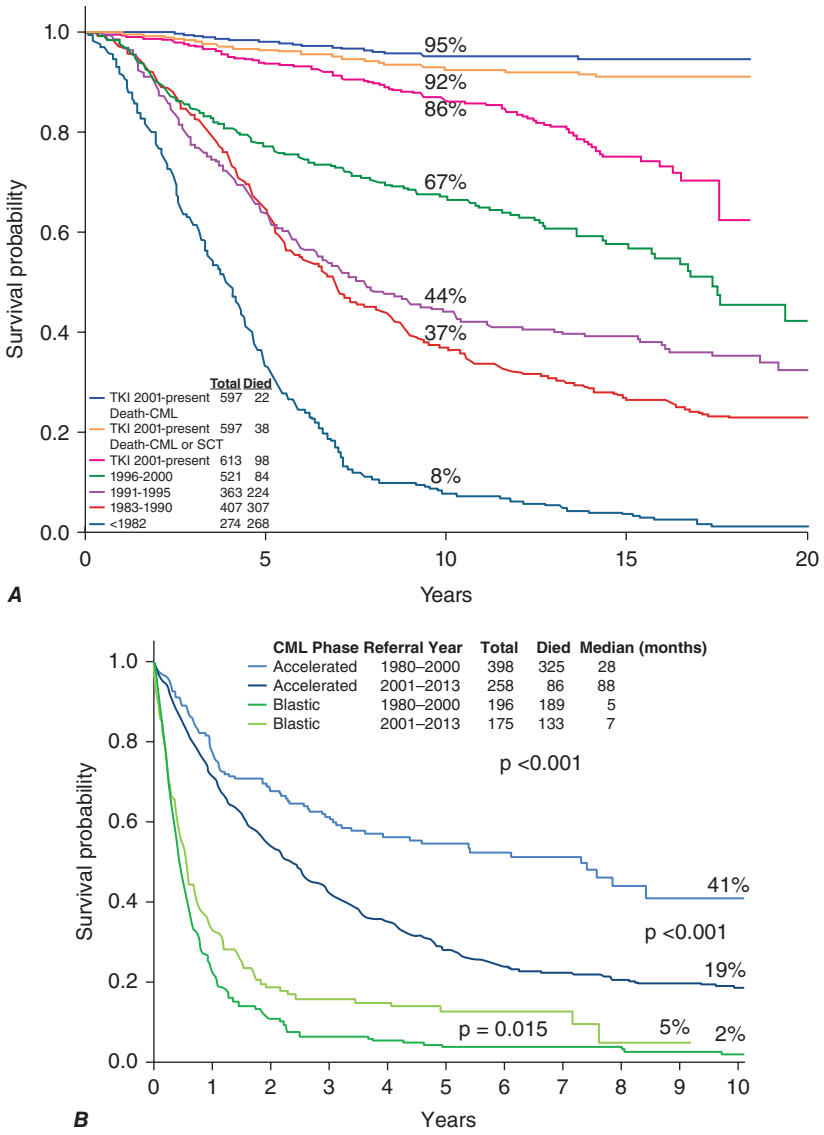

FIGURE 105-2 ***A.*** Survival in newly diagnosed chronic-phase chronic myeloid leukemia (CML) by era of therapy (MD Anderson Cancer Center experience from 1965 to present). Top blue curve is survival with tyrosine kinase inhibitors (TKIs), accounting for only CML-related deaths. The orange curve (second from top) accounts for deaths related to CML or CML treatment complications (e.g., deaths following allogeneic stem cell transplant [SCT]). The red curve (third from top) is survival including all deaths regardless of causality (old age, car accidents, suicide, gun shots, second cancers, complications of unrelated surgeries, infections, others). The difference in the denominators, 613 minus 597 cases, is because 16 deaths were from unknown/undocumented causes (outside MD Anderson and no good tracking for cause of death). ***B.*** Survival in patients with accelerated- and blastic-phase CML referred to MD Anderson Cancer Center by era of therapy, demonstrating the significant survival benefit in the TKI era in accelerated-phase CML but the modest benefit in blastic-phase CML. Referred cases included de novo and post-chronic-phase transformations.

allow temporary therapy interruption in women pursuing pregnancy. The lack of achievement of MMR or DMR should not be considered as "failure" of a particular TKI therapy and/or an indication to change the TKI or to consider allogeneic SCT.

Long-term updates of randomized trials suggest that second-generation TKIs and imatinib are similarly effective in lower-risk CML; second-generation TKIs may offer a therapeutic advantage among patients with high-risk CML.

TREATMENT

Chronic Myeloid Leukemia

Since 2001, six drugs have been approved by the U.S. Food and Drug Administration (FDA) for the treatment of CML. These include five oral TKIs: imatinib (Gleevec, Glivec), nilotinib (Tasigna), dasatinib (Sprycel), bosutinib (Bosulif), and ponatinib (Iclusig). Dasatinib, nilotinib, and bosutinib are referred to as second-generation TKIs; ponatinib is referred to as a third-generation TKI. Nilotinib is similar in structure to imatinib but 30 times more potent. Dasatinib and bosutinib inhibit the SRC family of kinases in addition to ABL1, with dasatinib reported to be 300 times more potent and bosutinib 30–50 times more potent than imatinib. In contrast to all other TKIs, bosutinib has no activity against c-Kit or platelet-derived growth factor receptor (PDGFR). Ponatinib is highly effective against wild-type and mutant *BCR/ABL1* clones. It is also the only available BCR-ABL1 TKI active against T315I, a gatekeeper mutation resistant to the other four ATP-competitive TKIs **(Table 105-2)**. Ponatinib also inhibits vascular endothelial growth factor receptor (VEGFR), which may be at least partly responsible for the high incidence of hypertension observed with this agent (Table 105-2). Imatinib 400 mg orally daily, nilotinib 300 mg orally twice a day (on an empty stomach), dasatinib 100 mg orally daily, and bosutinib 400 mg orally daily are approved for frontline therapy of CML. Dasatinib 50 mg orally daily is as effective in frontline therapy as 100 mg daily, and significantly less toxic. All four are also approved for salvage therapy (nilotinib 400 mg twice daily; bosutinib 500 mg daily; others at the same dose as frontline therapy), in addition to ponatinib

TABLE 105-2 Medical Therapeutic Options in Chronic Myeloid Leukemia

AGENT (BRAND NAME)	APPROVED INDICATIONS	DOSE SCHEDULE	NOTABLE TOXICITIES
Imatinib mesylate (Gleevec)	All phases	400 mg daily	See text
Dasatinib (Sprycel)	All phases	First-line: 100 mg daily Salvage: 100 mg daily in chronic phase; 140 mg daily in transformation	Myelosuppression; pleural and pericardial effusions; pulmonary hypertension
Nilotinib (Tasigna)	All phases except blastic phase	First-line: 300 mg twice daily Salvage: 400 mg twice daily	Diabetes; arterio-occlusive disease; pancreatitis
Bosutinib (Bosulif)	All phases	First line: 400 mg daily Salvage: 500 mg daily	Diarrhea; liver toxicity; renal dysfunction
Ponatinib (Iclusig)	Optimal TKI if T315I mutation Failure of ≥2 tyrosine kinase inhibitors	45 mg daily (may consider lower starting doses in the future, e.g., 30 mg daily). (Lower the dose to 15 mg daily once a complete cytogenetic response is achieved).	Skin rashes (10–20%); pancreatitis (5%); arterio-occlusive disease (10–20%); systemic hypertension (10–15%)
Omacetaxine mepesuccinate (Synribo)	Failure ≥2 tyrosine kinase inhibitors	1.25 mg/m^2 subcutaneously twice daily for 14 days of induction; 7 days of maintenance every month (may consider shorter dose schedules, 7 days of induction, 2–5 days of maintenance)	Myelosuppression

(45 mg daily). Ponatinib 45 mg daily may be associated with serious side effects: arterio-occlusive events, pancreatitis, hypertension, and skin rashes. A response-directed dose adjusted regimen, with a starting dose of 45 mg and reduction to 15 mg once a cytogenetic response is achieved, has resulted in a reduced incidence of arterio-occlusive events and has become standard. Imatinib, dasatinib (140 mg daily), bosutinib, and ponatinib are also approved for the treatment of CML in transformation (accelerated and blastic phase), whereas nilotinib is only approved for chronic and accelerated phase. The sixth approved drug is omacetaxine (Synribo), a protein synthesis inhibitor with presumed more selective inhibition of the synthesis of the BCR-ABL1 oncoprotein. It is approved for the treatment of chronic- and accelerated-phase CML after failure of two or more TKIs, at 1.25 mg/m^2 subcutaneously twice a day for 14 days for induction and for 7 days for consolidation-maintenance. The main adverse event of omacetaxine is prolonged myelosuppression; thus, many experts use shorter schedules (e.g., omacetaxine 5–7 days induction and 2–5 days maintenance), often combined with a TKI (Table 105-2).

Imatinib, dasatinib, bosutinib, and nilotinib are all acceptable frontline therapies in CML. The long-term results of imatinib are very favorable. The 10-year follow-up results show a cumulative complete cytogenetic response rate (occurring at least once) of 83%, with 60–65% of patients being in complete cytogenetic response at 5-year follow-up. The estimated 10-year survival rate is ~85%. Among patients continuing on imatinib, the annual rate of transformation to accelerated-blastic phase in years 4–8 is <1%. In three randomized studies, one comparing nilotinib 300 mg twice daily or 400 mg twice daily with imatinib (ENESTnd), another comparing dasatinib 100 mg daily with imatinib (DASISION), and a third comparing bosutinib 400 mg daily with imatinib (BFORE), the second-generation TKIs were associated with better outcomes in early surrogate endpoints, including higher rates of complete cytogenetic responses (85–87% vs 77–82%), MMRs (5-year rates 76–77% vs 60–64%), and MR4.5 (5-year rates 42–53% vs 31–33%), with lower rates of transformation to accelerated and blastic phase (2–5% vs 7%). However, no study has shown a survival benefit with second-generation TKIs. This may be because the rate of complete cytogenetic response is ultimately similarly high with imatinib versus second-generation TKIs, and also because sequential therapy with TKIs (following close observation and treatment change at progression) provides highly effective therapy for most patients; this ensures adequate long-term outcome despite relapse or intolerance after initial therapy.

Salvage therapy in chronic phase with dasatinib, nilotinib, bosutinib, or ponatinib is associated with complete cytogenetic response rates of 30–60%, depending on the salvage status (cytogenetic vs hematologic relapse), prior response to other TKIs, number of prior TKIs used, and the mutations at the time of relapse. Complete cytogenetic responses are generally durable, particularly in the absence of clonal evolution. Ponatinib is the only TKI active in the setting of T315I mutation, with complete cytogenetic response rates of 50–70% among patients who have received two or more TKIs. The estimated 5-year survival rates with new TKIs as salvage are 70–75% (compared with <50% before their availability). For example, with dasatinib salvage after imatinib failure in chronic-phase CML, the estimated 7-year rate of major molecular was 46%, the estimated 7-year survival rate was 65%, and progression-free survival rate was 42%. Thus, TKIs in the salvage setting have already reduced the annual mortality from the historical rate of 10–15% to ≤5%.

The goal of CML therapy is survival prolongation. The achievement of treatment-free remission (TFR) status has become a therapeutic goal of increased interest (sustained DMR or CMR after discontinuation of TKI therapy). In current practice, with the availability of appropriate TKI therapy and with compliance, monitoring, and changing of TKI therapy as indicated by response/resistance and side effects, patients can have a near-normal life expectancy, with a "relative" survival similar to that of the general population. Therefore, in standard practice, achievement and maintenance of a complete cytogenetic response are the aims of therapy, because complete cytogenetic response is the only outcome associated with survival prolongation. Lack of achievement of an MMR (protects against events; associated with longer event-free survival) or of DMR (offers the potential of treatment discontinuation and of TFR) should not be considered indications to change TKI therapy or to consider allogeneic SCT. A general practice rule is to continue the particular TKI chosen at the most tolerable dose schedule not associated with grade 3–4 side effects or with bothersome chronic side effects, for as long as possible, until either cytogenetic relapse or the persistence of unacceptable side effects. These two factors (i.e., cytogenetic relapse and intolerable side effects) are the indicators of "failure" of a particular TKI therapy. A second emerging general practice rule is that patients with CML should always receive daily TKI therapy throughout their lifetime (chronic, transformation), either alone (chronic) or in combinations (possibly for those in transformation, although combinations not formally approved), except perhaps in situations of "molecular cure" (TFR; elective discontinuation of TKI if DMR sustained for >2 to 5 years, followed by close monitoring) or after allogeneic SCT with undetectable disease.

Because of the increasing prevalence of CML (cost of TKI therapy) and the emerging evidence of possible organ toxicities with long-term use (e.g., renal with imatinib and bosutinib; arterio-occlusive with nilotinib, dasatinib, and ponatinib), a goal of therapy

of increasing interest in CML is to achieve eradication of the disease (molecular "cure" or TFR) that is prolonged and durable, with recovery of nonneoplastic, nonclonal hematopoiesis off TKI therapy. The first step toward this aim is to obtain the highest rates of DMR lasting for at least 2 or more years. This is currently achievable in about 25–30% of patients treated with imatinib and in 40–45% of patients treated with second-generation TKIs. Approximately 50–60% of those who meet these criteria and discontinue therapy remain free from therapy and in DMR-MMR. As a result, TFR rates are estimated to be about 15–20% after imatinib therapy and 25–30% after second-generation TKIs.

Recommendations provided by the National Comprehensive Cancer Network (NCCN) and by the European LeukemiaNet (ELN) propose optimal/expected, suboptimal/warning, and failure response scenarios at different time points of TKI treatment duration. Unfortunately, they may have been misinterpreted in current practice because oncologists often report that their aim of treatment is the achievement of MMR and disease eradication. Significantly, a substantial proportion of oncologists consider a change of TKI therapy in a patient in complete cytogenetic response if they note loss of MMR (increase of *BCR-ABL1* transcripts [IS] from ≤0.1% to >0.1%). This perception may be the result of confusion regarding the aims of the NCCN and ELN guidelines, which have been updated often as a result of maturing data and have multiple treatment endpoint considerations. Although such endpoints may have been suggested as possible criteria for failure or suboptimal response, it is important to emphasize that no randomized study has yet shown that a change of TKI treatment in patients with complete cytogenetic response because of a loss of MMR, versus changing at the time of cytogenetic relapse, improves survival or other long-term outcomes. This is likely because of the high efficacy of salvage TKI therapy at the time of cytogenetic relapse.

Side effects of TKIs are generally mild to moderate, although with long-term TKI therapy, they could affect the patient's quality of life. Serious side effects occur in <5–10% of patients. With imatinib therapy, common mild to moderate side effects include fluid retention, weight gain, nausea, diarrhea, skin rashes, periorbital edema, bone or muscle aches, fatigue, and others (rates of 10–20%). In general, second-generation TKIs are associated with lower rates of these bothersome adverse events. However, dasatinib 100 mg daily is associated with higher rates of myelosuppression (20–30%), particularly thrombocytopenia, with pleural (10–25%) or pericardial effusions (≤5%), and with pulmonary hypertension (<5%). A lower dose of dasatinib (50 mg daily instead of 100 mg daily) used in frontline CML therapy has resulted in similar efficacy and a lower incidence of serious side effects (pleural effusions <5%, myelosuppression <10%). Nilotinib is associated with higher rates of hyperglycemia (10–20%), pruritus and skin rashes, hyperbilirubinemia (typically among patients with Gilbert's syndrome and mostly of no clinical consequences), and headaches. Nilotinib is also associated with occasional instances of pancreatitis (<5%). Nilotinib 300–400 mg twice daily is associated with a 10-year cumulative incidence of cardiovascular complications of 15–25%. Bosutinib is associated with higher rates of liver toxicity, renal dysfunction, and early and self-limited gastrointestinal adverse events, particularly diarrhea (70–85%). Occasionally, the gastrointestinal symptoms mimic chronic severe enterocolitis, which reverses with treatment discontinuation. Ponatinib 45 mg daily is associated with higher rates of serious skin rashes (10–15%), pancreatitis (10%), elevations of amylase/lipase (10%), and systemic hypertension (50–60%; severe in 20%). Arterio-occlusive events (cardiovascular, cerebrovascular, and peripheral arterial) have been reported with most TKIs. The incidence appears to be highest with ponatinib, but both nilotinib and dasatinib are associated with these events at an incidence significantly higher than imatinib. Among the TKIs, bosutinib is associated with the lowest incidence of cardiovascular events. Nilotinib and dasatinib may cause prolongation of the QTc interval; therefore, they should be evaluated cautiously in patients with prolonged QTc interval on electrocardiogram (>470–480 ms), and drugs given for other medical conditions should have relatively smaller or no effects on QTc. These side effects can often be dose-dependent and are generally reversible with treatment interruptions and dose reductions. Dose reductions can be individualized. However, the lowest estimated effective doses of TKIs (from different studies and treatment practices) are imatinib 100–200 mg daily; nilotinib 150 mg twice daily or 200 mg daily; dasatinib 20 mg daily; bosutinib 200–300 mg daily; and ponatinib 15 mg daily.

With long-term follow-up, rare but clinically relevant serious toxicities are emerging. Renal dysfunction and occasionally renal failure (creatinine elevations >2–3 mg/dL) are observed in 2–3% of patients, more frequently with imatinib and bosutinib than other TKIs, and usually reverse with TKI discontinuation and/or dose reduction. Rarely, patients may develop TKI-related peripheral neuropathy or even central neurotoxicities that are misdiagnosed as dementia or Alzheimer's disease; they may reverse slowly after TKI discontinuation. Pulmonary hypertension has been reported with dasatinib (<1–2%) and should be considered in a patient with shortness of breath and a normal chest x-ray (echocardiogram with emphasis on measurement of pulmonary artery pressure). This may be reversible with dasatinib discontinuation and occasionally the use of sildenafil citrate. Systemic hypertension has been observed more often with ponatinib. Hyperglycemia and occasionally diabetes have been noted more frequently with nilotinib. Finally, mid- and small-vessel arterio-occlusive and vasospastic events have been reported at low but significant rates with nilotinib and ponatinib and should be considered possibly TKI-related and represent indications to interrupt or reduce the dose of the TKI. These events include angina, coronary artery disease, myocardial infarction, peripheral arterial occlusive disease, transient ischemic attacks, cerebral vascular accidents, Raynaud's phenomenon, and accelerated atherosclerosis. Although these events are uncommon (<5%) (10-year cumulative rates of 15% with nilotinib 300 mg BID and 20–25% with 400 mg BID, compared with <5% with imatinib), they are clinically significant for the patient's long-term prognosis and occur at significantly higher rates than in the general population, particularly among patients with other risk factors for such events. Serious arterio-occlusive and vasospastic events are more common with ponatinib 45 mg daily (5-year rates 20%).

Discontinuation of TKIs and Treatment-Free Remissions Several studies have confirmed that TKI discontinuation among patients who achieve DMR (MR4.5) for longer than 2–3 years can result in TFR rates of 40–60%. Discontinuation of TKI therapy after 5+ years of CMR is associated with TFR rates of 70–80% or greater. Since the incidence of durable MR4.5 (*BCR-ABL* transcripts [IS] ≤0.0032%) is 30–60%, ~15–30% of all patients with CML on TKI therapy may achieve TFR. This approach is ready for community practice provided it is done under optimal conditions. These include the following: patients must have low or intermediate Sokal risk CML in first chronic phase (no evidence or history of transformation), with history of quantifiable *BCR-ABL1* transcripts (e13a2, e14a2), on long-term TKI therapy (5–8+ years), with documented DMR for >2–3 years (assessed every 6 months during this time span and with a PCR with adequate sensitivity), and should be monitored at referral centers that offer rigorous testing of residual CML disease. Patients must also be compliant to frequent monitoring (PCR studies every 1–2 months for the first 6 months, then every 2 months until 2 years and every 3–6 months thereafter).

ALLOGENEIC STEM CELL TRANSPLANT

Allogeneic SCT, a curative modality in CML, is associated with long-term survival rates of 40–60% when implemented in chronic phase. It is associated with early (1-year) mortality rates of 5–30%. Although the 5- to 10-year survival rates were reported to be ~50–60% (and considered as cure rates), ~10–15% of patients die in the subsequent 1–2 decades from subtle long-term complications of the transplant (rather than from CML relapse). These are related

to chronic graft-versus-host disease (GVHD), organ dysfunction, development of second cancers, occasional late relapses, and hazard ratios for mortality higher than in the normal population. Other significant morbidities include infertility, chronic immune-mediated complications, cataracts, hip necrosis, and other morbidities affecting quality of life. The cure and early mortality rates in chronic-phase CML are also associated with several factors: patient age, duration of chronic phase, whether the donor is related or unrelated, degree of matching, preparative regimen, and others. In accelerated-phase CML, the cure rates with allogeneic SCT are 30–50%, depending on the definition of accelerated disease. Patients with clonal evolution as the only criterion have cure rates of up to 40–50%. Patients undergoing allogeneic SCT in second chronic phase have cure rates of 40–50%. The cure rates with allogeneic SCT in blastic-phase CML are ≤20%. Post–allogeneic SCT strategies are now implemented in the setting of molecular or cytogenetic relapse or in hematologic relapse/transformation. These include the use of TKIs for prevention or treatment of relapse, donor lymphocyte infusions, and second allogeneic SCTs, among others. TKIs appear to be highly successful at reinducing cytogenetic/molecular remissions in the setting of cytogenetic or molecular relapse after allogeneic SCT.

Choice and Timing of Allogeneic SCT Allogeneic SCT was considered first-line CML therapy before 2000. The maturing positive experience with TKIs has now relegated its use to after first-line TKI failures. An important question is the optimal timing and sequence of TKIs and allogeneic SCT (whether allogeneic SCT should be used as second- or third-line therapy). Among patients who present with or evolve to blastic phase, combinations of chemotherapy and TKIs should be used to induce remission, followed by allogeneic SCT as soon as possible. The same applies to patients who evolve from chronic to accelerated phase. Patients with de novo accelerated-phase CML may do well with long-term TKI therapy (estimated 8-year survival rate 75%); the timing of allogeneic SCT depends on their optimal response to TKI (achievement of complete cytogenetic response). Among patients who relapse in chronic phase, the treatment sequence depends on several factors: (1) patient age and availability of appropriate donors; (2) risk of allogeneic SCT; (3) presence or absence of clonal evolution and mutations; (4) patient's prior history and comorbidities; and (5) patient and physician preferences **(Table 105-3)**. Patients with T315I mutations at relapse should be offered ponatinib and considered for allogeneic SCT particularly if in blastic phase and perhaps also in accelerated phase (because of the short follow-up with ponatinib). Patients with mutations involving Y253H, E255K/V, and F359V/C/I respond better to dasatinib or bosutinib. Patients with mutations involving V299L, T315A, and F317L/F/I/C respond better to nilotinib. Comorbidities such as diabetes, hypertension, pulmonary hypertension, chronic lung disease, cardiac conditions, and pancreatitis may influence the choice for or against a particular TKI. Patients with clonal evolution, unfavorable mutations, or lack of major/complete cytogenetic response within 1 year of salvage TKI therapy have short remission durations and should consider allogeneic SCT as more urgent in the setting of salvage. Patients without clonal evolution or mutations at relapse and who achieve a complete cytogenetic response with TKI salvage have long-lasting complete remissions and may delay the option of allogeneic SCT to third-line therapy. Finally, older patients (age 65–70 years or older) and those with high risk of mortality with allogeneic SCT may forgo this curative option for several years of disease control in chronic phase with or without cytogenetic response (Table 105-3). In emerging nations, where generic imatinib is now available at the annual price of $400–3000, frontline imatinib is a cost-effective therapy. However, second-line therapy with allogeneic SCT, a one-time curative option with a cost of $20,000–100,000, may be considered (in preference to second-generation TKIs—annual cost above $40,000–100,000) as a more cost-effective national health care strategy in CML. Table 105-3 summarizes a general guidance to the choice of TKIs versus allogeneic SCT.

TABLE 105-3 General Suggestions Regarding the Use of Tyrosine Kinase Inhibitors (TKIs) and Allogeneic Stem Cell Transplantation (SCT) in Chronic Myeloid Leukemia (CML)

CML PHASE	USE OF TKI	CONSIDERATION OF ALLOGENEIC SCT
Accelerated or blastic	Interim therapy to achieve minimal CML burden	As soon as possible (exception: de novo accelerated phase)
T315I mutation	Ponatinib to achieve minimal CML burden	Depends on longer term follow-up results of ponatinib efficacy
Imatinib failure in chronic phase; no clonal evolution, no mutations, good initial response; no T315I	Second-line TKIs long term	Third-line after second-line TKI failures
Clonal evolution or mutations, or no cytogenetic response to second-line TKI	Interim therapy with alternative second-generation TKI or ponatinib to achieve minimal CML burden	Second-line
Older patients (≥65–70 years) after imatinib failure in chronic phase	Salvage TKIs as longer-term therapy	May forgo allogeneic SCT in favor of good quality of life and survival in chronic phase
Imatinib failure; emerging nation	—	Second-line: curative, one-time cost $20,000–100,000 (vs >$40,000–100,000/year with TKI)

Note: Mutations involving Y253H, E255K/V, or F359V/C/I: prefer dasatinib or bosutinib. Mutations involving V299L, T315A, or F317L/F/I/C: prefer nilotinib.

MONITORING THERAPY IN CML

Achievement of complete cytogenetic response by 12 months of imatinib therapy and its persistence later, the only consistent prognostic factor associated with prolonged survival, is now the main therapeutic endpoint in CML. Failure to achieve a complete cytogenetic response by 12 months or occurrence of later cytogenetic or hematologic relapse is considered as treatment failure and an indication to change therapy. Because salvage therapy with other TKIs may re-establish good outcome, it is important to ensure patient compliance to continued TKI therapy and change therapy when cytogenetic relapse is confirmed unless this is related to nonadherence. Patients on frontline imatinib therapy should be closely monitored until documentation of complete cytogenetic response, at which time they can be monitored every 6 months with peripheral blood PCR, or more frequently (e.g., every 3 months), if there are concerns about changes in *BCR-ABL1* transcripts. Cytogenetic relapse on imatinib is an indication of treatment failure and need to change TKI therapy. Mutational analysis in this instance helps in the selection of the next TKI and identifies mutations in 30–50% of patients. Mutational studies by standard Sanger sequencing (which is the technique currently available in most clinical laboratories) in patients in complete cytogenetic response (in whom there may be concerns of increasing *BCR-ABL1* transcripts) identify mutations in ≤5% and are therefore not indicated. Earlier response has been identified as a prognostic factor for long-term outcome, including achievement of partial cytogenetic response (*BCR-ABL1* transcripts ≤10%) by 3–6 months of therapy. Failure to achieve such a response has been associated with significantly worse survival.

The use of second-generation TKIs (dasatinib, bosutinib, nilotinib) as frontline therapy changed the monitoring approach slightly. Patients are expected to achieve major cytogenetic response (or *BCR-ABL1* transcripts ≤10%) by 3–6 months of therapy. Failure to do so is associated with worse event-free survival, transformation

rates, and survival. However, the 3- to 5-year estimated survival among such patients is still high, ~80–90%, which is better than what would be anticipated if such patients were offered allogeneic SCT at that time. Changes of therapy for patients with "slow" response have not been proven to be of long-term benefit compared to changes when more obvious signs of resistance appear. Thus, slow response to therapy is considered a warning signal, but it is not known whether changing therapy to other TKIs at that time would improve longer-term outcome.

TREATMENT OF ACCELERATED AND BLASTIC PHASES

Patients in accelerated or blastic phase may receive therapy with TKIs, preferably second- or third-generation TKIs (dasatinib, nilotinib, bosutinib, ponatinib), alone or in combination with chemotherapy, to reduce the CML burden, before undergoing allogeneic SCT. Response rates (major hematologic) with single-agent TKIs range from 30 to 50% in accelerated phase and from 20 to 30% in blastic phase. Cytogenetic responses, particularly complete cytogenetic responses, are uncommon (10–30%) and transient in blastic phase. Studies of TKIs in combination with chemotherapy show that combined TKI-chemotherapy strategies increase the response rates and their durability and improve survival. This is particularly true in CML lymphoid blastic phase, where the combination of anti-ALL chemotherapy with TKIs results in complete response rates of 70% and median survival times of 3 years (compared with historical response rates of 40–50% and median survival times of 12–18 months). This allows many patients to undergo allogeneic SCT in a state of minimal CML burden or second chronic phase, which are associated with higher probability of long-term survival. In CML nonlymphoid blastic phase, anti–acute myeloid leukemia chemotherapy combined with TKIs results in CR rates of 30–50% and median survival times of 9–12 months (compared with historical response rates of 20–30% and median survival times of 3–5 months). In accelerated phase, response to single TKIs is significant in conditions where "softer" accelerated phase criteria are considered (e.g., clonal evolution alone, thrombocytosis alone, significant splenomegaly or resistance to hydroxyurea, but without evidence of high blast and basophil percentages). In accelerated phase, combinations frequently include TKIs with low-intensity chemotherapy such as low-dose cytarabine, decitabine, interferon α, hydroxyurea, or others.

OTHER TREATMENTS AND SPECIAL THERAPEUTIC CONSIDERATIONS

Interferon α Interferon α is considered in combination with TKIs (an investigational approach), sometimes after CML failure on TKIs, occasionally in patients during pregnancy, or as part of investigational strategies with TKIs to eradicate residual molecular disease.

Chemotherapeutic Agents Hydroxyurea remains a safe and effective agent (at daily doses of 0.5–10 g) to reduce initial CML burden, as a temporary measure in between definitive therapies, or in combination with TKIs to sustain complete hematologic or cytogenetic responses. Busulfan is often used in allogeneic SCT preparative regimens. Because of its side effects (delayed myelosuppression, Addison-like disease, pulmonary and cardiac fibrosis, myelofibrosis), it is now rarely used in the chronic management of CML. Low-dose cytarabine, decitabine, anthracyclines, 6-mercaptopurine, 6-thioguanine, thiotepa, anagrelide, and other agents are sometimes useful in different CML settings to control the disease burden.

Others Splenectomy is now seldom considered to alleviate symptoms of massive splenomegaly and/or hypersplenism. Splenic irradiation is rarely used, if at all, because of the postirradiation adhesions and complications. Leukapheresis is occasionally used in patients presenting with extreme leukocytosis and leukostatic complications. Single doses of high-dose cytarabine or high doses of hydroxyurea, with tumor lysis management, may be as effective and less cumbersome.

Special Considerations Women with CML who become pregnant should discontinue TKI therapy immediately. Among 125 babies delivered to women with CML who discontinued imatinib therapy as soon as the pregnancy was known, three babies were born with neurologic, skeletal, and renal malformations, suggesting the teratogenicity of imatinib known from animal studies. A similar experience has been reported with dasatinib, where the incidence of malformations was reported to be higher, 10–12%. There are no or little data with other TKIs. Control of CML during pregnancy can be managed with leukapheresis for severe symptomatic leukocytosis in the first trimester and with hydroxyurea subsequently until delivery. There are reports of successful pregnancies and deliveries of normal babies with interferon α therapy and registry studies in essential thrombocytosis of its safety, but interferon α has side effects that may be troublesome during pregnancy, can be antiangiogenic, and may increase the risk of spontaneous abortions.

Approximately 10–15% of patients on TKI therapy may develop chromosomal abnormalities in the Ph-negative cells. These may involve loss of chromosome Y, trisomy 8, 20q–, chromosome 5 or 7 abnormalities, and others. Most chromosomal abnormalities disappear spontaneously and may be indicative of the genetic instability of the hematopoietic stem cells that predisposes the patient to develop CML in the first place. Rarely (in <1% of instances), abnormalities involving chromosomes 5 or 7 may be truly clonal and evolve into myelodysplastic syndrome or acute myeloid leukemia. This is thought to be part of the natural course of patients in whom CML was suppressed and who live long enough to develop other hematologic malignancies.

GLOBAL ASPECTS OF CML

Routine physical examinations and blood tests in the United States and advanced countries result in early detection of CML in most patients. About 50–70% of patients with CML are diagnosed incidentally, and high-risk CML as defined by prognostic models (e.g., Sokal risk groups) is found in only 10% of patients. This is not the same situation in emerging nations where most patients are diagnosed following evaluation for symptoms and many present with high tumor burden, such as massive splenomegaly, and advanced phases of CML (high-risk CML documented in 20–30%). Therefore, the prognosis of such patients on TKI therapy may be worse than the published experience.

The high cost of TKI therapies (annual costs of $90,000–140,000 in the United States; lower but variable in the rest of the world) makes the general affordability of such treatments difficult. Although TKI treatment penetration is high in nations where cost of therapy is not an issue (e.g., Sweden, European Union), it may be less so in other nations, even in advanced ones like the United States, where out-of-pocket expenses may be prohibitive to a subset of patients. Although the estimated 10-year survival in CML is >85% in single-institution studies (e.g., MD Anderson Cancer Center), in national studies in countries with TKI affordability (Sweden) (**Figs.** 105-2 and **105-3**) or in clinical trials (where all patients have access to TKIs throughout their care), the estimated 10-year survival worldwide, even 16 years after the introduction of TKI therapies, is likely to be <50%. The Surveillance, Epidemiology, and End Results (SEER) data from the United States report an estimated 5-year survival rate of 60% in the era of TKIs. It appears that the treatment penetration of imatinib and other TKIs into CML therapy worldwide is still not optimal.

The current high cost of TKI therapies poses two additional considerations. The first are the treatment pathways and guidelines in nations where TKIs may not be affordable by patients or the health care system. In these conditions, there are trends of pathways advocating allogeneic SCT as frontline or second-line therapy (i.e., after imatinib failure; as a onetime cost of $20,000–100,000) despite the associated mortality and morbidities. The second is the choice of frontline TKI therapy. Imatinib is now available in generic forms at affordable costs ($400–10,000 per

The accelerated- and blastic-phase cases are de novo presentations. The favorable outcome with de novo blastic phase may be due to use of 20% blasts or more to define blastic phase. *(With permission from Dr. Martin Hoglund, Swedish CML Registry, 2013.)*

year). Dasatinib is available in generic forms in many geographies. Safe and effective generic TKIs may become preferred frontline and salvage therapies in CML, precluding the necessity of an allogeneic SCT in first salvage in poorer nations.

106 Acute Lymphoid Leukemia

Dieter Hoelzer

In acute lymphoblastic leukemia (ALL), the malignant clone arises from hematopoietic progenitors in the bone marrow or lymphatic system resulting in an increase of immature nonfunctioning leukemic cells. Infiltration of bone marrow leads to anemia, granulocytopenia, and thrombocytopenia with the clinical manifestations of fatigue, weakness, infection, and hemorrhage. These symptoms are more often the reason a patient first seeks medical advice rather than consequences of tumor bulk, such as lymph node enlargement, hepatosplenomegaly caused by leukemic infiltration, or symptoms of the central nervous system (meningeosis leukemica).

INCIDENCE AND AGE

ALL is the most frequent neoplastic disease in children with an early peak at the age of 3–4 years. The incidence in adults ranges from 0.7 to 1.8/100 000 per year, being somewhat higher in adolescents and young adults (AYAs), decreasing in adults, but increasing again in elderly people. Thus, Philadelphia chromosome–positive ALL (Ph+ ALL; *BCR/ABL* translocation) is observed in half of elderly B-lineage patients. The frequency of immunologic, cytogenetic, and genetic subtypes changes substantially with age.

ETIOLOGY

The etiology of acute leukemias is unknown. Internal and external factors influence the incidence of leukemia. Exposure to ionizing radiation or to chemicals, including prior chemotherapy, is associated with an increased risk of developing leukemia, more often observed in acute myeloid leukemia (AML). However, increasingly, secondary ALLs have been observed, particularly after cytostatic treatment with alkylating agents and topoisomerase inhibitors as treatment for primary tumors, most often for AML, myelodysplastic syndromes, or breast cancer.

CONGENITAL DISORDERS

Patients with some rare congenital chromosomal abnormalities have a higher risk of development of acute leukemia (e.g., Klinefelter's syndrome, Fanconi's anemia, Bloom's syndrome, ataxia-telangiectasia, and neurofibromatosis). Those with Down's syndrome have a twentyfold increased incidence of leukemia; ALL is increased in childhood and AML at an older age.

INFECTIOUS AGENTS

No direct evidence implicates viruses as a major cause of human acute leukemia. However, viruses are involved in the pathogenesis of two lymphoid neoplasias. In the endemic African type of Burkitt's lymphoma, the Epstein-Barr virus, a DNA virus of the herpes family, has been implicated as a potential causative agent (see **Chap. 194**). Endemic infection with human T-cell leukemia virus I in Japan and the Caribbean has been shown to be an etiologic agent for rare cases of adult T-cell leukemia/lymphoma (see **Chap. 201**).

DIAGNOSIS AND CLASSIFICATION

The diagnosis of acute leukemia is first made by examination of the peripheral blood and bone marrow. For further classification of the leukemic blast cells, cytochemical stains, immunologic markers, and cytogenetic and molecular analysis are required. The immunologic markers are still the major criteria to subdivide into B-cell lineage or T-cell lineage ALL leukemias.

PERIPHERAL BLOOD

Peripheral blood counts and a differential count from a Wright-Giemsa–stained blood smear are essential at the time of presentation. The white blood cell (WBC) count in ~40% of ALL patients is reduced or normal **(Table 106-1)**. Only 16% of patients have a WBC above

TABLE 106-1 Laboratory Values at Diagnosis of Acute Lymphoblastic Leukemia (ALL)

		ALL
NO.		**1273***
Initial white blood cell count ($\times 10^9$/L)	<10	41%
	10–50	31%
	>50–100	28%

100×10^5/L. It is noteworthy that in 8% of ALL patients, no circulating leukemic blast cells were observed. Thus, in the frequently used automatic blood cell counting, the diagnosis may not be detected.

Peripheral blood characteristically shows anemia, thrombocytopenia, and neutropenia. Nearly one-third of patients have hemoglobin levels <7–8 g/dL. A platelet count below the critical number of 20×10^9/L and neutropenia (neutrophils $<0.5 \times 10^9$/L), which is associated with a higher risk of infection, are each noted in one-fifth of adults with ALL.

BONE MARROW EXAMINATION

Bone marrow aspirates/biopsies are important to assess immunologic, cytogenetic, and genomic markers. Direct smears from the bone marrow are essential to confirm the diagnosis of acute leukemia and to distinguish between AML and ALL. The bone marrow is usually heavily packed with leukemic blast cells with >90% in ~70% of patients, and thus, the normal hemopoietic elements are greatly reduced or absent. A biopsy of the bone marrow will further demonstrate marked hypercellularity with replacement of fat spaces, normal elements, and occasionally increased fibrosis.

LUMBAR PUNCTURE

The examination of the cerebrospinal fluid is an essential routine diagnostic measure for ALL. Central nervous system (CNS) leukemia is diagnosed if ≥5 cells/μL or leukemic blast cells were observed by morphology in cerebrospinal fluid. Opinions differ as to when the first lumbar puncture should be done—i.e., either delay lumbar puncture until remission is achieved to avoid seeding of the CNS with leukemic blast cells from the peripheral blood during the spinal tap, or perform the lumbar puncture before treatment starts, since early recognition of CNS disease will lead to immediate CNS-specific therapy. Lumbar puncture is restricted to patients with an adequate platelet count ($>20 \times 10^9$/L) and without manifest clinical hemorrhages. To eliminate potentially transferred blast cells, patients should receive intrathecal methotrexate at the first lumbar puncture.

MORPHOLOGIC SUBTYPES IN ALL

The French-American-British (FAB) classification distinguished three subgroups. L1 and L2 morphology has no clinical consequences. Only the L3 morphology, observed in up to 5% of adult patients, is indicative for mature B-cell lineage ALL (B-ALL) (see Chap. 62).

IMMUNOLOGIC SUBTYPES

A series of monoclonal antibodies is employed to identify antigens expressed on the surface of leukemic cells, corresponding to the pathways of normal B-cell differentiation (see Fig. 108-2). The aim of the immunologic classification is to subdivide ALLs according to the presence or absence of B-cell or T-cell markers. A marker is considered positive if >20% of the cells are stained with the monoclonal antibody.

There are different immunologic classifications, such as that of the European Group for the Immunological Characterization of Leukemias (EGIL), with clear therapeutic implications. Table 106-2 gives a simplified correlation of immunologic subtypes, cytogenetics and molecular aberrations, and clinical characteristics.

B-Cell Lineage ALL (B-ALL) More than 70% of adult ALLs are of B-cell origin, and the most frequent immunologic subtype, common ALL, is characterized by the presence of the ALL antigen CD10 without markers of relatively mature B cells such as cytoplasmic or surface membrane immunoglobulins. Pre-B-ALL (early B-ALL) is characterized by the expression of cytoplasmic immunoglobulin, which is negative in common ALL, but otherwise is identical with respect to all other cell markers. Pro-B-ALL corresponds to early B-cell differentiation and was formerly termed non-T-, non-B-ALL or null ALL because neither T-cell nor B-cell features could be demonstrated. This subtype is HLA-DR, terminal deoxynucleotidyl transferase, and CD19 positive and composes ~12% of adult ALLs. Mature B-ALL is seen in 3–4% of adults and is also known as Burkitt's leukemia. In mature B-ALL, blast cells express surface antigens of mature B cells, including the sIgM.

T-Cell Lineage ALL (T-ALL) Approximately 25% of adult ALLs are of T-cell lineage. All cases express the T-cell antigen CD7 and cytoplasmatic CD3 (CyCD3) or surface CD3. According to their phase of T-cell differentiation, they may express other T-cell antigens (e.g., the E-rosette receptor CD2 and/or the cortical thymocyte antigen CD1a). Early pro/pre-T-ALL (also termed early T precursor ALL [ETP-ALL]), cortical or thymic T-ALL, and mature T-ALL can be distinguished with these markers. ETP-ALL is characterized by lack of CD1a and CD8, weak CD5 expression, and at least one myeloid/stem cell marker.

Biphenotypic or Mixed Leukemias Biphenotypic leukemias are defined as those expressing markers of both lymphoid and myeloid lineages on the same leukemic cells. Bilineage leukemias are those with two populations of blast cells with either lymphoid or myeloid antigens. It is not clear whether these patients should receive an ALL or AML treatment protocol. In pediatric studies, starting with a pediatric ALL protocol seemed preferable, which was then followed by AML consolidation elements.

CYTOGENETIC AND MOLECULAR ANALYSIS

Cytogenetic and molecular analyses should be performed in all cases in ALL. They are important to define ALL subtypes, can identify independent prognostic markers of disease-free survival, and may determine specific targeted therapies.

The diagnostic techniques for ALL are standard cytogenetics, fluorescence in situ hybridization, and reverse transcriptase polymerase chain reaction. These methods allow the detection of Ph+ ALL, with the chromosomal translocation t(9;22)(q34;q11) and the detection of the corresponding *BCR-ABL1* gene rearrangement. Further ALL entities that have been identified are t(4;11)(q21;q23)/*MLL-AFA4*, abn11q23/*MLL*, and t(1;19)(q23;p13)/*PBX-E2A*.

Gene expression profiling, single nucleotide polymorphism array analysis, array-comparative genomic hybridization, and next-generation sequencing recognize the newly defined ALL entities: ETP-ALL and Ph-like ALL.

Ph-like ALL, also known as *BCR-ABL1*-like ALL, is characterized by genetic lesions similar to Ph+ ALL, associated with *IKZF1* (Ikaros) gene deletion, *CLRF2* (gene for cytokine-like receptor-2) overexpression, and tyrosine kinase activating rearrangements involving *ABL1*, *JAK2*, *PDGFRB*, and several other genes; however, it is *BCR-ABL1* negative. The frequency is 10% in children and 25–30% in young adults but does not increase further with age like Ph+ ALL. Treatment based on the underlying genetic lesion with BCR-ABL inhibitors

TABLE 106-2 Immunologic, Cytogenetic, Molecular, and Clinical Characteristics of Adult Acute Lymphoblastic Leukemia (ALL)

SUBTYPES	MARKER	INCIDENCE	FREQUENT CYTOGENETIC ABERRATIONS	GENETIC ABERRATIONS AND FUSION TRANSCRIPTS	CLINICAL CHARACTERISTICS	RELAPSE KINETICS AND LOCALIZATION
B-lineage ALL (B-ALL)	**HLA-DR+, TdT+, CD19+, and/or CD79a+, and/or CD22+**	**76%**				
Pro B-ALL	No additional differentiation markers Frequent myeloid coexpression (>50%) CD10–	12%	t(4;11) (q21;q23)	70% *ALL1-AF4* (20% Flt3 in MLL+)	High WBC (>100,000/µL) (26%)	Mainly BM (>90%)
Common ALL	CD10+	49%	t(9;22)(q34;q11) del(6q)	33% *BCR–ABL* with 54% *IKFZ1* del >25% *CDKN2A/B*	Higher age >50 years (24%)	Mainly BM (>90%) Prolonged relapse kinetics (up to 5–7 years)
Pre-B-ALL	CD10±, cyIg+	11%	t(9;22)(q34;q11) t(1;19)(q23;p13)	4% t(1;19)/*PBX-E2A*		
Mature B-ALL	CD10±, sIg+	4%	t(8;14)(q24;q32) t(2;8)(p12;q24) t(8;22)(q24;q11)		Higher age >55 years (27%) Frequent organ involvement (32%) and CNS involvement (13%)	Frequent CNS (10%) Short relapse kinetics (up to 1–1.5 years)
T-lineage ALL (T-ALL)	**cyCD3 or sCD3**	**24%**	t(10;14)(q24;q11) t(11;14)(p13;q11)	50% *NOTCH1B* 33% *HOX11b* 5% *HOX11L2b* 4% *NUP213-ABL1*	Younger age (90% <50 years) Frequent mediastinal tumors (60%) Frequent CNS involvement (8%) High WBC (>50/µL) (46%)	Frequent CNS (up to 10%) Extramedullary (6%) Intermediate relapse kinetics (up to 3–4 years) When relapsed, fast progression
Early Pro/ Pre T-ALL	No additional differentiation markers, mostly CD2–	6%				
Cortical T-ALL	CD1a+, sCD3±	12%				
Mature T-ALL	sCD3+, CD1a–	6%				

Abbreviations: BM, bone marrow; CNS, central nervous system; WBC, white blood cells.

(e.g., dasatinib) or JAK2 inhibitors (e.g., ruxolitinib) has so far had limited success in adults.

MINIMAL RESIDUAL DISEASE

Minimal residual disease (MRD) is the detection of residual leukemic cells that are not recognizable by light microscopy. Methods for determining MRD are based on the detection of leukemia-specific aberrant immunophenotypes by flow cytometry, the evaluation of leukemia-specific rearranged immunoglobulin or T-cell receptor sequences by real-time quantitative polymerase chain reaction, or the detection of fusion genes associated with chromosomal abnormalities (e.g., *BCR-ABL, MLL-AF4*). The detection limit with these methods is 10^{-3}–10^{-5} (0.1–0.001%). With new techniques such as next-generation sequencing (NGS) or digital droplet polymerase chain reaction (ddPCR), the sensitivity may increase to 10^{-5}–10^{-6}. The phenotypic aberrations are unique to each patient with ALL and can be detected in up to 95% of individuals. Collection of bone marrow at diagnosis for identification of patients' individual markers is essential for follow-up of MRD.

MOLECULAR RESPONSE AFTER INDUCTION THERAPY AND IMPACT ON OUTCOME

Achievement of molecular complete response/molecular remission is the most relevant independent prognostic factor for disease-free survival and overall survival in pediatric and adult ALL (**Table 106-3**). Patients with molecular complete remission after induction therapy had significantly superior outcomes in several studies, with a disease-free survival rate of ~70% compared to <40% for MRD-positive patients. Patients with molecular failure after induction should proceed to a targeted therapy to reduce the tumor load, followed by allogeneic stem cell transplantation (SCT), if possible.

PROGNOSTIC FACTORS, RISK STRATIFICATION, AND MRD

The aim of identification of prognostic parameters at diagnosis, which include age, white blood cell count, immunophenotype, and cytogenetic and genetic aberrations, is to stratify patients into risk groups: standard-risk patients are patients without any risk factor, and high-risk patients are those with one or more risk factors. High-risk patients are most often candidates for SCT in first complete remission (CR). MRD is thus the most important prognostic factor during therapy (**Fig. 106-1**); 20–30% of adult ALL patients who are MRD negative after induction will relapse. Potential reasons include loss of sensitivity, evolution of leukemic subclones, and extramedullary origin of disease. If the MRD status of a patient is not available, risk stratification should rely on clinical and laboratory risk factors evaluated at diagnosis.

TABLE 106-3 Response Parameters According to Minimal Residual Disease (MRD)

TERMINOLOGY	DEFINITION
Complete hematologic remission (CHR)	Leukemic cells not detectable by light microscopy (<5% blast cells in bone marrow [BM])
Complete molecular remission/MRD negativity	Patient in complete remission, MRD not detectable, ≤0.01% = ≤1 leukemia cell in 10,000 BM cells
Molecular failure/MRD positivity	Patient in complete hematologic remission, but not in molecular complete remission >0.01%
Molecular relapse/MRD positivity	Patient still in complete remission, had prior molecular complete remission, leukemic blast cells in BM not detectable (<5%)
Hematologic relapse	>5% blast cells in BM/blood

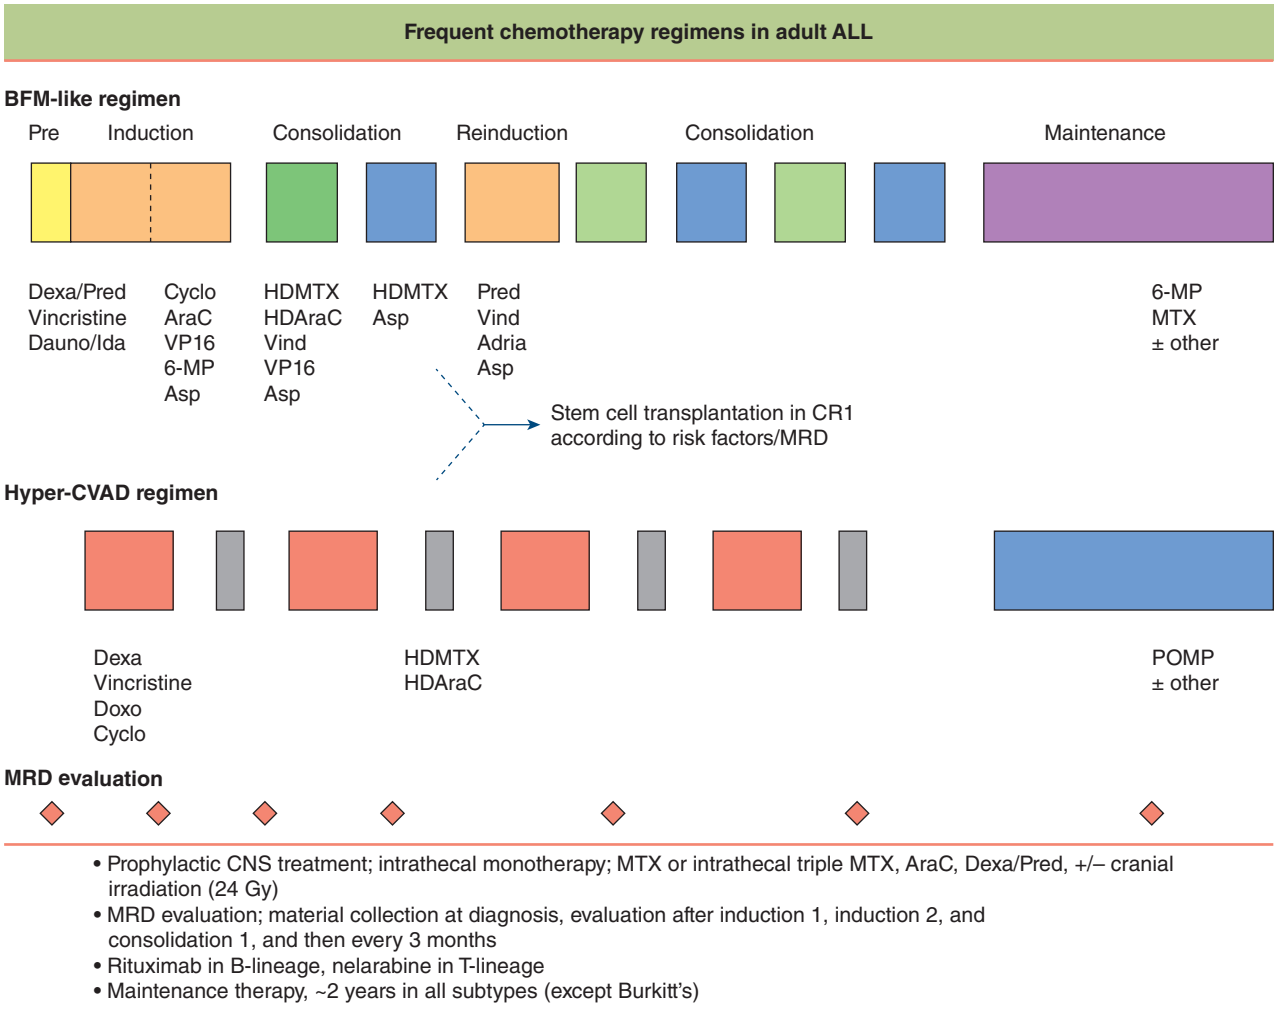

FIGURE 106-1 A schematic treatment algorithm in acute lymphoblastic leukemia (ALL). 6-MP, 6-mercaptopurine; Adria, Adriamycin (doxorubicin); AraC, cytarabine; Asp, asparaginase; BFM, Berlin-Frankfurt-Münster; CNS, central nervous system; CR1, first complete remission; Cyclo, cyclophosphamide; Dauno, daunorubicin; Dexa, dexamethasone; Doxo, doxorubicin; HD, high-dose; Hyper-CVAD, hyperfractionated cyclophosphamide, vincristine, doxorubicin, and dexamethasone; Ida, idarubicin; MRD, minimal residual disease; MTX, methotrexate; POMP, mercaptopurine, vincristine, methotrexate, and prednisolone; Pred, prednisolone; Vind, vindesine; VP16, etoposide.

TREATMENT PRINCIPLES

Treatment of ALL consists usually of pre-phase therapy, induction therapy, consolidation cycles, and maintenance treatment. Treatment should start immediately when the diagnosis of ALL is established.

Pre-Phase Therapy Pre-phase therapy consisting of glucocorticoids (prednisone 20–60 mg/d or dexamethasone 6–16 mg/d, both IV or PO) alone or in combination with another drug (e.g., vincristine, cyclophosphamide) is usually given for ~5–7 days. It allows safe tumor reduction to avoid tumor lysis syndrome, to initiate supportive therapy, such as substitution of platelets/erythrocytes, or to treat infections. The time required for pre-phase therapy will also allow time to obtain results of the diagnostic workup (e.g., cytogenetics, molecular genetics).

Induction Therapy The goal of induction therapy is the achievement of a CR or, even better, a molecular CR. With current regimens, the CR rate has increased to 80–90% and is higher for standard-risk patients (>90%) and lower for high-risk patients (~60%).

Induction regimens are centered around vincristine, glucocorticoids, and anthracyclines with or without cyclophosphamide or cytarabine. L-Asparaginase is the only ALL-specific drug and is now more intensively used in adults. Pegylated asparaginase has the advantage of a significantly longer period of asparagine depletion. Dexamethasone is often preferred to prednisone because it penetrates the blood-brain barrier and also acts on resting leukemic blast cells.

Two chemotherapy regimens are widespread (Fig. 106-1). One is patterned after the pediatric BFM (Berlin-Frankfurt-Münster) protocol, which is mostly used in European adult ALL trials. Another approach is to repeat two different alternating intensive chemotherapy cycles, identical for induction and consolidation, for eight cycles, such as Hyper-CVAD (hyperfractionated cyclophosphamide, vincristine, doxorubicin, and dexamethasone) protocol, which is preferentially used in the United States but also in many other parts of the world.

Postremission Consolidation Usual protocols use six to eight courses and often contain systemic high-dose (HD) therapy to reach sufficient drug levels in sanctuary sites such as the CNS. Most often HD methotrexate (1–1.5 g/m^2 and up to 3–5 g/m^2) and/or HD cytarabine (4–12 doses at 1–3 g/m^2) are administered.

Maintenance Therapy Maintenance therapy, a strategy transferred from childhood ALL, is mandatory. It consists of 6-mercaptopurine and methotrexate plus intrathecal therapy. The potential effect of further intensification cycles during maintenance remains unclear. The duration of maintenance therapy for T-ALL and B-ALL is 2–2.5 years, except for Burkitt's leukemia, for which it is not required. In Ph+ ALL, patients also require maintenance therapy that should include a tyrosine kinase inhibitor (TKI), most likely the TKI that has been used during induction and consolidation therapy. It is also standard to give a TKI after allogeneic SCT. The duration of maintenance therapy with a TKI is also 2–2.5 years and should be guided by MRD evaluation. TKI use is often interrupted or switched to another TKI if toxicity occurs.

TREATMENT OF ALL PATIENTS ACCORDING TO AGE

The outcome of ALL is strictly related to the age of a patient, with cure rates of ~90% in children, decreasing to <10% in elderly or frail

TABLE 106-4 Best Results in Recent Studies for Adult Acute Lymphoblastic Leukemia (ALL)

SUBTYPE	TREATMENT	OVERALL SURVIVAL
Burkitt's leukemia	Short intensive chemotherapy + rituximab; no SCT; no maintenance	80–90%
B-lineage ALL, Ph–		
AYA 15–35/45 years	Pediatric inspired, few/no SCT	≥70–80%
Adults 45–55 years	Intensive chemotherapy +/– SCT	50–60%
Elderly 55–70 years	Less intensive chemotherapy + immunotherapy	~30%
Frail >70/75 years	Various	≤10%
B-lineage ALL, Ph+		
Ph BCR-ABL	Intensive chemotherapy + TKI +/– SCT	60–70%
Ph-like ALL	Chemotherapy + dasatinib/JAK inhibitors	≤50%
T-lineage ALL		
Early (ETP)	Intensive chemotherapy + nelarabine + SCT	40–50%
Cortical/thymic	Intensive chemotherapy + nelarabine, no SCT	70%
Mature	Intensive chemotherapy + nelarabine + SCT	30–50%

Abbreviations: AYA, adolescent and young adult; ETP, early T precursor; Ph, Philadelphia chromosome; SCT, stem cell transplantation; TKI, tyrosine kinase inhibitor.

patients. Thus, age-adapted protocols have emerged, where the age limits are directed by the hematologic and nonhematologic toxicities. Table 106-4 provides a summary of the best results obtained in adult ALL according to ALL subtype, age, and treatment. Molecular CRs are often durable. The major risk of relapse is in the first 2 years; thereafter, relapse is much less likely.

PROPHYLAXIS AND TREATMENT OF CENTRAL NERVOUS SYSTEM LEUKEMIA

Prophylactic CNS therapy in ALL is essential in order to prevent CNS leukemia and to avoid spread of leukemic cells from the CNS back to the periphery. Treatment options include intrathecal therapy, systemic HD chemotherapy, and cranial radiation therapy (CRT). Intrathecal therapy mostly consists of methotrexate as a single drug or in combination with cytosine arabinoside (AC) with or without glucocorticoids. The route of intrathecal therapy application is generally lumbar puncture. Systemic HD chemotherapy may comprise HDAC or HD methotrexate since both drugs reach cytotoxic drug levels in the CSF and show effectiveness in overt CNS leukemia. CRT (18–24 Gy in 12 fractions over 16 days) is also effective as preventive treatment of CNS leukemia. Using combined modalities for CNS prophylaxis, the CNS relapse rate has decreased to 2–5%.

Particular attention to CNS prophylaxis is required for targeted therapies. In Ph+ ALL, not all TKIs cross the blood-brain barrier equally. Dasatinib and probably ponatinib do cross the blood-brain barrier, whereas imatinib and nilotinib do not. In addition to immunotherapy, intrathecal therapy is required because most antibodies do not enter the CNS.

CNS involvement at diagnosis is observed in 5–10% of adult patients and is higher in mature B-ALL (up to 10–15%) and T-ALL (up to 10%). Treatment consists of the standard chemotherapy with additional intrathecal applications 3–5 times per week until blast cells are cleared in the spinal fluid. Patients with initial CNS involvement have a similar overall survival as CNS-negative patients.

Relapse in CNS is usually accompanied by bone marrow involvement, and if blast cells are not seen morphologically, MRD as a sign of discrete infiltration is positive in nearly all cases. CNS relapse requires local as well as systemic therapy. The outcome after CNS relapse is dismal, and salvage chemotherapy followed by allogeneic SCT is the most effective option. Chimeric antigen receptor (CAR) T cells (most often targeting CD19) can cross the blood-brain barrier and achieve CRs in patients with CNS relapse.

STEM CELL TRANSPLANTATION

SCT is an essential part of the treatment strategy for adult ALL. Peripheral blood cells are increasingly being used as a stem cell source, instead of bone marrow. In addition, a shift from sibling stem cell donors to matched unrelated donors or haploidentical transplants from relatives has occurred. Indications for SCT in first CR are controversial. However, in most studies, SCT is recommended for high-risk patients defined either by conventional prognostic factors or by MRD positivity. High-risk patients transplanted in first CR have a survival rate of 50% or greater; decreasing transplant-related mortality from 20–30% to 10–15% has contributed substantially to better outcomes. For standard-risk patients with sustained molecular remission, allogeneic SCT in first CR is not recommended. Autologous SCT should be restricted to MRD-negative patients, *BCR-ABL*–negative patients, Ph+ patients, and older patients because it is less toxic but associated with a substantially higher relapse rate. For all relapsed adult ALL patients, an allogeneic SCT is thus far the only curative option.

PEDIATRIC-INSPIRED THERAPIES FOR ADOLESCENTS AND YOUNG ADULTS

The principle of pediatric-inspired therapies is to have higher doses and more applications of ALL-specific drugs such as glucocorticoids, vincristine, and L-asparaginase and fewer myeloablative anthracyclines or alkylating agents, with strict adherence to time-dose intensity, thereby reducing the role of SCT. The overall survival rates for AYAs are 70–80%.

ADULT ALL

The treatment results for adult ALL patients have greatly improved with more intensive chemotherapy, optimized SCT, and better supportive care. In several recent multicenter prospective trials, the overall survival rate for standard-risk patients was >70% with chemotherapy alone, and for high-risk patients, the overall survival rate has increased from 20–30% to >50%.

ELDERLY ALL

Palliative treatment regimens for elderly patients have failed, with CR rates of ~40%, a high early death rate of 24%, and a poor overall survival of only a few months. Intensive chemotherapy has also failed, with a higher CR rate of 56%, but still an early death rate of 23%, and only moderate improvement of overall survival to 14 months. Specific elderly ALL protocols with less intensive therapy based on glucocorticoids, vincristine, and asparaginase, largely avoiding anthracyclines and alkylating agents, have improved outcomes. The early treatment-related death rate decreased to <10%, CR rates improved to ~90%, and overall survival of ~30 months was noted.

Frail patients above the age of 70–75 years have very poor survival of <10%. Hopefully, this will improve with ongoing targeted therapies with either TKIs in Ph+ ALL or immunotherapies.

TARGETED THERAPIES

Substantial progress in adult ALL has been made in the past decade by the introduction of new targeted therapies, including TKIs and immunotherapeutic approaches (Table 106-5).

TYROSINE KINASE INHIBITORS IN PHILADELPHIA-POSITIVE ALL

Patients with Ph+ ALL constitute ~25% of adult B-ALL patients, with the frequency increasing to ~50% among elderly patients. In the pre-imatinib era, CR rates were 60–70%; survival with chemotherapy was ~10%, and after allogeneic SCT, it was ~30%. With the first-generation TKI imatinib, CR rates increased to 80–90%, the rate of *BCR-ABL* negativity increased from 5 to 50%, and the 5- to 10-year overall survival improved to 50–70%.

Faster and deeper molecular responses are achieved with second-generation TKIs (dasatinib, nilotinib), and these responses apparently

TABLE 106-5 Targeted Therapies in Adult Acute Lymphoblastic Leukemia (ALL)
Tyrosine Kinase Inhibitors (TKIs)
Ph/BCR-ABL+ ALL
TKIs
Imatinib, dasatinib, nilotinib, bosutinib, ponatinib
Ph/BCR-ABL-like ALL
ABL1, ABL2: dasatinib; JAK2: ruxolitinib
Immunologic Approaches

Monovalent antibodies
Bivalent antibodies against the tumor and CD3 (e.g., blinatumomab)
Adoptive cellular therapy
T cells engineered to kill leukemic cells
Checkpoint Inhibitors

translate into a survival benefit. The third-generation TKI ponatinib is also effective in tumors bearing mutations (particularly T315I) that convey resistance to earlier-generation TKIs.

Treating adult Ph+ ALL with an allogeneic SCT in first CR is still a good treatment option for adult patients, with a 5-year overall survival of 60–70%. In elderly patients, when low-intensity chemotherapy was combined with dasatinib, the CR rate was >90%. In a next step, by combining mini-chemotherapy with a TKI and adding immunotherapy with inotuzumab (an anti-CD22 antibody), the CR rate was >90% and the overall survival improved further. A pilot experience with a chemotherapy-free regimen composed of dexamethasone, the TKI dasatinib, and the bispecific antibody blinatumomab (anti-CD19 and anti-CD3) demonstrated a CR rate of 98% and 2-year overall and disease-free survival rates of 95% and 88%, respectively. Blinatumomab eliminates Ph+ leukemic cells with resistant mutations.

IMMUNOTHERAPEUTIC APPROACHES

Treatments involving monoclonal antibodies or activated T cells are currently changing the treatment paradigm of ALL. The prerequisite is that B-lineage blast cells express a variety of specific antigens, such as CD19, CD20, and CD22 (Table 106-6) that are targetable with a wide variety of monoclonal antibodies. A new treatment principle is the activation of the patient's T cells to destroy their CD19+ leukemic blasts.

Anti-CD20 The anti-CD20 monoclonal antibody rituximab has improved the outcome of patients with de novo Burkitt's leukemia/lymphoma. With repeated short cycles of intensive chemotherapy combined with rituximab, the overall survival increased to >80%. Rituximab is now included in most B-ALL regimens and is given at the usual dose of 375 mg/m^2 on day −1 before chemotherapy for at least eight or more cycles. This leads to a significant increase in MRD negativity and improved survival.

Anti-CD22 Monoclonal antibodies directed against CD22 are linked to cytotoxic agents, such as calicheamicin (inotuzumab ozogamicin), or to plant or bacterial toxins (epratuzumab). In a randomized trial of relapsed or refractory ALL patients, the CR rate was 66% and significantly superior to the CR rate with standard chemotherapy. Inotuzumab is now included in first-line therapy for Ph+ and Ph– patients.

Anti-CD19 Targeting CD19 is of great interest because this antigen is highly expressed in all B-lineage cells, most likely including early lymphoid precursor cells. A new promising approach is the bispecific antibody blinatumomab, which combines single-chain antibodies to CD19 and CD3, such that T cells lyse the CD19-bearing B cells.

Blinatumomab is particularly effective in MRD-positive patients, with a 70–80% conversion to MRD negativity, translating into improved overall survival; ~25% of MRD-negative patients survived without any further treatment. Blinatumomab has also moved to frontline therapy.

CAR-T Cells The adoptive transfer of CAR-modified T cells directed against CD19 is a promising approach for the treatment of CD19+ childhood or adult ALL. In the first three larger studies in adults with relapsed or refractory ALL, the CR rate ranged from 67 to 91% with MRD negativity in 60–81% of the patients who achieved CR. Overall survival is 50% or more at ≥2 years, which is remarkable for these heavily pretreated patients. CAR-T cells are also effective in CNS leukemia and in other extramedullary sites. CAR-T cell therapy in relapsed or refractory ALL was first considered as a bridge to allogeneic SCT, applied in 10–50% of patients, but the necessity for an allogeneic SCT after CAR-T cells is unclear. CAR-T cell therapies are also moving to the frontline. CD19-negative relapses after CAR-T cell therapy or blinatumomab due to downregulation of CD19 expression are a relevant obstacle.

Toxicities of Immunotherapies The anti-CD22 agent inotuzumab ozogamicin is associated with hepatotoxicity, including veno-occlusive disease, particularly after allogeneic SCT, but can be managed by reduced dosing and limitation of cycles. For anti-CD19 therapies, cytokine release syndrome and severe neurotoxicity are the most prominent toxicities and often require intensive care unit care (more so after CAR-T cells than blinatumomab). Management of these complications has improved with early recognition. Because toxic death after immunotherapies is very low compared to intensive chemotherapy or allogeneic SCT, immunotherapies are now increasingly included in frontline therapy.

TABLE 106-6 Expression of Antigens in B-Cell Lineage Acute Lymphoblastic Leukemia (ALL) for Potential Antibody Therapy			
SURFACE ANTIGEN	ALL SUBTYPES	EXPRESSION ON LBC[a]	MONOCLONAL ANTIBODY
CD20	Burkitt's lymphoma/ leukemia	86–100%	Rituximab
	B-precursor	30–40%	Ofatumumab
CD22	B-precursor	93–98%	Inotuzumab
	Mature B-ALL	~100%	Epratuzumab
			Moxetumomab pasudotox
CD19	B-precursor	95–<100%	T cell–activating therapies
	Mature B-ALL	94–<100%	Blinatumomab
			Bispecific CD3/CD19
			Chimeric antigen receptor modified T cells (CAR T cells)

TREATMENT OF T-ALL

Immunotherapy for T-ALL is still not available and intensive chemotherapy is still the mainstay in combination with the T cell–specific drug nelarabine. Currently, γ-secretase targeting *NOTCH1*, checkpoint inhibitors such as bortezomib and venetoclax, and HDAC inhibitors are being explored.

CONCLUSION AND FUTURE DIRECTIONS

Cytogenetic and molecular analysis at diagnosis allows identification of ALL subentities, requiring different treatment options. Evaluation of MRD is the most important parameter for treatment decisions. The greatest progress has been achieved by targeted therapies, such as TKIs for Ph+ ALL and new immunotherapeutic approaches. This will lead to further improved outcome of adult ALL patients, 50% of whom are already surviving 5–10 years and are most likely cured. New options and advances, such as low-intensity chemotherapy, reduction of SCT, incorporation of targeted therapies, and reduction of toxicities, will improve the quality of life of patients and lead to individualized approaches for each patient.

107 Chronic Lymphocytic Leukemia

Jennifer A. Woyach, John C. Byrd

Chronic lymphocytic leukemia (CLL) is a monoclonal proliferation of mature B lymphocytes defined by an absolute number of malignant cells in the blood (5×10^9/mL). The presence of malignant B cells under this count in the blood without nodal, spleen, or liver involvement and absent cytopenias is a precursor of this disease called *monoclonal B cell lymphocytosis* (MBL) with ~1–2% chance per year of progressing to overt CLL. CLL is a heterogeneous disease in terms of natural history, with some patients presenting asymptomatically and never requiring therapy, whereas others present with symptomatic disease, require multiple lines of therapy, and eventually die of their disease. Over the past 10–15 years, the understanding of CLL origin and biology has grown exponentially, leading first to more refined disease definition, prognostic markers, and, subsequently, introduction of novel therapies that have significantly changed the natural history of this disease. In this chapter, we review the epidemiology, biology, and management of CLL, with a focus on new knowledge that is currently changing standards of care.

EPIDEMIOLOGY

CLL is primarily a disease of older adults, with a median age at diagnosis of 71 and an age-adjusted incidence of 4.5/100,000 people in the United States. The prevalence of CLL has increased over the past decades due to improvements in therapy for this disease and also survival of older patients from other medical ailments. In 1980, the 5-year overall survival of patients was 69%, and this increased to 87.9% in 2007 and is likely even higher today. The male-to-female ratio is 2:1; however, as patients age, the ratio becomes more even, and over the age of 80, the incidence is equal between men and women. The disease is most common in Caucasians, less common in Hispanic and African Americans, and rare in the Asian population.

Unlike many other malignancies, there have been no definitive links between CLL and exposures. Indeed, CLL is one of the only types of leukemia not linked to radiation exposure. Agent Orange exposure has been implicated, and CLL is thus a service-connected condition for those who were exposed to Agent Orange in the Vietnam conflict.

CLL is one of the most familial-associated malignancies, and the first-degree relative of a CLL patient has an 8.5-fold elevated risk of developing CLL than the general population. MBL is also more common in families with two first-degree relatives having CLL, further supporting a genetic predisposition of this disease. Despite this, specific genes conferring risk in the familial setting outside of specific families have been difficult to identify. In genome-wide association studies (GWAS), ~30 single nucleotide polymorphisms have been identified, which is estimated to account for 19% of the familial risk of CLL. Genes involved in apoptosis, telomere function, B-cell receptor (BCR) activation, and B-cell differentiation have all been implicated in GWAS. Variants in shelterin complex proteins involved in telomere maintenance such as POT1 have been identified in a small number of families.

BIOLOGY AND PATHOPHYSIOLOGY

CELL OF ORIGIN

The cell of origin in CLL has not definitively been established. The morphology, immunophenotype, and gene expression pattern of CLL cells are that of a mature B cell **(Fig. 107-1)**, and so it has been presumed that the initiating cell is a mature lymphocyte, perhaps memory B cells. However, many facets of CLL biology do not support this idea, including antigen-binding characteristics of CLL cells and the presence of stereotyped BCRs. Other possibilities include a stepwise process including a series of transforming events at various stages of B-cell development, potentially including de-differentiation of more mature cells. The self-renewing, multipotent hematopoietic stem cell (HSC) might also be the originating cell of CLL, postulated based on transplant studies in mice showing clonal leukemic cell development with different characteristics from donor leukemia after transplantation of HSCs. More work will be required to elucidate the origins of CLL.

B-CELL RECEPTOR SIGNALING IN CLL

Perhaps the most important advancement in CLL biology is the understanding of the role of BCR signaling in the disease. CLL has distinct BCR signaling as compared to normal B cells, which is characterized by low-level IgM expression, variable response to antigen stimulation, and tonic activation of antiapoptotic signaling pathways that promote tumor survival. CLL cells by gene expression profiling share many features with antigen-activated mature B cells, suggesting a role for activation of BCR signaling in the disease pathogenesis. Tissue-based microarrays have revealed upregulation of BCR pathway genes in the lymph nodes and bone marrow compared to the peripheral blood, suggesting a particular importance of this pathway in microenvironmental homing.

Fitting with the role of BCR signaling in CLL, one of the most influential prognostic factors identified in this disease is the mutational status of the immunoglobulin heavy chain variable (IGHV) region. During normal B-cell maturation, the variable regions of the

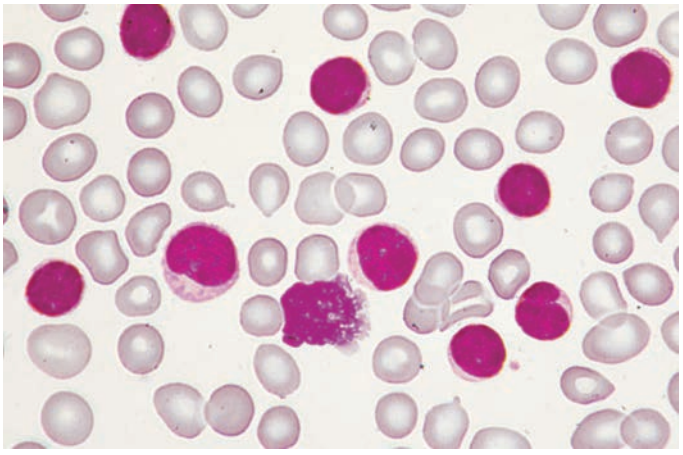

FIGURE 107-1 Chronic lymphoid leukemia in the peripheral blood. *(From M Lichtman et al [eds]: Williams Hematology, 7th ed. New York, McGraw-Hill, 2005.)*

immunoglobulin heavy chain undergo somatic hypermutation. In CLL, ~60% of patients have IGHV that is ≥2% mutated from germline. This may indicate a more mature, postgerminal center progenitor, and is typically associated with a more indolent disease course. Conversely, ~40% of patients will have IGHV <2% mutated from germline, which is associated with more rapid progression of disease and short survival prior to the era of therapeutics that target BCR. Unfavorable biologic properties including enhanced telomerase activity, overexpression of activation-induced cytidine deaminase, increased nuclear factor-κB (NF-κB) activity, high-risk genomic mutations (e.g., *NOTCH1*, *SF3B1*, *TP53*, *ATM*), and clonal evolution are also associated with IGHV unmutated disease.

Because IGHV sequencing was initially cumbersome to perform, a number of surrogate factors have been identified; however, none yet have been shown to be equal or superior to IGHV sequencing. The most prevalent of these surrogate markers are Zap-70 expression, *ZAP-70* methylation, and surface CD38 expression. Zap-70 protein is a normal intracellular T-cell signaling protein that is aberrantly expressed in most IGHV unmutated CLL cells. CD38 is a marker that is also more highly expressed on the surface of IGHV unmutated CLL cells. Both of these prognostic factors are widely used but limited in their applicability. Zap-70 protein status is difficult to measure by flow cytometry and has low reproducibility. Measurement of methylation status of the *ZAP-70* promoter is much more precise but not widely available. CD38 expression is easier to measure by flow cytometry but not as highly predictive of outcomes and can change during the course of disease.

CYTOGENETIC ABNORMALITIES

Besides IGHV mutational status, recurrent cytogenetic abnormalities are the most robust prognostic factor clinically available in CLL. These abnormalities are typically identified by fluorescent in situ hybridization (FISH) analysis; however, stimulated metaphase karyotype has a role as well. The most well-characterized abnormalities include del(13)(q14.3), trisomy 12, del(11)(q22.3), and del(17)(p13.1) **(Fig. 107-2)**. The presence of sole del(13)(q14.3) is associated with more indolent disease, prolonged survival, and good response to traditional therapies. Usually, this abnormality is not seen on banded karyotype analysis, and when present on karyotype, it indicates a larger deletion involving the retinoblastoma gene, which negates the favorable prognosis associated with this marker. Trisomy 12 has a more intermediate prognosis. The del(11)(q23.3) results in deletion of the *ATM* gene and is associated with bulky lymphadenopathy and aggressive disease in young patients, with inferior prognosis, and more rapid progression to symptomatic disease. The del(17)(p13.1) results in loss of one allele of the tumor suppressor TP53 and is associated with the poorest prognosis in CLL with rapid disease progression, poor response to traditional therapies, and shorter survival. Other abnormalities have been shown to be important in smaller studies but are not routinely performed at all centers. Finally, complex karyotype (three or more abnormalities) on stimulated metaphase karyotype analysis has significant adverse impact on time to treatment and overall survival, with data indicating that increasing complexity is even more deleterious to response and survival.

Clonal evolution, or acquisition of cytogenetic or molecular abnormalities, is common in CLL, especially in patients with IGHV unmutated CLL. Because the tumor cytogenetics can change over time, it is recommended that FISH, with or without cytogenetics, is checked before every line of therapy, mostly to evaluate acquisition of del(17)(p13.1).

GENE MUTATIONS AND MIR ALTERATIONS

Compared with many other malignancies, the genome in CLL is relatively simple, with an average CLL genome carrying ~20 nonsynonymous alterations and ~5 structural abnormalities. And, unlike many other hematologic malignancies, there is no unifying genetic lesion, and most recurrent genetic driving mutations exist at frequencies of <5%. Whole genome and whole exome sequencing have identified the most common mutations in CLL to be in *SF3B1*, *NOTCH1*, *MYD88*, *ATM*, and *TP53* **(Table 107-1)**. Most of the identified mutations in these genes are common among different malignancies, and with the exception of *MYD88*, they are generally identified with much higher frequency in IGHV unmutated disease.

NOTCH1 mutations are present in ~15% of CLL patients and are commonly associated with trisomy 12. Although multiple different mutations are seen, most are located within the PEST (proline, glutamic acid, serine, and threonine) domain and result in constitutive NOTCH signaling. *NOTCH1* mutations have been associated with lower sensitivity to CD20 antibody therapy and increased risk of transformation to aggressive diffuse large B-cell lymphoma (DLBCL; Richter's transformation), although its relevance in the era of targeted therapies is less clear. *SF3B1* is a component of the RNA spliceosome and is mutated in 10–15% of CLL cases. Mutations appear to be associated with

intermediate-risk disease, and, functionally, *SF3B1* may be important in the response to DNA damage.

Mutations of the tumor suppressor *TP53* are found in ~5% of CLL patients with previously untreated early-stage disease and up to 40% with later stages. Seventy percent of the time, these mutations coexist with del(17)(p13.1), effectively eliminating TP53 function. As expected, and consistent with other malignancies, *TP53* mutations are associated with a poor prognosis and expected lack of response to DNA-damaging therapies.

ATM mutations, which are heterogeneous and occur throughout the gene, occur in 10–15% of CLL patients. *ATM* mutations often coexist with del(11)(q22.3), eliminating *ATM* on the alternate allele. Similar to *TP53*, mutations in *ATM* tend to result in impaired response to DNA damage, which can reduce responsiveness to chemotherapy.

In contrast to the aforementioned mutations, those in *MYD88* tend to occur in IGHV mutated CLL and be associated with a more indolent prognosis. This gene is involved in Toll-like receptor signaling, and the most common mutation, L265P, results in constitutive activation and NF-κB activity.

Along with abnormalities in coding genes, it has become apparent that noncoding genes such as microRNAs are recurrently altered in CLL. The most common cytogenetic abnormality, del(13)(q14.3), results in loss of the miR15/16 cluster, which is important in the pathogenesis of CLL. In normal cells, miR15A/miR16A inhibits antiapoptotic gene expression (including *BCL2*, *CCND1*, *CCND3*, and *CDK6*), and this specific deletion allows for overexpression of these genes and thus increased cell survival. Loss of other miR expression such as miR-181a leads to overexpression of antiapoptotic proteins such as MCL-1 and TCL1. Overexpression of miR-155, an onco-miR associated with B cell transformation, has also been documented in the majority of CLL patients.

IMMUNOLOGY

CLL is characterized by dysregulation of the normal immune system in addition to the malignant immune cells. Besides numerical abnormalities due to bone marrow dysfunction, even in the early stages of disease, there are skewed ratios of immune cells and functional abnormalities. Innate immune system defects associated with CLL include reduced complement proteins and activity, qualitative neutrophil defects, and functional defects of natural killer cells.

More focus has been placed on the impairments in the adaptive immune system in this disease. Within the CD4+ T-cell compartment, a qualitative defect is noted similar to chronic antigen stimulation inducing a phenotype of T-cell exhaustion typical of what is seen in chronic viral infections such as hepatitis. This has been demonstrated to lead to impaired T-cell cytotoxic capacity and reduced proliferative ability. Additionally, there are physical changes in the T-cell cytoskeleton that cause impaired immune synapse formation with antigen presenting cells. In addition to a lack of capacity to respond to pathogens, the T-cell defect in CLL also likely leads to tumor cell tolerance. During the course of the disease, the polarization of the CD4+ T cells shifts from a Th1 (cytotoxic) phenotype to a Th2 phenotype, which leads to expansion of immunosuppressive cytokines such as interleukin 10 (IL-10). Additionally, in the later stage of disease, T regulatory cells are expanded, which contributes to an immunosuppressive phenotype.

Other components of the immune microenvironment are altered as well to form a more supportive environment for the malignant cells. M2 monocytes have been shown to differentiate into a type of tumor-associated macrophage known as a *nurse-like cell* in CLL. These cells promote survival by secreting chemokines and cytokines that increase migration and activation.

The humoral immune system in CLL is also dysregulated, as is expected for a malignancy that results in very few normal B cells. Hypogammaglobulinemia is very common and affects all subclasses of immunoglobulins, occurring in ~85% of patients at some time in their disease course, and is more common as disease progresses. A correlation between low IgG and IgA and infection risk has been established, but isolated IgM reduction does not seem to be associated with excess infection risk. Also, CLL cells can secrete monoclonal IgM or IgG in a small number of cases, and this can correlate with disease progression.

CLINICAL PRESENTATION AND DIAGNOSIS OF CLL

CLINICAL PRESENTATION AND DIAGNOSIS

The presentation of CLL most commonly occurs as an incidental diagnosis made at the time of medical evaluation for another cause. In this regard, CLL is most commonly diagnosed on routine blood work demonstrating an elevated lymphocyte count in asymptomatic individuals, although some patients present with symptoms and require early therapy. When noting either an elevated total white blood cell (WBC) count with lymphocytic predominance or a normal WBC with a differential showing a lymphocytosis, the next step is to perform flow cytometry on the peripheral blood. In CLL, this will reveal the typical immunophenotype that includes the typical B cell markers CD19, CD20, CD22, and CD23; the T-cell marker CD5 (CD5 is also expressed on the B1 subset of B cells that typically has unmutated immunoglobulin and responds to antigens independent of cognate T cell help); and dim surface immunoglobulin of either kappa or lambda type (Table 107-2). Atypical phenotypes can be seen as well and usually can be differentiated on the basis of morphology, cytogenetics, or clinical presentation. In cases in which the clonal B cell count based on flow cytometry is $\geq 5 \times 10^9$/L, no further workup is needed to confirm the diagnosis of CLL.

Some patients will present with a small clonal proliferation of CLL cells in the peripheral blood but will also have lymphadenopathy or

TABLE 107-2 Typical Immunophenotype of CLL Compared with Other B Cell Malignancies

DISEASE	CD5	CD10	CD19	CD20	CD23	CYCLIN D1	SURFACE IG
CLL	+	–	+	+ (dim)	+	–	+ (dim)

Abbreviation: CLL, chronic lymphocytic leukemia.

splenomegaly. In these cases, the likely diagnosis is small lymphocytic lymphoma (SLL), a semantic designation from CLL that denotes a primarily tissue-based disease rather than bone marrow/blood-based disease. The genetic and molecular features of SLL are identical to those of CLL. The retention of the cells in tissues may be related to the expression of a particular adhesion molecule. Thus, SLL patients are managed identically to CLL patients, and often in the later stages of disease, these patients will have blood and bone marrow involvement as well.

MONOCLONAL B-CELL LYMPHOCYTOSIS

Patients who do not meet the diagnostic criteria for CLL based on quantification of clonal B cells in the peripheral blood and who do not have associated signs of CLL including lymphadenopathy, organomegaly, or cytopenias have a disorder known as monoclonal B-cell lymphocytosis (MBL), which is now thought to precede every case of CLL. Analogous to monoclonal gammopathy of uncertain significance (MGUS) in myeloma, not all MBL progresses to CLL. MBL is initially characterized by a CLL-like immunophenotype in ~75% of cases but can also be atypical (CD23 negative or bright CD20) or CD5 negative. More relevant for prognosis is characterization by count, with low-count MBL defining those patients with $<0.5 \times 10^9$ clonal B cells/L, and high-count MBL defining those with $>0.5 \times 10^9$ but $<5 \times 10^9$/L. Patients with low-count MBL have a negligible rate of progression to CLL, whereas those with high count progress to overt CLL at a rate of 1–2% per year, warranting continued monitoring. Population-based studies have estimated the prevalence of MBL to be up to ~12% in the general population, where it is most common in elderly men. It is especially common in first-degree relatives of CLL patients, where the frequency is ~18%.

Although the risk of MBL progression is relatively low, it has become apparent that patients still experience complications that suggest an immune dysfunction in MBL that is similar to that seen with CLL. Rates of serious infections requiring hospitalization appear to be significantly increased in MBL, similar to the rates seen in CLL. In a case-control study, patients with MBL had a 16% chance of hospitalization over a 4-year time period, compared with 18.4% in patients with newly diagnosed CLL. Secondary cancers also appear to be increased in MBL. These data suggest that monitoring for patients with MBL should focus on vaccinations and age-appropriate cancer screening, as the probability of complications appears to be higher than the risk of progression in most of these patients. Follow-up for patients with MBL can occur with the primary care physician as this does not represent a malignancy, whereas CLL is mostly comanaged with both a primary care physician and a hematologist.

COMPLICATIONS OF CLL

A significant amount of morbidity and mortality related to CLL is due to complications of the disease. In general, complications besides disease progression include infections, secondary cancers, autoimmune complications, and transformation to a more aggressive clonally related lymphoma.

INFECTIONS

Infections are a leading cause of both disease-related morbidity and death in patients with CLL, with ~30–50% of deaths in CLL patients attributed to infection. Owing to the immune dysfunction associated with the disease, patients are at risk for both typical and atypical infections. Besides this baseline risk of infections, most CLL therapies can increase infection risk. For many nucleoside analogue–based chemotherapy regimens used in CLL, prophylaxis for *Pneumocystis* pneumonia is indicated for at least 6 months following therapy to allow recovery of functional T cells. Viral prophylaxis is also indicated for many chemotherapy regimens and for patients with a history of varicella-zoster to diminish reactivation and morbidity from this virus.

Because of the abnormalities in cellular and humoral immunity, vaccine responses in CLL are limited in many patients, especially in the later stages of disease. In one study, one dose of 13-valent pneumococcal vaccine produced an adequate immune response in only 58% of patients compared with 100% in age-matched controls. Despite the known limitations, vaccination against influenza and pneumococcal pneumonia is recommended in CLL. The recombinant zoster vaccine has approximately a 60% response in previously untreated CLL, is safe, and should be considered for this patient group. In contrast, live vaccines should be avoided in the setting of CLL because of the small risk of viral reactivation with an immunocompromised host.

As discussed earlier, hypogammaglobulinemia is common in CLL and can be associated with significant risk for infections, primarily of mucocutaneous etiology such as sinusitis and bronchitis. In addition, women can have frequent urinary tract infections. While administration of prophylactic intravenous immunoglobulin (IVIg) has not been shown to improve survival, it has been shown to reduce the number of minor or moderate bacterial infections and thus is indicated in patients with hypogammaglobulinemia who suffer from recurrent infections or have pulmonary bronchiectasis. We also administer at least one dose of immunoglobulin to CLL patients who develop influenza with coexisting hypogammaglobulinemia to diminish risk of postinfluenza pneumococcal pneumonia. IVIg is also indicated in patients who have been hospitalized for a serious infection and in those whose IgG level is <300–500 mg/dL.

SECONDARY MALIGNANCIES

Multiple population-based studies have shown that patients with CLL are at an elevated risk to develop other cancers, with a rate up to three times that of the general population, even in the absence of cytotoxic chemotherapy. The most common types of cancers seen in CLL are skin, prostate, and breast cancers, although other cancers are seen as well. Skin cancers are particularly common, with a rate that is 8- to 15-fold higher than in the general population, and may behave more aggressively. All CLL patients should be counseled on the use of sunscreen while outdoors and should undergo preventative skin examinations.

In one single-center study, older age at CLL diagnosis, male sex, high β_2-microglobulin, high lactate dehydrogenase (LDH), and chronic kidney disease were associated with excess risk of other cancers; other CLL-specific risk factors have not shown association with other cancer risk.

While cancer risk is higher, no specific recommendations for increased cancer screening in CLL patients have been validated. Age- and sex-appropriate screenings should be recommended.

Conflicting data exist regarding the risk of cancers following CLL-specific therapy. Chemoimmunotherapy, in particular alkylator-containing regimens, seems to be associated with an increased risk for secondary cancers. Secondary cancers are also seen in the setting of targeted therapies. Bruton tyrosine kinase (BTK) inhibitors appear to have a secondary cancer risk similar to what is seen in the CLL population in general, but potentially a higher rate of nonmelanoma skin cancers. With short follow-up, the risk of secondary cancers appears to be slightly higher with venetoclax-based regimens than chlorambucil-based chemoimmunotherapy, and further evaluation of this trend is ongoing.

AUTOIMMUNE COMPLICATIONS

Autoimmune complications are frequent in CLL. Most commonly, these include autoimmune cytopenias, but autoimmune complications of other organs including glomerulonephritis, vasculitis, and neuropathies have also been reported. Of the autoimmune cytopenias, the most common is autoimmune hemolytic anemia (AIHA), which is an antibody-mediated destruction of autologous red blood cells (RBCs). Second most common is immune thrombocytopenia (ITP), which shares some features with AIHA and has a similar mechanism targeting platelets. These two syndromes may occur in isolation, occur sequentially in the same patient, or present in combination as Evan's syndrome. Pure red cell aplasia (PRCA) and autoimmune granulocytopenia (AIG) are comparatively rare and can occur alone or in combination with other autoimmune cytopenias. It is difficult to tease out whether autoimmune cytopenias lead to worse prognosis in CLL because of various complicating factors. However, it is clear that these can lead to significant morbidity, both due to the process itself and due to therapies required for management.

AIHA usually presents as an isolated anemia with an elevated reticulocyte count and features of hemolysis including elevated bilirubin and LDH and low haptoglobin. Detection of a warm IgG antibody on the surface of RBCs with a Coombs test can help solidify the diagnosis, although Coombs-negative cases can occur. Immediate therapy is almost always necessary and consists of transfusion and immunosuppression. Glucocorticoids are often used for initial therapy, although in most cases, additional treatment is needed due to either poor response or recurrence with taper of glucocorticoid dosing. Rituximab can be successful, and therapy directed toward the underlying CLL is often effective in more resistant cases. Transfusion of blood in cases of robust AIHA must be initiated with caution as transfusion reactions can be seen due to poorly matched blood, but should be pursued in those with severe, symptomatic anemia. Death from uncontrolled AIHA can occur in the absence of appropriate supportive care **(Chap. 100)**.

ITP can be more difficult to diagnose as it may be difficult to differentiate from progression of disease due to the lack of laboratory tests that identify platelet destruction from this mechanism. Signs that point toward ITP include isolated thrombocytopenia and rapid decline in platelet levels in the absence of an alternative etiology. A bone marrow biopsy showing normal or increased megakaryocytes can be used to confirm the diagnosis but is often not necessary. In CLL, treatment for ITP is usually instituted when platelet levels drop to 20,000–30,000 or if evidence of bleeding complications or need for invasive procedures develops. Like AIHA, initial therapy consists of glucocorticoids and IVIg, with rituximab also being an effective method to induce long-term remissions. Also, the thrombopoietin receptor agonists romiplostim and eltrombopag are effective in secondary ITP. In many cases, ITP can be successfully treated without treating the underlying CLL. In cases in which anemia or thrombocytopenia appears, it is important to investigate the mechanism because the approach to therapy of autoimmune cytopenias in CLL differs from cytopenias due to marrow replacement **(Chap. 115)**.

RICHTER'S TRANSFORMATION

One of the most devastating complications of CLL is Richter's transformation, which is transformation of CLL to an aggressive lymphoma, most commonly DLBCL. The World Health Organization also recognizes Hodgkin's lymphoma (HL) as a variant of Richter's transformation; other aggressive lymphomas are rarely identified. Some older series have included prolymphocytic transformation in this category, although this has much less prognostic impact on long-term outcome. The prevalence of Richter's transformation is difficult to estimate based on previous studies, but one prospective observational study estimated a rate of 0.5% per year for DLBCL and 0.05% per year for HL. Risk factors for development include bulky lymphadenopathy, *NOTCH1* mutations, del(17)(p13.1), and a specific stereotyped IGHV usage. Lymphomas arising in the setting of CLL can either be clonally related or unrelated to the initial CLL, with prognosis significantly better for clonally unrelated lymphomas. In addition, patients with Hodgkin's transformation have improved outcome, particularly in the absence of prior fludarabine treatment. B-cell prolymphocytic leukemia (PLL) arising from CLL is currently classified as Richter's transformation as well; however, clinical features and therapy are quite different, so these two should be differentiated for therapeutic purposes.

Clinical signs of Richter's transformation include rapid progression in adenopathy, often in a specific area, and constitutional symptoms including fatigue, night sweats, fever, and weight loss. LDH is usually high. In suspected cases, the first step is ^{18}FDG-PET/CT (fluorodeoxyglucose–positron emission tomography combined with computed tomography) scan to localize an area for biopsy. Standardized uptake values (SUVs) <5 are consistent with CLL and can rule out Richter's transformation in many cases. SUVs >5 are suspicious for Richter's transformation, with SUVs ≥10 being very concerning. Excisional biopsy is the preferred mode of diagnosis, and fine-needle aspiration should be discouraged.

Therapy for DLBCL Richter's transformation usually involves combination chemoimmunotherapy (e.g., R-CHOP [rituximab, cyclophosphamide, doxorubicin, vincristine, and prednisolone], dose-adjusted EPOCH-R [etoposide, prednisone, vincristine, cyclophosphamide, doxorubicin, and rituximab]; **Chap. 108**). Outcomes may be poor with median survivals of 6–16 months in most series for clonally related Richter's versus ~5 years for clonally unrelated. For fit patients who achieve a response with therapy, stem cell transplantation has the possibility to induce long-term remissions and should be explored. In addition, chimeric antigen receptor T-cell (CAR-T) therapy has shown promising results in small groups of patients and remains an area of active clinical investigation. Patients with Hodgkin's disease can be treated according to the algorithm for this disease, with many individuals being cured.

WORKUP OF CLL AND APPROACH TO THERAPY

WORKUP AND STAGING

Workup of a patient with a new diagnosis of CLL based on typical immunophenotyping includes a detailed history of infectious disease; family history of CLL; and careful physical examination with attention to the lymph nodes, spleen, and liver. In patients desiring to know the expected natural history of their CLL, prognostic testing using FISH and stimulated karyotype and sequencing for *TP53* and *IGHV* mutation status can be performed. Imaging with CT scan is usually not necessary unless there are symptoms and concern for intraabdominal nodes out of proportion to peripheral nodes. Bone marrow biopsy is not undertaken until therapy is initiated except in cases of unexplained cytopenias.

STAGING

There are two widely used staging systems in CLL. The Rai staging system is used more commonly in the United States, whereas the Binet system is more commonly used in Europe. Both characterize CLL on the basis of disease bulk and marrow failure **(Table 107-3)**. Both rely on physical examination and laboratory studies and do not require imaging or bone marrow analysis. While the initial staging systems could reliably predict survival in CLL, with the changes in therapy since the original description of the stages, the impact of initial stage on survival is not as clear. Cytogenetic and genomic testing can help refine outcomes of these staging tests. An international collaboration integrated both clinical and genomic staging to better predict outcome at diagnosis and time of initial treatment, which led to development of the CLL International Prognostic Index **(Table 107-4)**. This index has been shown to be useful in prediction of both time to first treatment and outcome with chemoimmunotherapy. Validation in the setting of novel targeted therapies has not occurred.

CRITERIA FOR THE INITIATION OF THERAPY

Currently, a watchful waiting strategy is used for most patients with CLL, with therapy reserved for patients with symptomatic disease. This recommendation is based on multiple trials showing no survival advantage with earlier therapy, although this question continues to be a focus of active investigation.

With the exception of patients participating on early intervention studies in CLL, disease-related symptoms that require the initiation of therapy are outlined in **Table 107-5**. Except for the rare patient who

TABLE 107-3 Staging of CLL

Rai Staging System	
Low risk (stage 0)	Lymphocytosis only
Intermediate risk (stage I/II)	Lymphocytosis with lymphadenopathy, with or without splenomegaly or hepatomegaly
High risk (stage III/IV)	Lymphocytosis with anemia or thrombocytopenia due to bone marrow involvement
Binet Staging System	
A	<3 areas of lymphadenopathy
B	≥3 areas of lymphadenopathy
C	Hemoglobin ≤10 g/dL and/or platelets <100,000/μL

presents with disease requiring urgent therapy, most times, these symptoms can be monitored over short periods to determine relatedness to CLL and need for therapy.

INITIAL THERAPY FOR CLL

Over the past decade, the initial therapy of CLL has dramatically changed. Whereas chemoimmunotherapy was once standard for all patients, now most patients are treated with oral therapies targeted against BTK or BCL2 with or without a CD20 monoclonal antibody. This continues to be an area of active investigation, with standards of care shifting rapidly. The major classes of these therapies are outlined here.

BTK Inhibitors BTK is an attractive target in CLL because, unlike other kinases in the BCR pathway, BTK does not have natural redundancy and is relatively selective for B cells, so inhibition leads to a predominant B cell–specific phenotype. The first-in-class BTK inhibitor is ibrutinib, which is relatively selective for BTK but also inhibits a number of structurally similar kinases. As initial therapy, ibrutinib was initially compared with chlorambucil (RESONATE 2 study), and there was an 84% lower risk of progression or death with ibrutinib, with 70% of ibrutinib-treated patients alive and progression-free at 5 years. Subsequent studies compared ibrutinib alone or with the anti-CD20 antibody rituximab to standard chemoimmunotherapy with fludarabine plus cyclophosphamide plus rituximab (FCR) in younger patients (<70 years; E1912 study) or bendamustine plus rituximab (BR) in older patients (≥65 years; A041202 study). In younger patients, ibrutinib plus rituximab (IR) showed increased progression-free survival (PFS) and overall survival (OS) when compared with FCR, with a 3-year PFS of 89% for IR compared with 71% for FCR. In older patients, ibrutinib alone as well as with rituximab showed superior PFS compared with BR, with 24-month PFS rates of 88% for IR, 87% for ibrutinib alone, and 74% for BR. IR was not superior to ibrutinib alone, and OS was not different in this trial at 24 months. Side effects distinct to ibrutinib include arthralgias/myalgias, rash, diarrhea, dyspepsia, increased risk of bleeding (particularly when on anticoagulation therapy or with surgery), hypertension, and atrial fibrillation.

The second-generation BTK inhibitor acalabrutinib is more specific for BTK than ibrutinib and consequentially shows better tolerability, with less incidence of atrial fibrillation, myalgias/arthralgias, and skin and nail changes than reported with ibrutinib. In the frontline setting, acalabrutinib and acalabrutinib plus obinutuzumab were compared with chlorambucil plus obinutuzumab. Both acalabrutinib alone and acalabrutinib with obinutuzumab showed superior 30-month PFS compared with chlorambucil plus obinutuzumab (82%, 90%, and 34%, respectively), with improved PFS for acalabrutinib plus obinutuzumab compared with acalabrutinib alone in an unplanned post hoc analysis.

TABLE 107-5 Criteria for the Initiation of Therapy

Symptoms Indicating Need for Therapy in CLL
Evidence of progressive marrow failure (worsening of anemia or thrombocytopenia not due to autoimmune destruction)
Massive (≥6 cm below costal margin), progressive, or symptomatic splenomegaly
Massive (≥10 cm), progressive, or symptomatic lymphadenopathy
Progressive lymphocytosis with an increase of ≥50% over a 2-month period or lymphocyte doubling time <6 months
Autoimmune anemia or thrombocytopenia not responsive to standard therapy
Symptomatic or functional extranodal involvement
Constitutional symptoms (one or more of the following: unintentional weight loss ≥10% over 6 months, significant fatigue, fevers ≥100.5°C for 2+ weeks without infection, night sweats for >1 month without infection)

Abbreviation: CLL, chronic lymphocytic leukemia.

BCL2 Inhibitor Venetoclax is an orally bioavailable, selective inhibitor of the antiapoptotic protein BCL2, which is upregulated in CLL. Unlike with BTK inhibitors, where many phase 3 studies support benefit over chemoimmunotherapy, only one study has been published with venetoclax. The CLL14 study compared venetoclax plus obinutuzumab (VO) to chlorambucil plus obinutuzumab in previously untreated patients with coexisting medical conditions. Unlike BTK inhibitors, which are administered continuously until disease progression, VO treatment is given for a 1-year fixed duration. At 3 years of follow-up, PFS was 82% in the VO group compared with 50% in the chlorambucil plus obinutuzumab group. No difference has been observed in OS with this follow-up. Side effects associated with venetoclax include tumor lysis syndrome, neutropenia, and nausea.

PI3K Inhibitors Inhibitors of PI3K delta have been studied in CLL due to the specificity of the delta isoform for B lymphocytes. Two agents, idelalisib and duvelisib, are approved for use in relapsed CLL, but trials of idelalisib in frontline CLL demonstrated toxicity that precluded further development in this area. Toxicities seen with idelalisib and duvelisib include pneumonitis, diarrhea/colitis, and transaminitis. More recently, a second-generation PI3K delta inhibitor umbralisib was combined with the anti-CD20 antibody ublituximab in the frontline setting and compared with chlorambucil plus obinutuzumab. Twenty-four-month PFS was 61% for ublituximab plus umbralisib compared with 40% with chlorambucil plus obinutuzumab. PI3K inhibitor–specific toxicities appear to be lower with umbralisib compared with idelalisib and duvelisib, but comparative trials are lacking. As outcome with this combination appears inferior to that with BTK inhibitors or BCL2 inhibitors, it is unlikely this treatment will be used in CLL outside of rare circumstances where other classes of drugs are contraindicated.

Chemoimmunotherapy For the most part, targeted therapy has supplanted chemoimmunotherapy in CLL. However, long-term follow-up of studies of FCR has demonstrated that a subset of patients treated with this regimen can have durable responses over 10 years, with a likely cure of CLL. This group is composed almost exclusively of patients with mutated *IGHV* and favorable cytogenetics. However, despite the efficacy of this regimen, short- and long-term toxicities limit its adaptability to many patients with *IGHV* mutated disease. Short-term toxicities are mostly related to myelosuppression and include neutropenia and infection. Long-term cytopenias are less common, but they do occur. Also, there is about a 3–5% risk of therapy-related myeloid neoplasm with this regimen that is almost always fatal. In the E1912 study of FCR versus IR, at follow-up, there was no difference in PFS or OS between FCR and IR for patients with mutated *IGHV*, suggesting that there may remain a place for this regimen in clinical practice. In addition, current studies are focused on limiting chemotherapy and/or adding novel agents in efforts to achieve cure but limit toxicity.

THERAPY OF RELAPSED CLL

Currently, the mainstays of treatment for relapsed CLL are the same classes as initial therapy. The optimal sequencing of targeted agents in

TABLE 107-6 Response Criteria in CLL

	LYMPHOCYTE COUNT	LYMPH NODES[a]	SPLEEN/LIVER SIZE[b]	BONE MARROW[c]	PERIPHERAL BLOOD COUNTS
CR	<4000/μL	None >1.5 cm	Not palpable	Normocellular, <30% lymphocytes, no B lymphoid nodules	• Platelet count >100,000/μL • Hemoglobin >11 g/dL • Neutrophils >1500/μL
PR	Decrease ≥50% from baseline	Decrease ≥50% from baseline	Decrease ≥50% from baseline	Infiltrate ≤50% of baseline	One of the following: • Platelet count >100,000/μL or ≥50% from baseline • Hemoglobin >11 g/dL or ≥50% from baseline • Neutrophils >1500/μL or ≥50% from baseline
Stable disease	Not meeting CR/PR/PD criteria	Not meeting CR/PR/PD criteria	Not meeting CR/PR/PD criteria	Not meeting CR/PR/PD criteria	Not meeting CR/PR/PD criteria
PD	Increase ≥50%	Increase ≥50%	Increase ≥50%		• Platelet count ≤50% of baseline due to CLL • Hemoglobin decrease >2 g/dL due to CLL

[a]Refers to sum of the products of multiple lymph nodes evaluated by CT scan. [b]Based on physical examination. [c]Bone marrow only required to confirm CR.

Abbreviations: CLL, chronic lymphocytic leukemia; CR, complete response; PD, progressive disease; PR, partial response.

CLL has not been established; however, the available data suggest that the sequence of either BTK inhibitor and then BCL2 inhibitor or the reverse are both acceptable. In a trial of venetoclax for patients who had relapsed after ibrutinib therapy, the overall response rate (ORR) was 65% with a median PFS of ~2 years in a very heavily pretreated patient population. Retrospective data of BTK inhibitor given after venetoclax suggests that this sequence is effective as well, with an ORR of 84% and median PFS of 32 months. PI3K inhibitors also have activity in relapsed CLL; however, activity following both BTK and BCL2 inhibitors is likely minimal. In addition, many new agents are in development in CLL including novel oral targeted therapies, antibodies, and immune-based treatments.

Immune Therapies Immune therapies in CLL are currently focused in the relapsed setting and include allogenic stem cell transplantation, CAR-T therapy, and oral immunomodulatory agents such as lenalidomide.

Stem cell transplantation is a curative approach to CLL. Because most CLL patients are older and many have significant comorbidities, myeloablative transplantations incur extensive morbidity and mortality, making them prohibitive in many individuals. Reduced-intensity conditioning (RIC) allogeneic transplantations have been successfully incorporated into the treatment of patients up to ~75 years in age but still have a ≥50% frequency of chronic graft-versus-host disease. This is still considered a standard treatment in CLL but has fallen out of favor with the introduction of well-tolerated novel agents, as well as clinical trials of CAR-T cells. CD19 CAR-T cell trials have not been as successful in CLL as they have been in other B cell malignancies due to the immunosuppression associated with the disease. Many current trials are focused on optimizing CD19 CAR-T cells by adding agents such as BTK inhibitors or PI3K inhibitors or modifying the CAR-T structure, and other studies are testing different targets outside of CD19. In addition, recent studies have shown that natural killer (NK) cell CAR cells also can induce clinical response in CLL patients. This area remains a focus of intense investigation in CLL.

ASSESSING RESPONSE TO THERAPY AND MINIMAL RESIDUAL DISEASE IN CLL

Following the completion of therapy or during therapy for indefinite targeted agents, response is initially assessed using physical examination and laboratory studies (Table 107-6). If residual disease is not detected using these methodologies, CT scans are used to assess response. Bone marrow biopsies with flow cytometry are indicated if no disease is detected to confirm complete response.

It has been established in various malignancies that complete tumor eradication is associated with longer survival. In CLL, if no malignant cells can be detected in the bone marrow down to a level of 1 CLL cell in 10^4 leukocytes (0.01%), the patient is said to be negative for minimal residual disease (MRD). Following combination chemoimmunotherapy, eradication of MRD correlates with long-term survival and potentially cure in a subset of patients receiving FCR chemoimmunotherapy. Undetectable MRD in blood or bone marrow is also associated with improvement in PFS in venetoclax-based regimens. However, eradication of MRD has not been shown to be a meaningful endpoint with BTK or PI3K inhibitors as monotherapy. Higher sensitivity of 1 CLL in 10^6 leukocytes (0.0001%) can be obtained using next-generation sequencing methods such as ClonoSeq. This technique is currently available in clinical practice, although at this point, there are no data confirming that increased sensitivity is clinically meaningful, and studies are underway to support the need for this higher sensitivity with novel combination approaches of BTK/BCL2 inhibitor regimens.

CONCLUSION

CLL is treated only when it becomes symptomatic. At the time of therapy, FCR chemoimmunotherapy in a small subset of young patients with very-good-risk CLL is potentially curative. In the majority of patients with symptomatic CLL, targeted therapy directed at BTK or BCL2 can produce durable remissions and allow patients many years of disease-free survival.

108 Non-Hodgkin's Lymphoma

Caron A. Jacobson, Dan L. Longo

Non-Hodgkin's lymphomas (NHL) are cancers of mature B, T, and natural killer (NK) cells. They were distinguished from Hodgkin's lymphoma (HL) upon recognition of the Reed-Sternberg (RS) cell and differ from HL with respect to their biologic and clinical characteristics. Whereas ~80–85% of patients with HL will be cured of their lymphoma by chemotherapy with or without radiotherapy, the prognosis and natural history of NHL tends to be more variable. NHL can be classified as either a mature B-NHL or a mature T/NK-NHL depending on whether the cancerous lymphocyte is a B, T, or NK cell, respectively. Within each category are lymphomas that grow quickly and behave aggressively, as well as lymphomas that are more indolent, or slow growing, in nature. For a list of the World Health Organization (WHO) classification of lymphoid neoplasms, see **Table 108-1**.

EPIDEMIOLOGY AND ETIOLOGY

In 2020, >77,000 new cases of NHL were diagnosed in the United States, ~4% of all new cancers in both males and females, making it the seventh most common cause of cancer-related death in both women and men. The incidence is nearly 10 times the incidence of HL. There is a slight male-to-female predominance and a higher incidence for Caucasians than for African Americans. The incidence rises steadily with age, especially after age 40, but lymphomas are also among the most common malignancies in adolescent and young adult patients. The incidence of NHL has nearly doubled over the past 20–40 years and continues to rise by 1.5–2% each year. Patients with both primary and secondary immunodeficiency states are predisposed to developing NHL. These include patients with HIV infection, patients who have undergone organ transplantation, and patients with inherited immune deficiencies and autoimmune conditions. The 5-year survival rates for NHL are 72% for Caucasians and 63% for African Americans.

TABLE 108-1 WHO Classification of Lymphoid Malignancies

B CELL	T CELL
Mature (peripheral) B-cell neoplasms	Mature (peripheral) T-cell neoplasms
Lymphoplasmacytic lymphoma (Waldenström's macroglobulinemia)	T-cell granular lymphocytic leukemia
Hairy cell leukemia	Adult T-cell leukemia/lymphoma (HTLV-1+)
Splenic marginal zone B-cell lymphoma	Extranodal NK/T-cell lymphoma, nasal type
Extranodal marginal zone B-cell lymphoma of MALT type	Enteropathy-associated T-cell lymphoma
Nodal marginal zone B-cell lymphoma	Hepatosplenic T-cell lymphoma
Follicular lymphoma	Subcutaneous panniculitis-like T-cell lymphoma
Mantle cell lymphoma	Mycosis fungoides
Diffuse large B-cell lymphoma (including subtypes)	Sezary syndrome
High-grade B-cell lymphoma with MYC and BCL2 and/or BCL6 rearrangements	Peripheral T-cell lymphoma NOS
High-grade B-cell lymphoma NOS	Angioimmunoblastic T-cell lymphoma
Burkitt's lymphoma/Burkitt's cell leukemia	Anaplastic large-cell lymphoma, ALK+
Primary mediastinal large B-cell lymphoma	Anaplastic large-cell lymphoma, ALK–
Plasmablastic lymphoma	
Primary effusion lymphoma	
HHV8+ DLBCL NOS	
Intravascular large B-cell lymphoma	
ALK+ large B-cell lymphoma	

Abbreviations: DLBCL, diffuse large B-cell lymphoma; HHV, human herpesvirus; HTLV, human T-cell lymphotropic virus; MALT, mucosa-associated lymphoid tissue; NK, natural killer; NOS, not otherwise specified; WHO, World Health Organization.

Source: Adapted from SH Swerdlow et al: *WHO Classification of Tumours of Haematopoietic and Lymphoid Tissues*, 5th ed. IARC, 2016.

The incidence of NHL and the patterns of expression of the various subtypes differ geographically and across age groups. T-cell lymphomas are more common in Asia than in Western countries, whereas certain subtypes of B-cell lymphomas such as follicular lymphoma (FL) are more common in Western countries. A specific subtype of NHL known as the angiocentric nasal T/NK cell lymphoma has a striking geographic occurrence, being most frequent in southern Asia and parts of Latin America. Another subtype of NHL associated with infection by human T-cell lymphotropic virus (HTLV) 1 is seen particularly in southern Japan and the Caribbean. Likewise, there are differences in the age-dependent incidence of NHL by histologic subtype, with aggressive lymphomas like diffuse large B-cell lymphoma (DLBCL) and Burkitt's lymphoma (BL) being the most common entities in children, and DLBCL and indolent lymphomas including FL being the most common forms in adults. The relative frequencies of the various types of lymphoid malignancies, including HL, plasma cell disorders, and lymphoid leukemias, is shown in **Fig. 108-1.**

A number of environmental factors have been implicated in the occurrence of NHL, including infectious agents, chemical exposures, and medical treatments. Several studies have demonstrated an association between exposure to agricultural chemicals and an increased incidence of NHL. Patients treated for HL can develop NHL; it is unclear whether this is a consequence of the HL or its treatment, especially radiation.

Several NHLs are associated with infectious agents **(Table 108-2)**. Epstein-Barr virus (EBV) is associated with the development of BL in Central Africa and the occurrence of aggressive NHL in immunosuppressed patients in Western countries. The majority of primary central nervous system (CNS) lymphomas are associated with EBV. EBV infection is strongly associated with the occurrence of extranodal nasal NK/T-cell lymphomas in Asia and South America. HTLV-1 infects T cells and leads directly to the development of adult T-cell lymphoma (ATL) in a small percentage of patients infected as babies through ingestion of breast milk of infected mothers. The median age of patients with ATL is ~56 years; thus, HTLV-1 demonstrates a long latency from infection to oncogenesis **(Chap. 201)**. Infection with HIV predisposes to the development of aggressive, B-cell NHL. This may be through overexpression of interleukin 6 by infected macrophages. Infection of the stomach by the bacterium *Helicobacter pylori* induces the development of gastric mucosa-associated lymphoid tissue (MALT) lymphomas. This association is supported by evidence that patients treated with antibiotics to eradicate *H. pylori* have regression of their MALT lymphoma. The bacterium does not transform lymphocytes to produce the lymphoma; instead, a vigorous immune response is made to the bacterium, and the chronic antigenic stimulation leads to the neoplasia. MALT lymphomas of the skin may be related to *Borrelia* sp. infections in Europe, those of the eyes to *Chlamydophila psittaci*, and those of the small intestine to *Campylobacter jejuni*. Chronic hepatitis C virus infection has been associated with the development of lymphoplasmacytic lymphoma and splenic marginal zone lymphoma (MZL). Human herpesvirus 8 is associated with primary effusion lymphoma in HIV-infected persons and multicentric Castleman's disease, a diffuse lymphadenopathy associated with systemic symptoms of fever, malaise, and weight loss.

In addition to infectious agents, a number of other diseases or exposures may predispose to developing lymphoma **(Table 108-3)**. Diseases of inherited and acquired immunodeficiency as well as autoimmune diseases are associated with an increased incidence of lymphoma. The association between immunosuppression and induction of NHLs is compelling because if the immunosuppression can be reversed, a percentage of these lymphomas regress spontaneously. The incidence of NHL is nearly a hundredfold increased for patients undergoing organ transplantation necessitating chronic immunosuppression and is greatest in the first year posttransplant. About 30% of these arise as

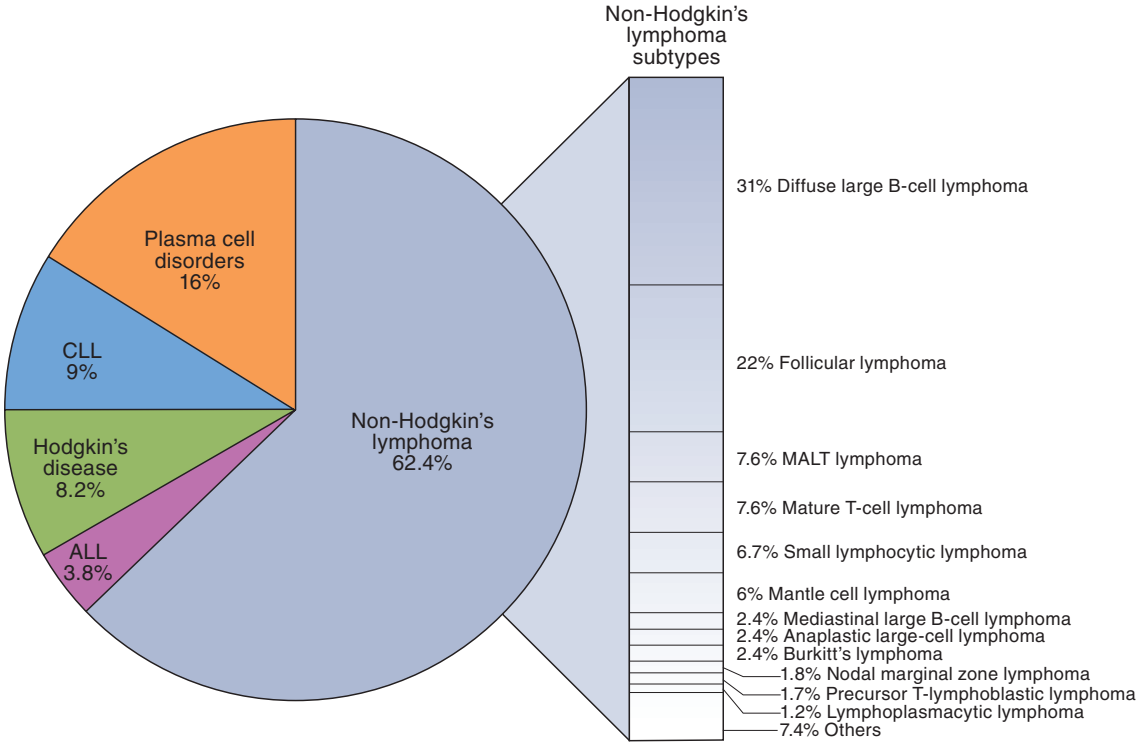

FIGURE 108-1 Relative frequency of lymphoid malignancies. ALL, acute lymphoid leukemia; CLL, chronic lymphocytic leukemia; MALT, mucosa-associated lymphoid tissue.

a polyclonal B-cell proliferation that evolves into a clonal B cell malignancy. The NHLs that occur in the context of immunosuppression or immunodeficiency, including HIV infection, are frequently associated with EBV. Histologically, DLBCLs are most frequently associated with immunosuppression and autoimmune diseases, although almost all histologies can be seen, especially MALT lymphomas in the context of autoimmune diseases such as Sjögren's syndrome and Hashimoto's thyroiditis. The rare inherited immunodeficiency diseases X-linked lymphoproliferative syndrome, Wiskott-Aldrich syndrome, Chédiak-Higashi syndrome, ataxia-telangiectasia, and common variable immunodeficiency syndrome are complicated by highly aggressive lymphomas. The elevated incidence of lymphoma in iatrogenic immunosuppression, AIDS, and autoimmune disease argues strongly for immune dysregulation contributing in the pathogenesis of some lymphomas. An increased risk of NHL has been observed in first-degree relatives with NHL, HL, or chronic lymphocytic leukemia (CLL). In large database studies, ~9% of patients with lymphoma or CLL have a first-degree relative with a lymphoproliferative disorder.

TABLE 108-2 Infectious Agents Associated with the Development of Lymphoid Malignancies

INFECTIOUS AGENT	LYMPHOID MALIGNANCY
Epstein-Barr virus	Burkitt's lymphoma
	Post–organ transplant lymphoma
	Primary CNS diffuse large B-cell lymphoma
	Hodgkin's lymphoma
	Extranodal NK/T-cell lymphoma, nasal type
HTLV-1	Adult T-cell leukemia/lymphoma
HIV	Diffuse large B-cell lymphoma
	Burkitt's lymphoma
Hepatitis C virus	Lymphoplasmacytic lymphoma
Helicobacter pylori	Gastric MALT lymphoma
Human herpesvirus 8	Primary effusion lymphoma
	Multicentric Castleman's disease

Abbreviations: CNS, central nervous system; HIV, human immunodeficiency virus; HTLV, human T-cell lymphotropic virus; MALT, mucosa-associated lymphoid tissue; NK, natural killer.

IMMUNOLOGY

All lymphoid cells are derived from a common hematopoietic progenitor that gives rise to lymphoid, myeloid, erythroid, monocyte, and megakaryocyte lineages. Through the ordered and sequential activation of a series of transcription factors, the cell first becomes committed to the lymphoid lineage and then gives rise to B and T cells.

About 90% of all lymphomas are of B cell origin. A cell becomes committed to B cell development when it expresses the master B lineage transcription factor PAX5, which ultimately results in a transcriptional program that leads to the rearrangement of its immunoglobulin genes, which involves chromosomal recombination as well as somatic hypermutation to create an immunoglobulin gene that is unique to that B cell. The sequence of cellular changes, including changes in cell-surface phenotype that characterizes normal B cell development, is shown in **Fig. 108-2.** Most B-cell lymphomas arise following the process of immunoglobulin gene recombination and somatic hypermutation, which leads to class switching and affinity maturation of the mature immunoglobulin, respectively, suggesting that it is the error-prone nature of these genetic events that contributes to oncogenesis. Certainly the frequency of chromosomal translocations that result in the activation of an oncogene or the inactivation of a tumor-suppressor gene in B-cell NHL may be the result of these normal cellular processes gone awry (see below). In addition, the key roles of the transcription factors MYC and BCL6 and the antiapoptotic protein BCL2 in the

TABLE 108-3 Diseases or Exposures Associated with Increased Risk of Development of Malignant Lymphoma

Inherited immunodeficiency disease	Autoimmune disease
Klinefelter's syndrome	Sjögren's syndrome
Chédiak-Higashi syndrome	Celiac sprue
Ataxia-telangiectasia syndrome	Rheumatoid arthritis and systemic lupus erythematosus
Wiskott-Aldrich syndrome	Chemical or drug exposures
Common variable immunodeficiency disease	Phenytoin
Acquired immunodeficiency diseases	Dioxin, phenoxy herbicides
Iatrogenic immunosuppression	Radiation
HIV-1 infection	Prior chemotherapy and radiation therapy
Acquired hypogammaglobulinemia	

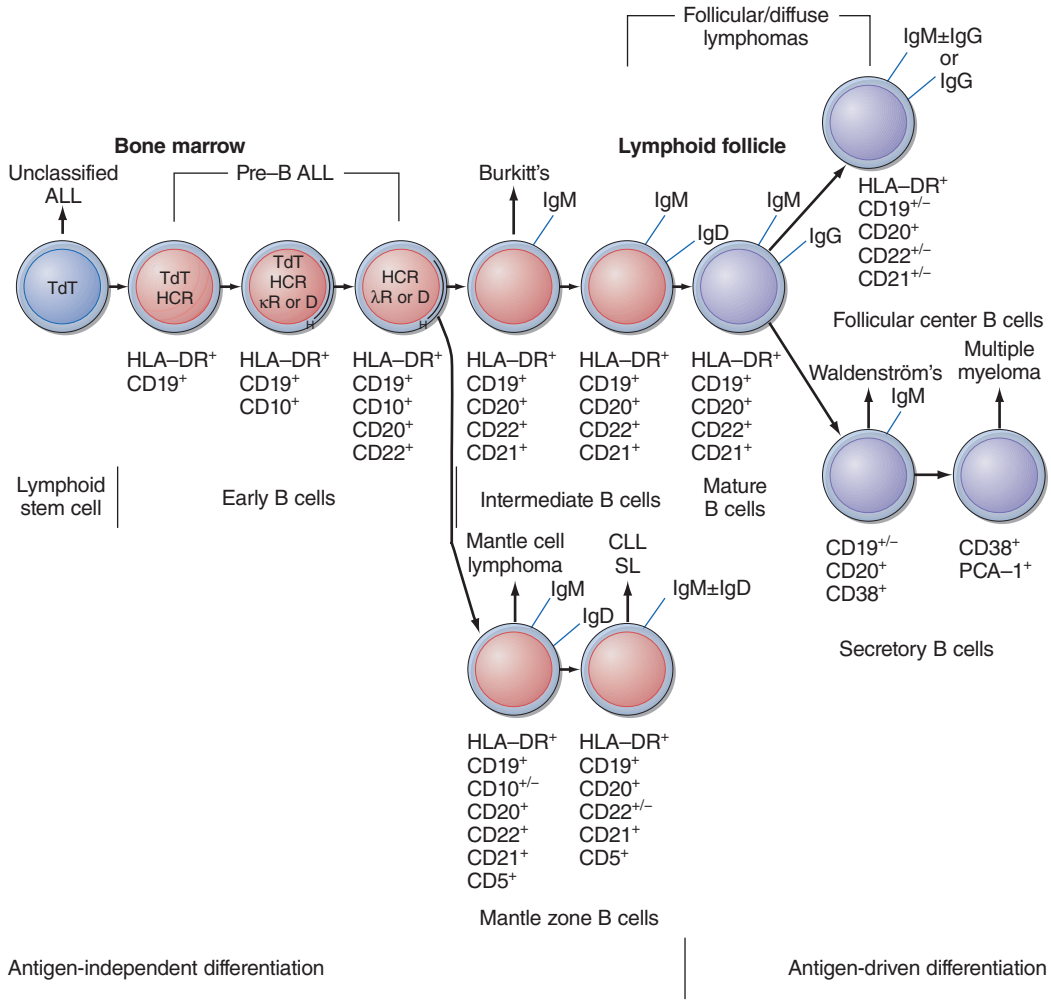

FIGURE 108-2 Pathway of normal B-cell differentiation and relationship to B-cell lymphomas. HLA-DR, CD10, CD19, CD20, CD21, CD22, CD5, and CD38 are cell markers used to distinguish stages of development. Terminal transferase (TdT) is a cellular enzyme. Immunoglobulin heavy chain gene rearrangement (HCR) and light chain gene rearrangement or deletion (κR or D, λR or D) occur early in B-cell development. The approximate normal stage of differentiation associated with particular lymphomas is shown. ALL, acute lymphoid leukemia; CLL, chronic lymphocytic leukemia; SL, small lymphocytic lymphoma.

process of B cell development explain why the genes encoding these proteins are commonly mutated in B-cell lymphomas.

A cell becomes committed to T-cell differentiation upon migration to the thymus and rearrangement of T-cell receptor (TCR) genes. This requires the expression of the T-cell master regulatory transcription factor, NOTCH-1. As in B cells, the development of the mature TCR involves the rearrangement and recombination of the TCR loci, which is error-prone and potentially oncogenic. The sequence of the events that characterize T-cell development is depicted in **Fig. 108-3**.

Although lymphoid malignancies often retain the cell-surface phenotype of lymphoid cells at particular stages of differentiation, this information is of little clinical or prognostic consequence. The so-called stage of differentiation of a malignant lymphoma does not predict its natural history. The antigen footprint, or immunophenotype, of the cell, however, is valuable diagnostically as it allows for the distinguishing of specific NHL subtypes. It can be detected by flow cytometry of single-cell suspension from blood, bone marrow, body fluid, or disaggregated tissue using fluorescently labeled antibodies against these antigens or by immunohistochemical staining of paraffin-embedded tissue sections with enzyme-linked antibodies against these antigens followed by a colorimetric reaction.

As already mentioned, malignancies of lymphoid cells are associated with recurring genetic abnormalities including chromosomal translocations and genetic mutations that may in part be the result of aberrant immunoglobulin or TCR development. While specific genetic abnormalities have not been identified for all subtypes of lymphoid malignancies, it is presumed that they exist. As previously discussed, B cells are even more susceptible to acquiring mutations during their maturation in germinal centers; the generation of antibody of higher affinity requires the introduction of mutations into the variable region genes in the germinal centers. Given this, other nonimmunoglobulin genes, e.g., *bcl-6*, may acquire mutations as well. Likewise, many lymphomas contain balanced chromosomal translocations involving the antigen receptor genes; immunoglobulin genes on chromosomes 2, 14, and 22 in B cells; and T-cell antigen receptor genes on chromosomes 7 and 14 in T cells. The rearrangement of chromosome segments to generate mature antigen receptors must create a site of vulnerability to aberrant recombination. Examples of this type of event include the (8;14)(q24;q32) translocation in BL, involving the *MYC* proto-oncogene and the IgH gene; the (14;18)(q32;q32) translocation in FL, involving the *BCL2* proto-oncogene and the IgH gene; and the (11;14)(q13;q32) translocation in mantle cell lymphoma (MCL), involving the gene encoding cyclin D1 (*CCDN1*) and the IgH gene. Less commonly, chromosomal translocations produce fusion genes that encode chimeric oncogenic proteins. Examples of this include the (2;5)(p23;q35) translocation involving the *ALK* and *NPM1* genes in anaplastic large-cell lymphoma (ALCL) and the t(11;18)(q21;q21) translocation involving the *API2* and *MLT* genes in MALT lymphoma. **Table 108-4** presents the most common translocations and associated oncogenes for various subtypes of lymphoid malignancies.

Gene profiling using array technology allows the simultaneous assessment of the expression of thousands of genes. This technology provides the possibility to identify new genes with pathologic importance in lymphomas, the identification of patterns of gene expression with diagnostic and/or prognostic significance, and the identification of new therapeutic targets. Recognition of patterns of gene expression

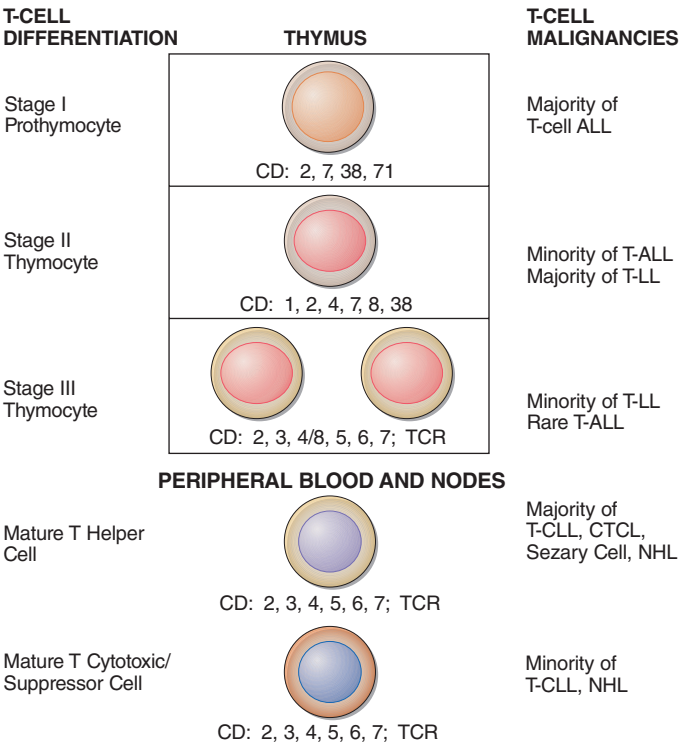

FIGURE 108-3 Pathway of normal T-cell differentiation and relationship to T-cell lymphomas. CD1, CD2, CD3, CD4, CD5, CD6, CD7, CD8, CD38, and CD71 are cell markers used to distinguish stages of development. T-cell antigen receptors (TCR) rearrange in the thymus, and mature T cells emigrate to nodes and peripheral blood. is complicated and requires sophisticated mathematical techniques. Early successes using this technology in lymphoma include the identification of previously unrecognized subtypes of DLBCL whose gene expression patterns resemble either those of follicular or germinal center B (GCB) cells or activated peripheral blood B cells (ABC). Patients whose lymphomas have a GCB-like pattern of gene expression have a considerably better prognosis than those whose lymphomas have a pattern resembling ABCs. This improved prognosis is independent of other known prognostic factors. These subcategories have been more specifically refined into five subcategories, using more advanced genetic sequencing techniques, that differ with respect to biology and driver genes, as well as prognosis, and may have important treatment implications in the future. Similar information is being generated in FL and MCL. The challenge remains to provide information from such techniques in a clinically useful time frame.

APPROACH TO THE PATIENT

Regardless of the type of lymphoid malignancy, the initial evaluation of the patient should include performance of a careful history and physical examination. These will help confirm the diagnosis, identify those manifestations of the disease that might require prompt attention, and aid in the selection of further studies to optimally characterize the patient's status to allow the best choice of therapy. It is difficult to overemphasize the importance of a carefully done history and physical examination. They might provide observations that lead to reconsidering the diagnosis, provide hints at etiology, clarify the stage, and allow the physician to establish rapport with the patient that will make it possible to develop and carry out a therapeutic plan.

The duration of symptoms and pace of symptomatic progression are important in distinguishing aggressive from more indolent lymphomas, as are the presence or absence of "B" symptoms, such as fevers, night sweats, or unexplained weight loss. Patients should be asked about localizing symptoms that may point toward lymphomatous involvement of specific sites, such as the chest, abdomen, or CNS. Comorbid diagnoses that may impact therapy or monitoring on therapy should be reviewed and acknowledged, including a history of diabetes or congestive heart failure. A physical examination should pay close attention to all the peripherally accessible sites of lymph nodes; the liver and spleen size; Waldeyer's ring; whether there is a pleural or pericardial effusion or abdominal ascites; whether there is an abdominal, testicular, or breast mass; and whether there is cutaneous involvement because all of these findings may influence further evaluation and disease management.

Laboratory studies should include a complete blood count, routine chemistries, liver function tests, and serum protein electrophoresis to document the presence of circulating monoclonal paraproteins. The serum β_2-microglobulin level and serum lactate dehydrogenase (LDH) are important independent prognostic factors in NHL. Staging of certain diseases may involve a bone marrow biopsy; results of other laboratory and staging studies may also warrant a marrow evaluation. A lumbar puncture for evaluation of lymphomatous involvement may be indicated in the setting of concerning neurologic signs or symptoms or diseases that are high risk for CNS involvement. The latter may include disease involving the paranasal sinuses, testes, breast, kidneys, adrenal glands, and epidural space, as well as highly aggressive histologies like BL. Since HIV and hepatitis B and C infection can be risk factors for developing NHL, and since treatment for some NHLs can result in the potentially life-threatening reactivation of hepatitis B, patients with a new diagnosis of NHL should be screened for these viruses as well.

Lymphoma histology and clinical presentation dictate which imaging studies should be ordered. Chest, abdominal, and pelvic computed tomography (CT) scans are essential for accurate staging to assess lymphadenopathy for indolent lymphomas, whereas positron emission tomography (PET) using ^{18}F-fluorodeoxyglucose

TABLE 108-5 Staging Evaluation for Non-Hodgkin's Lymphoma

Physical examination
Documentation of B symptoms
Laboratory evaluation
Complete blood counts
Liver function tests
Uric acid
Calcium
Serum protein electrophoresis
Serum β_2-microglobulin
Chest radiograph
CT scan of abdomen, pelvis, and usually chest
Bone marrow biopsy
Lumbar puncture in lymphoblastic, Burkitt's, and diffuse large B cell lymphoma with positive marrow biopsy
Gallium scan (SPECT) or PET scan in large-cell lymphoma

Abbreviations: CT, computed tomography; PET, positron emission tomography; SPECT, single-photon emission computed tomography.
